Alternatively, in does, progestagens may be given for 11 days with eCG and prostaglandin administered on day 9, and fixed-time insemination performed on days 12 and 13. In regimens involving treatments other than prostaglandin alone, fertility may be reduced on the first estrus after treatment in ewes but not in does. During the nonbreeding season, melatonin implants (18 mg) induce fertile estrus 50–70 days after implant insertion. Better results are obtained when melatonin implants are inserted early or during the transitional period. The implant is biodegradable and does not need to be removed. Estrus synchronization may be improved by using an estrus synchronization protocol at the end of implant action. During the nonbreeding season, a source of gonadotropin is also required. The most common gonadotropin used is eCG, administered at the end of a progestagen treatment (or 24 hr before device removal). The dose of eCG depends on the season, breed, age, and postpartum interval, among other factors. A high eCG dose is characterized by superovulation, low fertility, shortened estrous cycles, pregnancy loss, and problems with multiple lambs or kids. The repetitive use of eCG has produced antibodies against eCG in certain sheep and goats, resulting in modification in the time of ovulation and consequent reduction of fertility when artificial insemination at a fixed time is done.

PIGS

In pigs, estrus synchronization may be easily achieved by synchronized weaning of lactating sows; estrus is seen 4–10 days later. Administration IM of a commercially available combination of equine chorionic gonadotropin (eCG; 400 IU) and human chorionic gonadotropin (hCG; 200 IU), per 5 mL dose, given as a single injection within 12 hr after weaning, tightens the synchronization, and estrus is seen 4–5 days after weaning. This eCG and hCG combination also induces estrus in gilts with delayed puberty and in sows with postweaning anestrus. Exogenous prostaglandin induces luteolysis of the porcine corpus luteum only

after day 12 of the estrous cycle and, therefore, is not a practical agent for estrous cycle control; however, estrus may be synchronized by induction of abortion in sows pregnant >15 days by administration of PGF_{2α} (15 mg, IM, then 10 mg, IM, 12 hr later) or cloprostenol (1 mg, followed 24 hr later by 0.5 mg); sows return to estrus 4–10 days after treatment. Oral altrenogest (15–20 mg/day, PO, for 14–18 days) may be used for estrus synchronization and for improvement of farrowing rate and litter size in mature sows. In lactating sows, one daily dose of altrenogest from the day of weaning until 5 days before the planned breeding day is also effective and results in estrus 4–9 days after completion of treatment. Estrus may also be synchronized by using bovine norgestomet implants (one implant followed by addition of a second implant 9 days later) removed 19 days after initiation of treatment; neither treatment is currently approved in the USA for swine. Combination eCG and hCG may be given on the day of progestagen withdrawal to better synchronize estrus.

DOGS

In bitches, estrus suppression, for no more than 24 mo, can be accomplished by administration of mibolerone (an androgen, 30–180 mcg/day, PO, depending on the weight of the bitch). To be effective, treatment must be started at least 30 days before estrus. Estrus is variable but typically develops soon after cessation of treatment; fertility should be normal by the second estrus after treatment. If the bitch has already entered proestrus, the progestagen megestrol acetate (2.2 mg/kg/day, PO, for 8 days) may be used to stop the cycle. Administration must start in the first 3 days of proestrus (vulvar bleeding). The next estrus usually develops 4–6 wk earlier than expected. To delay estrus, treatment with megestrol acetate (0.55 mg/kg/day, PO, for 32 days) is begun in late anestrus (up to a few weeks before estrus is expected). After treatment, estrus is seen in 2–9 mo (typically 5–6 mo), and fertility is not affected.

Neither mibolerone nor megestrol acetate is recommended for use in bitches on their first estrus or in bitches primarily used for breeding. Adverse effects of progestins such as megestrol acetate include cystic endometrial hyperplasia and pyometra; long-term treatment may result in obesity, diabetes mellitus, and neoplasia of the uterus and mammary glands. Mibolerone may cause skin, vaginal, and clitoral changes.

Clinical use of deslorelin for estrus suppression is under investigation. Extended-release implants of deslorelin can suppress estrus for >1 yr in bitches without apparent adverse effects and with full return to fertility.

Estrus induction in bitches remains problematic, and none of the drugs presented below are approved for this use in the USA. Many methods have been proposed, but repeatability is low and fertility of the induced estrus is variable. Estrus induction in the bitch before endometrial involution is complete (135 days after the most recent estrus) can result in reduced fertility. The dopamine agonists cabergoline (5 mcg/kg/day, PO, until 2 days after onset of proestrus), metergoline (0.56–1.2 mg/kg, IM, every third day until proestrus), and bromocryptine (0.3 mg/bitch for 3 days followed by 0.6–2.5 mg per bitch for 3–6 days after onset of proestrus) are reported to induce fertile estrus in most bitches. Average length of treatment was 16–19 days. Two notable adverse effects of dopamine agonist treatment in the bitch are vomiting and coat color changes.

Use of deslorelin implants may also be effective for induction of estrus but has been associated with low progesterone values during diestrus and, subsequently, prolonged estrus suppression. Removal of the implant 10 days after insertion may overcome this problem. Induction of estrus with GnRH analogues continues to be investigated. Synchronous estrus using whole (2.1 mg) or half (1.05 mg) deslorelin implants after termination of diestrus with PGF₂ α has been reported. The PGF₂ α protocol started with a low dosage (50 mcg/kg, SC, bid) on the first day, followed by a moderate dosage (100 mcg/kg, SC, bid) on the second day, and then a full dosage (250 mcg/kg, SC, bid) for 5 days. Encouraging results have also been reported using a single 1.5-mg IM injection of a sustained-

release formulation of deslorelin marketed for use in mares.

The most widely studied gonadotropin for estrus induction in canids is equine chorionic gonadotropin (eCG), which is available in the USA only in a porcine product that contains a combination of 80 IU eCG and 40 IU hCG/mL. A single 5-mL injection of this product was highly effective for inducing proestrus in 89.5% of treated bitches, but ovulation rate was poor. However, whelping rates of 50%–84% have also been reported when eCG and hCG were used to induce estrus in bitches.

CATS

Megestrol acetate may be used to suppress estrus in queens by treating with 5 mg/cat daily for 3 days, then 2.5–5 mg once weekly for a maximum of 10 wk. Administration of megestrol acetate to queens is an extra-label use of the drug, and informed consent should be obtained from the owners. The queen should be allowed an estrus before resuming therapy. Mibolerone is also not approved for use in queens (because of hepato-toxicity) but is effective at 50 mcg/cat/day, PO. Longterm deslorelin implants have also suppressed estrus in cats, but the length of suppression is variable. Estrus may be induced in queens with follicle-stimulating hormone (FSH), 2 mg, IM, the first day, then 0.5–1 mg, IM, daily for 4 additional days. Recommended doses of human chorionic gonadotropin (hCG) range from 25 to 500 IU. The higher doses are more effective at inducing ovulation but may also result in oocyte degeneration. For queens with anovulation or for queens undergoing artificial insemination, ovulation of mature follicles (present on day 2 of estrus) may be induced by treatment with hCG at 250 IU, IM, or GnRH at 25 mcg, IM. Ovulation is reported to occur 25–27 hr after hCG administration to queens.

NUTRITION: BEEF CATTLE

NUTRITIONAL REQUIREMENTS

Beef cattle production, whether on range, improved pasture, or in the feedlot, is most economic when feedstuffs are used effectively. Young growing grass or other high-quality pasture crops usually supply

ample nutrients, such that mature and young growing cattle can consume sufficient good-quality mixed pasture (grasses and legumes) for normal growth and maintenance. However, mature pasture, crop residues, or forage crops harvested in a manner that results in shattering, leaching,

or spoilage may be so reduced in nutritive value (particularly energy, protein, phosphorus, and provitamin A or β -carotene) that they are suitable only in a maintenance ration for adult cattle. Such feedstuffs should be supplemented if used for any other purposes.

The mineral content of forages is influenced by the corresponding mineral levels in the soil and by excess levels of some minerals that reduce the availability of others. Mature forages also may be lower in mineral content, especially phosphorus. Normally, supplemental minerals are supplied in a free-choice mineral mix or force-fed in the total mixed ration.

Certain nutrients are required by beef cattle in the daily ration, whereas others can be stored in the body. When body stores of a nutrient are high, eg, vitamin A, dietary supplementation is unnecessary until such stores are depleted. However, it may be difficult to determine when body stores have been depleted until advanced signs of deficiency start to appear.

The following are dietary requirements for maintenance, growth, finishing, reproduction, and lactation in beef cattle.

Water: Water, although not considered a nutrient per se, is required for regulation of body temperature, as well as for growth, reproduction, lactation, digestion, metabolism, excretion, hydrolysis of nutrients, transportation of nutrients and waste in the body, joint lubrication, plus many more functions. Restricting water intake results in impaired performance. An animal will expire more quickly from a water deficiency than from a deficiency of any nutrient.

Because feeds themselves contain water, and the metabolism of ingested feeds releases water (called metabolic water), not all of the animal's water needs have to be met by drinking water. Thirst is the result of need, and animals drink to meet this need. The need for water results from an increase in the electrolyte concentration in the body fluids, which activates the thirst mechanism.

Many factors, including temperature and body weight, affect water consumption in cattle. An 800-lb (364-kg) heifer at an environmental temperature of 4.4°C (40°F) can be expected to consume 6.3 gal. (23 L) per day; at 21°C (70°F), this will increase to 9.2 gal. (34.8 L). At the same 4.4°C temperature, a 400-lb (182-kg) heifer will consume ~4 gal. (15.1 L). Note that water consumption and body weight are not correlated by a straight-line relationship. A 900-lb (409-kg)

lactating cow at the 4.4°C temperature will consume 11.4 gal. (43.1 L) per day.

Energy: Productive animals need essentially two types of energy. Energy of maintenance is that needed to maintain respiration, circulation, digestion, etc. Therefore, in calculating total energy needs, the net energy for maintenance, or NE_m , must be considered. The energy required for growth and reproduction is called the net energy for production, or NE_g . It is the amount of energy intake deposited as muscle and/or fat in animals gaining weight. (See TABLES 18–22.)

Except for prurulent calves, beef cattle can meet their maintenance energy requirements from roughages of reasonably good quality (green, leafy, fine-stemmed, free of mold and weeds). A shortage of energy may exist on overstocked pastures, with inadequate feed allowance or poor-quality forages, or during a drought. For production, additional energy from concentrates or co-product feeds may be necessary, especially when forages of fair to poor quality are consumed.

Especially in cold weather, roughages of varying quality may have similar maintenance energy values. Heat released during digestion and assimilation—called “heat increment”—contributes to the maintenance of body temperature for wintering stock.

Protein: Protein requirements currently are evaluated as metabolizable protein, which is interchangeable with absorbed protein. Metabolizable protein defines the protein more nearly as that which is available to the animal for maintenance and production. It is defined as the combination of the true protein absorbed by the intestine, supplied by microbial synthesized protein plus undegraded intake protein (UIP). The latter often has been called “bypass” protein.

Energy deficiency due to low feed intake or intake of poor quality feed is the most common deficiency that limits growth, development in heifers and bulls, milk production, and reproduction, with protein deficiency being the next most common. Protein deficiency of long duration eventually depresses appetite, with eventual weight loss and unthriftiness, even when ample energy is available.

Feedstuffs vary greatly in protein digestibility. For example, the protein of common grains and most protein supplements is ~75%–85% digestible, that of alfalfa hay ~70%, and that of grass hays usually

35%–50%. The protein of low-quality feeds, such as weathered grass hay, range grass, or cottonseed hulls, is digested poorly. Thus, even though total protein intake may appear to be adequate, metabolizable protein might be deficient.

A lack of protein in the diet adversely affects the microbial protein production in the rumen, which in turn reduces the utilization of low-protein feeds. Thus, much of the potential nutritive value of roughages (especially energy) may be lost if protein levels are inadequate.

Urea and other sources of nonprotein nitrogen (NPN) are used commonly in commercial protein supplements to supply one-third or more of the total nitrogen requirement. Such products are broken down readily by the ruminal microbial protein to ammonia and then synthesized to high-quality microbial protein. The use of NPN needs available sources of ample phosphorus, trace minerals, sulfur, and soluble carbohydrates for the microbial synthesis of utilizable protein. The amount of crude protein (% N × 6.25) supplied by NPN must be stated on the feed tag accompanying commercial supplements. Toxicity is not a serious problem when urea is fed at recommended levels and mixed thoroughly with the other ingredients of the ration. However, rapid ingestion of urea at levels ≥20 g/100 lb (45 kg) body wt may lead to toxicity (see p 3043). Several urea-molasses liquid supplements, containing as much as 10% urea, currently are self-fed to beef cattle. Caution should be exercised when cattle are started on such supplements.

Minerals: Qualitatively, beef cattle require the same mineral elements as do dairy cattle; however, the relative quantities of the several minerals are different (see TABLE 23, p 2262). The minerals most apt to be deficient in beef cattle diets are sodium (as salt), calcium, phosphorus, magnesium, zinc, copper, and selenium. In some areas, including the interior of the USA, iodine may be deficient in diets for pregnant cows; likewise, there are regional deficiencies (probably reflecting soil deficiencies) of several trace minerals, including copper, cobalt, and selenium. However, there are areas where some mineral elements (eg, selenium, molybdenum) are present at toxic levels. Attempts have been made to correct natural soil deficiencies for trace minerals by soil fertilization practices. Thus, it is implied that a beef producer needs to know the mineral and trace mineral content of the feedstuffs used in cattle rations. A general approach to prevent such deficiencies is to feed a commercial salt mineral mix developed for the geographic location of the herd.

The salt (NaCl) requirement for beef cattle is quite low (0.2% of the dry matter); however, there appears to be a satiety factor involved—almost all animals appear to seek out salt if it is not readily available. Range cattle may consume 2–2.5 lb (1 kg) salt/head/mo when forage is succulent but about half that amount when forage is mature and drier. When salt is added to a free-choice protein feed to limit intake, beef cows might consume >1 lb salt/day over long periods of time

TABLE 18

MEAN NUTRIENT CONTENT OF FEEDS COMMONLY USED IN BEEF CATTLE DIETS^a (continued)

Crude Protein (%)	Crude Fiber (%)	Ash (%)	NDF (%)	ADF (%)	Ca (%)	P (%)	Dry Matter (%)

without adverse effects if they have plenty of drinking water. Signs of a salt deficiency are rather nonspecific and include pica and reduced feed intake, growth, and milk production.

Calcium is the most abundant mineral element in the body; ~98% functions as a structural component of bones and teeth. The remaining 2% is distributed in extracellular fluids and soft tissues and is involved in such vital functions as blood clotting, membrane permeability, muscle contraction, transmission of nerve impulses, cardiac regulation, secretion of certain hormones, and activation and stabilization of certain enzymes. Most roughages are relatively good sources of calcium. Cereal hays and silages and such crop residues are relatively low in calcium. Although leguminous roughages are excellent sources of calcium, even nonlegume roughages may supply adequate calcium for maintenance of beef cattle. When cattle are fed such roughages produced on low-calcium soils, or when finishing cattle are fed high-grain diets with limited nonlegume roughage, a calcium deficiency may develop. Because lactating beef cows do not produce nearly the amount of milk that dairy cattle do, their calcium requirement is much less. Nevertheless, it is sound management to provide a free-choice salt mineral mixture tailored to the environment and production class of the grazing cattle. Salt should always be mixed with mineral, because salt drives intake. Cows have almost zero "nutritional wisdom," ie, they do not seek out feedstuffs or minerals when they are deficient, with the exception being sodium, so adding mineral to the salt generally improves intake among cattle with free-choice access to the mineral mix.

The total ration should provide a calcium: phosphorus ratio of 1.2 to 2:1, with cows at minimum of 1.2:1 and feedlot steers at minimum of 2:1. Wider ratios appear to be tolerated if the minimum requirements for each mineral element are met and if adequate vitamin D (exposure to sunlight) is available. Range cattle should be provided a mineral supplement that has as much or more phosphorus than calcium, because green forage is many times higher in calcium. Research has shown that intake among cattle receiving free-choice mineral mix is highly variable. One study showed that 14%–15% of cows with free-choice access to mineral in block or loose form consumed zero mineral. The only time cattle should be offered mineral free choice is when they are grazing and no other feed is being fed. If cows are consuming any other feed, the salt and mineral should be mixed with the ration so all cattle will ingest the prescribed amount of mineral.

Approximately 80% of the **phosphorus** in the body is found in the bones and teeth, with the remainder distributed among the soft tissues. Phosphorus may be deficient in some beef cattle rations, because roughages often are low in phosphorus. Furthermore, as forage plants mature, their phosphorus content declines, making mature and weathered forages a poor source. Phosphorus has been described as the most prevalent mineral deficiency for grazing cattle worldwide. Most natural protein supplements are fairly good sources of phosphorus. Because adequate phosphorus is critical for optimal performance of beef cattle, including growth, reproduction, and lactation, a phosphorus supplementation program is recommended using either a free-choice mineral mixture or direct

supplementation in the diet. In a phosphorus deficiency, reduced growth and efficiency of feed conversion, decreased appetite, impaired reproduction, reduced milk production, and weak, fragile bones can be expected. There does not appear to be any advantage to feeding more phosphorus than is recommended. Furthermore, feeding excess phosphorus contributes to increased environmental pollution. Good sources of supplemental phosphorus include steamed bone meal, mono- and dicalcium phosphate, defluorinated rock phosphate, and phosphoric acid. Corn co-products like corn gluten and distillers grains with solubles are also high in phosphorus. Because most grains are relatively good sources of phosphorus, feedlot cattle rarely suffer a phosphorus deficiency, although phytic acid chelation of phosphorus in grains may render up to one-half of it unavailable—especially for monogastric animals such as swine and poultry.

Magnesium maintains electrical potentials across nerve endings. In a deficiency, the lack of control of muscles is obvious. However, normally deficiencies are not anticipated. A magnesium deficiency in calves results in excitability, anorexia, hyperemia, convulsions, frothing at the mouth, and salivation, but such a condition is uncommon. Usually, a magnesium deficiency is seen in the spring in more mature grazing cattle under field conditions (ie, grass tetany, *see* p 996). The initial signs are nervousness, reduced feed intake, and muscular twitching about the face and ears. Animals are uncoordinated and walk with a stiff gait. In advanced stages, affected cows fall to the ground, convulse, and die shortly after. A blood sample from affected cows would show a serum magnesium level of <2 mg/dL, with a corresponding calcium deficiency. This condition is sufficiently prevalent that many beef cow herd managers supplement in the spring with magnesium oxide at 28–56 g/head/day. Beef cows generally do not like magnesium oxide; dilution by mixing it with ground corn or incorporating it into a free-choice liquid supplement improves acceptability.

Potassium is the major cation in intracellular fluid and is important in acid-base balance; it is involved in regulation of osmotic pressure, water balance, muscle contractions, nerve impulse transmission, and several enzymatic reactions. Potassium deficiencies normally are not anticipated in cattle diets because most forages are good sources, containing 1%–4%. In fact, the high potassium content of spring pasture grass is one of the highest risk factors for grass tetany

(*see* p 996). A potassium deficiency might be anticipated when diets extremely high in grain are fed (eg, in finishing cattle), because grains may contain <0.5% potassium. A marginal to deficient level of potassium in growing and finishing cattle results in decreased feed intake and rate of gain. However, this effect is subtle and probably would not be noticed other than by the very experienced cattle feeder. Body stores of potassium are small, and a deficiency may develop rapidly. It is good practice to supplement rations for growing and finishing cattle such that they will contain >0.6% potassium on a dry-matter basis.

Copper and **cobalt** deficiencies are likely more widespread than previously thought. Cobalt functions as a component of vitamin B₁₂. Cattle do not depend on dietary vitamin B₁₂, because ruminal microorganisms can synthesize it from dietary cobalt. In cattle, therefore, a cobalt deficiency is a relative vitamin B₁₂ deficiency, and such cattle show weight loss, poor immune function, unthriftiness, fatty degeneration of the liver, and pale skin and mucosa. Copper functions as an essential component of many enzyme systems, including those that involve the production of blood components. Recommended levels of cobalt and copper should be provided in the diet, either by supplementation of the total mixed ration or as part of the free-choice mineral mix or supplemental mix.

Iodine is an integral part of thyroxine and, as such, is largely responsible for control of many metabolic functions. Typically, coastal regions subjected to iodine-carrying winds off the ocean have abundant supplies of iodine; however, in inland soils (in the USA, especially between the Allegheny and Rocky mountains), the soil generally does not have sufficient iodine to meet most livestock needs. Iodine requirements in cattle can be met adequately by feeding stabilized iodized salt.

Selenium is part of the enzyme glutathione peroxidase, which catalyzes the reduction of hydrogen peroxide and lipid hydroperoxides, thus preventing oxidative damage to the body tissues. White muscle disease in calves (*see* p 1172), characterized by degeneration and necrosis of skeletal and heart muscles, is the result of a selenium deficiency. Vitamin E plays a role in preventing such conditions. Other signs of a selenium deficiency include unthriftiness, weight loss, reduced immune response, and decreased reproductive performance. Selenium can be included in mineral mixes at a level up to 120 ppm so that cattle intake is 3 mg/head/day.

Vitamins: Although cattle probably have a metabolic requirement for all the known vitamins, dietary sources of vitamins C and K and the B-vitamin complex are not necessary in all but the very young. Vitamin K and the B vitamins are synthesized in sufficient amounts by the

ruminal microflora, and vitamin C is synthesized in the tissues of all cattle. However, if rumen function is impaired, as by starvation, nutrient deficiencies, or excessive levels of antimicrobials, synthesis of these vitamins may be impaired.

Vitamin A can be synthesized from β -carotene contained in feedstuffs such as green forages and yellow corn. However, this ability varies among breeds; Holstein cattle perhaps are the most efficient converters of carotenes, whereas some

of the beef breeds are much less efficient. Therefore, providing supplemental vitamin A to beef cattle should be considered. Vitamin A is one of the few vitamins that cattle store in their livers—as much as a 6-mo supply. Cattle on a diet deficient in

vitamin A may not begin to show signs for several weeks. Newborn calves, which have small stores of vitamin A, depend on colostrum and milk to meet their needs. If the dam is fed a ration low in carotene or vitamin A during gestation (eg, in winter), severe deficiency signs may become

apparent in the young suckling calf within 2–4 wk of birth, while the dam may appear healthy.

It is sound practice to provide 2–5 lb (1–2 kg) of early-cut, good-quality legume or grass hay in the daily ration of stocker cattle and pregnant cows to prevent

^a Requirements for calcium and phosphorus are listed in the preceding nutrient requirement tables.

Adapted, with permission, from *Nutrient Requirements of Beef Cattle*, 2000, National Academy of Sciences, National Academy Press, Washington, DC.

vitamin A deficiency. Most commercial protein and mineral supplements are fortified with dry, stabilized vitamin A. The daily requirements for beef cattle appear to be ~5 mg of carotene or 2,000 IU of vitamin A/100 lb (45 kg) body wt; lactating cows may require twice this amount to maintain high vitamin levels in the milk.

Vitamin A deficiency under feedlot conditions can cause considerable loss to cattle feeders, especially if high-concentrate and corn silage rations low in carotene have been fed. Destruction of carotene during hay storage or in the GI tract, or the failure of beef cattle to convert carotene to vitamin A efficiently, may increase the need for supplemental vitamin A. Growing and finishing steers and heifers fed low-carotene diets for several months require 2,200 IU of vitamin A/kg of air-dry ration. Commercial vitamin A supplements are not expensive and should be used when such rations are fed and any danger of a deficiency exists. An alternative way to supply supplemental vitamin A is by IM injection: studies show

that an extremely high dose (6 million U) would be needed to supply adequate vitamin A for 7 mo. As with all vitamins and minerals, a steady supply in the diet is the ideal method for supplementation.

Vitamin D deficiency is comparatively rare in beef cattle, because they are usually outside in direct sunlight or fed sun-cured roughage. In northern latitudes during long winters, or in show calves kept in the barn or turned out only at night, a deficiency is possible. The ultraviolet rays of sunlight convert provitamin D found in the skin of animals (7-dehydrocholesterol) or in harvested plants (ergosterol) to active vitamin D. Direct exposure to sunlight, consumption of sun-cured feed, or supplementary vitamin D (300 IU/45 kg body wt) prevent a deficiency.

For the interrelationships of vitamin E and selenium in reproduction and in the etiology of various myopathies and the predisposition of a relative thiamine (vitamin B₁) deficiency, see NUTRITIONAL MYOPATHIES, p 1172. (See also POLIOENCEPHALOMALACIA, p 1281.)

FEEDING AND NUTRITIONAL MANAGEMENT

Feeds for beef cattle vary widely in quality, palatability, and essential nutrient content (see TABLE 18). To be most effective, any supplement must be patterned to fit the kind and quality of roughage available. Chemical analyses of roughages are very useful to determine their nutrient deficiencies and adequacies. Under certain systems of management, beef cattle are wintered on low-quality roughages and thus may not receive the recommended nutrients for optimal performance. If heifers are fed low-quality roughages during winter, they will produce inadequate quality and quantity of colostrum, take longer to deliver their calves, and have poor rebreeding rates. This can be prevented by ensuring that heifers are fed a balanced ration that will allow them to calve in body condition score 6.5–7 (0–9 scale). Cattle should always be fed an adequate ration that allows them to thrive in their given environment. (See TABLES 19–22.)

Feeding and nutritional management for three systems of beef production are discussed separately. (See BEEF CATTLE BREEDING HERDS, p 2119.)

The Breeding Herd

In many areas, producers follow a late winter/early spring calving program (February to May in the USA), depending on the available feed, growth of early pasture, and prevailing climate. Fall calving has become more prevalent, particularly in the south. Wintering the lactating cow presents a much greater nutritional problem than does wintering the pregnant, nonlactating cow. Spring-born calves commonly are weaned at 6–7 mo, and their dams bred back while on pasture. Heifers may be bred to calve first as 2-yr-olds (22–25 mo) if good winter feeding is practiced to ensure adequate development. Heifers should weigh 55%–60% of mature body wt at breeding time and should be fed well thereafter to allow for continued growth, good milk production, and prompt rebreeding.

Mature cows have greater body reserves and lower nutrient requirements than heifers; therefore, they can be wintered on rations of poorer quality. Their ration should provide a minimum of 8% total or crude protein in the dry matter; if it does not, then 1–2 lb (0.5–1 kg) of a 20%–30% protein supplement or its equivalent should be fed daily. A mineral mix and salt should be provided. Cows should calve in body condition score 5.5–6 (0–9 scale).

Under profitable systems of management, a mature beef cow should maintain her weight from fall to fall. Lactation requires more nutrients than gestation. However, feeding beef cows more than is necessary for satisfactory production, such as is frequently done in purebred herds and show herds, is also undesirable. Large accumulations of body fat may lead to lowered conception rates, difficult calving, a lower calf crop, and a shorter life span for the cow.

A system of “creep feeding” can be practiced in which suckling calves are allowed access to a grain mixture in a self-feeder in an enclosure or to high-quality forage in an adjacent pasture where only calves have access. A creep-feed mixture of high-fiber co-product feeds such as corn gluten, dry distiller’s grains, and soyhulls can be combined with a salt-vitamin-mineral mix to provide a palatable ration for the calves. The mixture should be rather large particles to prevent dustiness. A commercial 14%–16% protein creep feed may be used as an alternative.

Growing bull calves should also receive a balanced ration. Young bulls should not be fed large amounts of starch, with gains of 2.5–3.5 lb (1.1–1.6 kg) per day being very adequate. Yearling bulls grown on extremely high energy diets are more likely to have disease issues and reduced longevity in the breeding herd. Mature bulls commonly are wintered in the same manner as the cow herd, with a greater feed allowance during the late winter. In highly fitted show bulls, a gradual reduction in the ration and much exercise are needed before they will be in suitable shape and condition for pasture breeding. Breeding stock should have adequate nutrients in their ration and be gaining weight before and during the breeding season. Deficiency of several nutrients, especially carotene, phosphorus, energy, and protein, reduces fertility. These nutrients should be present in adequate amounts in the ration at least 6–8 wk before breeding.

Stocker Cattle

It is common practice to feed calves and yearlings to make moderate gains in winter, with faster and less expensive gains on summer pasture. Such cattle may be sold as feeders in the spring or finished out in dry lot the following fall. The cost of winter gain on harvested feeds invariably is higher than summer gain on pasture; hence, it is advisable to winter cattle so as to make the greatest possible gains on pasture. To maintain good health, weanling calves should gain >1 lb (0.5 kg)/day. Two pounds

(1 kg) of grain plus 1–2 lb (0.5–1 kg) of protein supplement are recommended in addition to nonlegume roughage. If legume roughage is fed, no protein supplement is needed. Older cattle, particularly if they enter the winter in fleshy condition, may just maintain their weight. A free-choice mineral mixture with trace mineralized salt should be supplied. Limited amounts of grain fed to yearling cattle on pasture during the late summer may increase their market value.

Finishing Cattle

This phase of beef production consists of full feeding of grain with limited amounts of roughage until market weight and finish are reached. Older cattle may reach finish weight on pasture alone (or with only a few pounds of grain/day) or after 60–90 days in the feedlot on high-grain rations to improve market grade and to remove any yellow tinges from their body fat (due to stored carotene from pasture forage). Weanling calves can be shipped directly to the feedlot and fed finishing rations for 150–250 days, whereas yearlings require ~150 days. Grain consumption of cattle on full-feed is ~2–2.5 lb/100 lb (1 kg/45 kg) body wt. Roughage consumption usually is limited to approximately one-fourth to one-third of the total concentrate consumption after cattle are on full-feed. Cattle consume ~3% of their body wt/day when self-fed mixed rations. For calves, ~1.5–2 lb (<1 kg) of a 33% protein supplement is required daily for best gains and market grades when nonlegume roughage is fed.

The grain (concentrate) allowance for finishing cattle should be increased gradually over 2–3 wk from the time they are started on a finishing program to get them on full feed. Feeding too much grain to finishing cattle too rapidly can lead to lactic acidosis or founder (*see* p 225).

PERFORMANCE MODIFIERS

See also GROWTH PROMOTANTS AND PRODUCTION ENHANCERS, p 2758.

There are three groups of performance modifiers used in beef cattle production: hormone-like growth enhancers; ruminal chemistry modifiers, which alter volatile fatty acid production in the rumen; and β -agonists, which increase muscle.

Hormone-like growth enhancers for finishing beef cattle have been used for almost 70 yr. There are many implant choices, and the specific implant protocol needs to be tailored to the cattle genetics, nutrition, and marketing plan. The average increase in daily gain due to the use of

effective implants is ~0.23 kg (0.5 lb)/day, and the improvement in the feed to gain ratio is 0.56 kg feed/kg gain.

Ionophores are antibiotics that alter the chemistry of the rumen by altering the rumen microflora to produce increased proportions of propionic acid and decreased proportions of acetic and butyric acids. These three acids, called volatile fatty acids (VFAs), are the products of ruminal fermentation and can be absorbed from the digestive tract of the cow and used as energy sources. Because propionic acid releases more energy per unit weight to the host cow upon oxidation than do the other two VFAs, it is important in beef cattle production.

In modern feedlot diets, ionophores improve feed efficiency by 2.5%–3.5%, decrease dry matter intake 3%, and increase average daily gain (ADG) 2.5%. A more dramatic improvement in ADG is seen in cattle fed ionophores on high-roughage diets than in cattle fed high-energy diets. This is explained by energy availability between the two systems. On high-energy diets, cattle eat until they meet energy requirements; thus, ionophores help them derive more energy per unit of ingested feed, and they eat less. On high-roughage diets, which have less energy per unit weight, cattle consume feed until the rumen will hold no more. In grazing or high forage feeding systems, if ionophores are fed, these cattle derive more energy per unit of feed consumed, and thus gain more. Additional benefits of feeding ionophores include improving the consistency of feed intake in cattle fed high-grain diets, thus reducing the incidence of ruminal acidosis along with control of coccidiosis.

β -Agonists are the newest of the performance modifiers used in feedlot operations. These feed additives are absorbed in the blood and distributed to muscle tissue, where they bind to specific β receptors. Their action results in increased protein synthesis, which results in increased muscle fiber size. The β -agonist ractopamine is fed for the final 28–42 days before slaughter, whereas zilpaterol is fed for the final 20–40 days before slaughter. Performance improvements of β -agonists include live slaughter wt 18–22 lbs, hot carcass wt 20–30 lbs, ADG (during β -agonist feeding period of 20–42 days) 8.5%–30%, feed efficiency (during β -agonist feeding period of 20–42 days) 12.5%–31%, and dressing percentage 0–1.5 units.

β -agonists can increase muscle shear force and reduce the percentage of cattle that grade prime and high choice, so use in cattle with low genetic potential for tenderness and/or marbling may be less advantageous.

NUTRITION: DAIRY CATTLE

NUTRITIONAL REQUIREMENTS

During lactation, dairy cows have very high nutritional requirements relative to most other species (*see* TABLE 24). Meeting these requirements, especially for energy and protein, is challenging. Diets must have sufficient nutrient concentrations to support production and metabolic health, while also supporting rumen health and the efficiency of fermentative digestion.

Feed Intake

Under nearly all practical management conditions, dairy cows and growing dairy heifers are fed *ad lib*. Thus, voluntary feed intake is the major limitation to nutrient supply in dairy cattle. Feed intake is usually characterized as dry matter intake (DMI) to compare diets of variable moisture concentrations. DMI is affected by both animal and feed factors. Body size, milk production, and stage of lactation or gestation are the major animal factors. At peak DMI, daily DMI of high-producing cows may be 5% of body wt, and even higher in extremely high-producing cows. More typical peak DMI values are in the range of 3.5%–4% of body wt. In mature cows, DMI as a percentage of body weight is lowest during the nonlactating, or dry, period. In most cows, DMI declines to its lowest rate in the last 2–3 wk of gestation. Typical DMI during this period is <2% of body wt/day, with intake rates depressed more in fat cows than in thin ones. Feed intake during this period has an important relationship to postpartum health, with low DMI and associated prepartum negative energy balance increasing the risk of postpartum disease. After calving, DMI increases as milk production increases; however, the rate of increase in feed consumption is such that energy intake lags behind energy requirements for the first several weeks of lactation. Milk production and associated energy requirements generally peak around 6–10 wk into lactation, whereas DMI usually does not peak until 12–14 wk into lactation. This lag in DMI relative to energy requirements creates a period of negative energy balance in early lactation. Cows are at greater risk of metabolic disease during this period than at other times during their lactation cycle. Management and nutritional strategies should be designed to maximize

DMI through the period of late gestation and early lactation.

Feed factors also affect DMI. Total ration moisture concentrations >50% generally decrease DMI, although this may be related more to fermentation characteristics than to moisture *per se*, because high-moisture feeds for dairy cattle are typically from fermented (ensiled) sources. Rations high (>30%) in neutral detergent fiber (NDF) may also limit feed intake, although the degree to which this occurs is related to the source of NDF. Environment also affects feed intake with temperatures above the thermal neutral zone (>20°C [68°F]), resulting in reduced DMI. Monitoring DMI, when possible, is a useful tool in diagnosing nutritional problems in diets of dairy cows.

Carbohydrates

Energy requirements for lactating dairy cows are met primarily by carbohydrate fractions of the diet. These consist of fibrous and nonfibrous carbohydrates. Fibrous carbohydrate proportions are generally measured as NDF and expressed as a percentage of dry matter. Nonfiber carbohydrate (NFC) proportions are calculated by subtracting the proportions (as dry matter) of NDF, crude protein, fat, and ash from 100%. Nonfiber carbohydrates primarily consist of sugars and fructans, starch, organic acids, and pectin. In fermented feeds, fermentation acids also contribute to the NFC fraction. The sum of sugars and starch is referred to as nonstructural carbohydrate (NSC), which should not be confused with NFC. Balancing fiber and NFC fractions to optimize energy intake and rumen health is a challenging aspect of dairy nutrition.

In general, fiber in the diet supports rumen health. Fiber in the rumen, especially fiber from forage sources that have not been finely chopped or ground, maintains rumen distention, which stimulates motility, cud chewing, and salivary flow. These actions affect the rumen environment favorably by stimulating the endogenous production of salivary buffers and a high rate of fluid movement through the rumen. Salivary buffers maintain rumen pH in a desirable range, while high fluid flow rates increase the efficiency of microbial energy and protein yield. Fiber, however, delivers less

dietary energy than NFC. Fiber is generally less fermentable in the rumen than NFC, and rumen fermentation is the major mechanism by which energy is provided, both for the animal and the rumen microbes. Therefore, diets with high NDF

concentrations promote rumen health but provide relatively less energy than diets high in NFC.

To increase the energy supply, dietary NDF concentrations are usually reduced by adding starch and other sources of NFC.

545	545	545	545	240	240	360	1,200

This increases the rate and extent of rumen fermentation, which leads to greater energy availability. Increased ruminal fermentation also leads to the increased production of volatile fatty acids, which tends to lower rumen pH. At rumen pH values <6.2, fiber digestion is reduced; at values ≤5.5, fiber digestion is severely diminished, feed intake may be reduced, and rumen health is generally compromised. There is a reciprocal relationship between NFC and NDF proportions, so the adverse effects of high dietary NFC may be especially evident as cud chewing and salivary flow may be simultaneously diminished because of reductions in dietary NDF.

Recommended minimum NDF concentrations depend on the source and physical effectiveness of the NDF and the dietary concentration of NFC. Fiber from forage sources is, in general, more effective at stimulating salivation and cud chewing than is fiber from nonforage sources. Thus, one variable in the assessment of dietary NDF adequacy is the proportion of NDF coming from forages. Minimum NDF concentrations in the diets for high producing cows are 25%-30%. When fiber sources from forage make up ≥75% of the NDF, then total NDF concentrations in the lower end of this range may be acceptable (see TABLE 25). When a smaller portion of total NDF is derived from

As the proportion of neutral detergent fiber (NDF) from forage sources decreases, the minimum requirement for total NDF increases. These represent minimum requirements; diets with higher NDF concentrations present no problem and are generally appropriate for animals with relatively low energy requirements.

forage sources, then total NDF concentrations should be in the upper end of this range. Maximum recommended NFC concentrations are 38%–44%. Diets with higher NFC concentrations will benefit from higher

proportions of NDF coming from forage sources. These recommendations must be viewed as broad guidelines rather than strict rules. Factors including the total fermentability of the diet as well as the fermentability of

^a Reprinted with permission from the National Academies Press, copyright 2001, National Academy of Sciences. Energy values are estimated based on a consumption rate 3 times the rate of consumption at maintenance. These are representative values intended primarily for relative comparison among feeds. Analyzed values of actual feed samples will vary substantially, especially among forages.

the NDF influence the NDF requirement. Diets with highly fermentable NDF sources require higher total concentrations of NDF but provide more energy per mass unit of NDF than diets with less fermentable NDF. Feeding management schemes such as totally mixed rations result in lower minimum NDF concentrations than feeding dietary components individually (see p 2265).

Energy

Dietary energy is usually measured in megacalories (Mcal) or megajoules (MJ). When the energy in a given feedstuff is expressed in terms of the Mcal or MJ actually available for metabolism, heat production, or storage in the animal, the term metabolizable energy (ME) is used. The efficiency of utilization of ME varies based on the physiologic functions supported, which include body maintenance,

growth, and lactation. The net energy (NE) system takes into account the differences in efficiency of ME utilization for each of these processes and assigns a separate NE value to individual feedstuffs based on each of these energy-requiring processes, ie, body maintenance, growth, and lactation. Thus, in the USA, in which the NE system is typically used, energy values of feedstuffs for ruminants are expressed as NE for maintenance (NE_M), NE for gain (NE_G), and NE for lactation (NE_L). This system is cumbersome and nonintuitive and has many computational disadvantages compared with alternative systems based directly on ME. However, the NE system has the major advantage of more equitably comparing the energy values of forages to concentrates when used in ruminant diets. TABLE 26 has typical values for ME, NE_L , NE_M , and NE_G for some feedstuffs commonly fed to dairy

cows. The values in these and other published tables are estimates of the energy delivered to lactating cows consuming feed at three times the maintenance consumption rate, ie, three times more feed than they would consume were they not in production. The listed values are typical averages for the feeds; the actual values for individual feeds may vary considerably, especially for forages. Laboratory analyses of feeds and forages are always advisable for both comparative evaluation and ration balancing. Values for ME and NE cannot be measured directly by typical laboratory analyses. These and any other energy values on a laboratory report are estimates, usually based on formulas with acid detergent fiber concentration as the primary independent variable. Many contemporary computer programs for ration evaluation or balancing in dairy cows do not rely on laboratory estimates of feed energy concentrations. Rather, they estimate the contributions of individual feeds to the energy supply based on feed characteristics, intake rates, and estimated rates of passage through the rumen. Such programs are frequently referred to as "models." When using programs of this type, the estimated energy values of individual feeds will diminish with increasing rates of feed intake.

In the USA, energy requirements of adult dairy cows are typically expressed in terms of NE_L. This applies to pregnant dry cows as well as lactating animals. Maintenance requirements for mature cows of various mature body weights are given in TABLE 27.

Energy requirements per kg of milk produced at various milk fat concentrations are given in TABLE 28.

The required dietary energy concentration is a function of the energy requirement and the feed intake rate. Calculated requirements for dietary energy concentration typically are very high in early lactation because the rate of milk production is high relative to the feed intake rate. However, the ration energy density concentrations required to meet the energy requirement of cows in very early lactation may be too high to be compatible with adequate dietary fiber concentrations (*see* p 2265). In general, diets with energy concentrations >1.71–1.76 Mcal/kg do not contain adequate fiber to support good rumen health and function. Thus, dairy cows in early lactation typically cannot meet their energy requirements and are expected to lose weight. During the first 3 wk of lactation, dairy cows commonly have rates of negative energy balance in the range of –5 to –10 Mcal/day. The risk of metabolic disease increases with the degree of negative energy balance, although there is great variability among individual cows in the capacity to adapt to negative energy balance without incurring metabolic disease. Feed intake, rather than milk production, is generally the most limiting factor influencing energy balance in early lactation dairy cows. Thus, nutritional management strategies that result in rapid increases in feed intake rates after calving are the most beneficial in terms of both cow health and productivity.

Fats

Supplemental fats can be added to increase energy concentration. Fat concentrations in typical dairy diets without supplemental fat are usually low, ~2.5% of dry matter. Supplemental fats may be added to attain a total ration fat concentration of ~6% of dry matter. Fats in ruminant diets can induce undesirable metabolic effects, both within the rumen microbial population and within the animal. Ramifications of these effects include reduced fiber digestion, indigestion and poor rumen health, and suppression of milk fat concentration. The major benefit of supplemental fat in ruminant diets is that dietary energy concentration can be increased without increasing the NFC concentration.

Fats may be supplemented from vegetable sources such as oil seeds, animal sources such as tallow, and specialty fat sources that are manufactured to be rumen inert, ie, not interact with the metabolism of rumen microbes. Supplemental fats from vegetable sources generally have a relatively high proportion of unsaturated fatty acids. Unsaturated fats adversely affect rumen microbial activity. In addition, these fatty acids are extensively converted to saturated fatty acids in the rumen. When fed in excessive dietary concentration, intermediate products from the saturation process may escape the rumen and be absorbed by intestinal digestion. Some of these products are trans-fatty acids, some of which directly suppress mammary butterfat synthesis. Supplemental fats from animal sources are more saturated and thus less detrimental to microbial activity and less apt to result in suppression of butterfat synthesis. Rumen-inert fats are designed to have little or no effect on rumen microbial activity and mammary butterfat synthesis. In general, when supplementing fats to

dairy diets, up to 400 g (~2% of diet dry matter) may be added as vegetable fats, particularly if the fats are added as oil seeds, which tend to be less detrimental than free oils. An additional 200–400 g may be added from highly saturated or preferably rumen-inert sources, generally not to exceed a total of 6.5% fat in the total dietary dry matter.

Protein

The protein requirements of lactating dairy cows are high because of the demand for amino acids for milk protein synthesis. Two systems of describing the dietary protein supply and requirements for dairy cows are in general use: the crude protein system and the metabolizable protein system. The crude protein system considers only the total amount of dietary protein, or protein equivalent from nonprotein nitrogen sources. Crude protein values are based on the measurement of total dietary nitrogen and the assumption that protein is 16% nitrogen. The crude protein system is relatively simple to use and has provided a traditional means of formulating dairy cow rations. TABLE 29 provides general guidelines for the required crude protein concentration of diets for large- and small-breed dairy cattle at various levels of production. It can be used for general evaluations of the protein adequacy of dairy diets. The metabolizable protein (MP) system is more complex than the crude protein system, and it was developed in recognition of the fact that not all crude protein provided to cows may be available for absorption as amino acids.

MP refers to amino acids absorbed from the small intestine and available for metabolism. MP in ruminants is derived from two sources: microbial protein synthesized in the rumen and dietary

TABLE 29

RECOMMENDED MINIMUM DIETARY PROTEIN CONCENTRATIONS FOR DAIRY COWS AT VARIOUS LEVELS OF PRODUCTION^a

55	18.3	12.1		

^a This table is intended to provide a general reference for initial evaluations of dairy diets, not a standard against which rations are balanced. Calculation of dietary metabolizable protein concentrations generally requires specialized software.

^b Crude protein requirements were generated by Spartan Dairy 3.0 (Michigan State University), assuming a mature cow in mid lactation.

^c Metabolizable protein requirements were generated by the Nutrient Requirements of Dairy Cattle Computer Program that accompanies *Nutrient Requirements of Dairy Cattle*, 2001, National Academy of Sciences, National Academy Press, Washington, DC.

proteins that escape rumen degradation. Protein escaping rumen degradation is referred to as rumen undegraded protein (RUP), while protein that is broken down in the rumen is referred to as rumen degraded protein (RDP). Both sources are important and must be considered in diet evaluation and formulation.

RUP passes unaltered through the rumen and forms a direct source of protein for intestinal digestion and amino acid absorption. Nitrogen from RDP, in contrast, must be incorporated into newly synthesized microbial protein before it will provide amino acids available for intestinal absorption. The efficiency with which RDP is recovered as microbial protein depends on the growth rate of the rumen microbes, which in turn depends on the supply of fermentable energy sources in the rumen. Thus, diets with sufficient RDP and relatively high energy concentrations will result in high yields of microbial protein, which will become available for intestinal digestion and absorption as MP. Calculations that balance dairy diets for MP must consider the complex interrelations among fermentable energy sources, RUP, and RDP.

In general, specialized software, commercially available, is necessary to formulate dairy diets using the MP system. Even with such software, many variables must be estimated with uncertainty. Therefore, calculations of MP supply must be recognized to be approximations.

Dietary ingredients vary in their proportion of RUP and RDP. In general, feeds with high moisture and high protein concentrations, eg, legume silages, will have a high proportion of RDP. In contrast, feeds that have been processed and especially those that have undergone drying will have relatively high proportions of RUP. The proportions of RUP and RDP in diets and individual ingredients are not fixed but can vary somewhat depending on intake rate. At high rates of feed intake, the rate of feed passage through the rumen is high; thus, there is less opportunity for rumen protein degradation than with the same feeds at lower intake rates. Therefore, on the same diet, RUP proportions are higher in animals with high rates of feed intake than in those with low rates of feed intake. Animals most likely to benefit from supplements selected for high RUP proportions are those with relatively

The relationship of dietary protein intake to metabolizable protein supply. The two branch points (indicated by 1 and 2) constitute the major variables relating the dietary crude protein supply to the metabolizable protein supply. The first branch point represents the proportion of protein that is degraded in the rumen. This branch point is influenced by inherent properties of the protein and the rate of ingesta passage through the rumen. The second branch point represents the proportion of nitrogen from degraded protein that is recaptured as microbial protein. This is influenced by the microbial growth rate, which depends on the supply of rumen available energy. Nitrogen that is not recaptured as microbial protein is absorbed from the rumen as ammonia and converted to urea by the liver. Some urea is recycled back to the rumen, but a large portion is excreted in urine. RUP, rumen undegraded protein; RDP, rumen degraded protein; N, nitrogen; MCP, metabolizable crude protein; MP, metabolizable protein.

high protein requirements and relatively low rates of feed intake. Cows in very early lactation and young, rapidly growing heifers are the primary examples. Supplements formulated for high RUP proportions are commonly known as rumen bypass protein supplements; however, even with these types of supplements, some portion of the protein is degraded in the rumen.

Along with overall protein requirements, dairy cows, as all other animals, have specific amino acid requirements. However, evaluating dairy cow diets relative to amino acid requirements is more difficult than making similar evaluations of diets for monogastric animals. This is because the amino acid supply for dairy cows and other ruminants is a combination of the amino acids provided by the microbial protein and the RUP. Microbial protein has an excellent amino acid profile, and diets with a large supply of microbial protein typically meet amino acid requirements if MP requirements are met. In some cases, however, high-producing dairy cows may benefit from the selection of RUP sources with specific amino acid profiles, or from adding rumen-protected forms of specific amino acids. Software is available that estimates the amino acid supply for dairy cows on different diets. The first limiting amino acids in typical dairy cow diets are lysine and methionine. With typical feedstuffs, if the MP requirement is met and the dietary lysine:methionine ratio is ~3:1, then the amino acid requirements for milk production are probably being optimized.

Water

The availability of high-quality water for ad lib consumption is critical. Insufficient water intake leads immediately to reduced feed intake and milk production. Water requirements of dairy cows are related to milk production, DMI, ration dry matter * concentration, salt or sodium intake, and ambient temperature. Various formulas have been devised to predict water requirements. Two formulas to estimate water consumption of lactating dairy cows are as follows:

$$FWI = 12.3 + 2.15 \times DMI + 0.73 \times \text{milk}$$

$$FWI = 15.99 + 1.58 \times DMI + 0.9 \times \text{milk} + 0.05 \times Na + 1.2 \times \text{minimum temperature}$$

Note: FWI is free water intake (water consumed by drinking rather than in feed), DMI is in kg/day, milk is in kg/day, Na is in g/day, and temperature is in °C. Water consumed as part of the diet contributes to the total water requirements; thus, diets with higher moisture concentrations result in lower FWI.

Providing adequate access to water is critical to encourage maximal water intake. Water should be placed near feed sources and in milking parlor return alleys, because most water is consumed in association with

feeding or after milking. For water troughs, a minimum of 5 cm of length per cow at a height of 90 cm is recommended. One water cup per 10 cows is recommended when cows are housed in groups and given water via drinking cups or fountains. Individual cow water intake rates are 4–15 L/min. Many cows may drink simultaneously, especially right after milking, so trough volumes and drinking cup flow rates should be great enough that water availability is not limited during times of peak demand. Water troughs and drinking cups should be cleaned frequently and positioned to avoid fecal contamination.

Poor water quality may result in reduced water consumption, with resultant decreases in feed consumption and milk production. Several factors determine water quality. Total dissolved solids (TDSs), also referred to as total soluble salts, is a major factor that refers to the total amount of inorganic solute in the water. TDS is generally expressed in units of mg/L or parts per million (ppm) which are numerically equivalent values (see TABLE 30). TDS is not equivalent to water hardness, which is a measure of the amount of calcium and magnesium in water. Water hardness has not been shown to affect dairy cow performance.

Other inorganic contaminants that affect water quality include nitrates, sulfates, and trace minerals. Concentrations of nitrate (expressed as nitrate nitrogen) < 10 mg/L are safe for ruminants. At concentrations >20 mg/L, cattle may be at risk, especially if nitrate concentrations in the feed are high.

Water with nitrate concentrations >40 mg/L should be avoided. General recommendations for sulfate concentrations in drinking water are <500 mg/L for calves and <1,000 mg/L for adult cattle. The specific sulfate salts present in water may affect the response of cattle; iron sulfate is the most potent depressor of water intake. TABLE 31 lists potential elemental contaminants of drinking water with upper-limit guidelines.

Minerals

Calcium and Phosphorus: Calcium requirements of lactating dairy cows are high relative to other species or to nonlactating cows because of the high calcium concentration in milk. Thus, inorganic sources of calcium, such as calcium carbonate or dicalcium phosphate, must be added to the rations of lactating dairy cows. For the first 6–8 wk of lactation, most dairy cows are in negative calcium balance, ie, calcium is mobilized from bone to meet the demand for milk production. This period of negative calcium balance does not appear to be detrimental so long as there is sufficient dietary calcium such that bone reserves can be replenished in later lactation. The availability of dietary calcium for absorption varies with dietary source. Dietary calcium from inorganic sources is generally absorbed with greater efficiency than that from organic sources. Furthermore, cows in negative calcium balance absorb calcium more efficiently than cows in positive calcium balance.

TABLE 30

GUIDELINES FOR-TOTAL SOLUBLE SALTS (TOTAL DISSOLVED SOLIDS) IN DRINKING WATER FOR CATTLE

Total Soluble Salts (mg/L)	Comments
<1,000	Safe and should pose no health problems.
1,000–2,999	Generally safe but may cause a mild temporary diarrhea in animals not accustomed to the water.
3,000–4,999	Water may be refused when first offered to animals or cause temporary diarrhea. Animal performance may be less than optimum because water intake is not maximized.
5,000–6,999	Pregnant or lactating animals should not drink such water. May be offered with reasonable safety to animals when maximum performance is not required.
≥7,000	These waters should not be offered to cattle. Health problems and/or poor production will result.

TABLE 31

CONCENTRATIONS OF POTENTIALLY TOXIC NUTRIENTS AND CONTAMINANTS IN DRINKING WATER GENERALLY CONSIDERED SAFE FOR CATTLE

Element	Upper-limit Guideline (mg/L or ppm)
Aluminum	0.5
Arsenic	0.05
Boron	5.0
Cadmium	0.005
Chromium	0.1
Cobalt	1.0
Copper	1.0
Fluorine	2.0
Lead	0.015
Manganese	0.05
Mercury	0.01
Nickel	0.25
Selenium	0.05
Vanadium	0.1
Zinc	5.0

When calculating calcium requirements, newer nutritional models take into account the variability in calcium availability from different sources. This availability generally ranges from 75%–85% for inorganic calcium supplements to a low of 30% for forage sources of calcium. This approach makes it difficult to generate general recommendations for total dietary calcium concentrations across various diets. Generally, diets with large portions of forage from legume sources will have minimum calcium concentration requirements in the range of 0.71%–0.75%, while diets with forages from primarily grass (including corn silage) sources will have minimum calcium concentration requirements in the range of 0.42%–0.47%.

Two approaches are taken with respect to the calcium supply for dry cows, each with the objective of preventing milk fever, or parturient paresis (*see* p 988). One approach is to place cows in a calcium-deficient state during the last 2–3 wk of gestation; the rationale is to stimulate parathyroid hormone secretion and skeletal calcium mobilization before calving. This makes calcium homeostatic mechanisms more

responsive at the time of parturition, allowing cows to maintain serum calcium concentrations during lactation. This approach requires diets with calcium concentrations near 0.3% of dry matter. Such diets are difficult to formulate with available feedstuffs while still meeting other nutritional requirements. Another approach is to feed an acidifying diet, usually referred to as a diet with a low or negative dietary cation-anion difference (DCAD). The low-calcium diet approach is not additive with the DCAD approach to milk fever prevention. When low-DCAD diets are fed, total dietary calcium concentrations should be near 0.9%, which is substantially greater than the requirement for a dry cow on a conventional diet.

Phosphorus nutrition for lactating dairy cows has dynamics similar to those of calcium. The efficiency of phosphorus absorption is affected by physiologic state and dietary source. As is the case with calcium, most dairy cows in early lactation are in negative phosphorus balance. Phosphorus mobilized from bone early in lactation is replaced during later lactation when feed intakes are higher. Young animals

and animals in negative phosphorus balance absorb phosphorus more efficiently than do older animals or animals in positive phosphorus balance. Phosphorus from inorganic sources is more available than that from organic feed sources.

Judiciously balancing diets to meet, but not exceed, phosphorus requirements is important for dairy cow performance and environmental stewardship. Excess phosphorus excreted in feces is one of the major pollutant risks associated with livestock production. Newer nutritional models account for variation in phosphorus availability from different sources, but there is less variation in availability among phosphorus sources than among calcium sources. In general, concentrates when fed to ruminants have a phosphorus availability of 70%, and forages close to 64%. Inorganic mineral supplements are usually rated at 75%–80% availability, but rock phosphate is very low, ~30%. Total dietary phosphorus concentration requirements for most dairy diets will be in the range of 0.35%–0.4%, and for dry cows, 0.3%–0.35%. Phosphorus supplementation for dry cows is seldom necessary.

The dietary calcium:phosphorus ratio is not of particular importance in ruminants. Ratios from 7:1 to 1:1 are acceptable, so long as the total amount of each element meets the dietary requirements.

Serum concentrations of calcium and inorganic phosphorus are of value in assessing the short-term homeostasis of these minerals but of little value in assessing longterm nutritional status. Bone ash concentrations are the best way to assess longterm calcium and phosphorus nutritional status.

Other Macrominerals: Other macrominerals required in dairy cow diets include sodium, potassium, chloride, magnesium, and sulfur. Of these, **sodium** generally needs to be supplemented, typically as sodium chloride or common salt. Insufficient dietary sodium results in reduced feed intake with subsequent reductions in animal performance. Signs of severe salt deficiency include licking and chewing on fences and other environmental objects, urine drinking, and general ill thrift. Milk production is reduced within 1–2 wk of removing supplemental salt from the diets of lactating cows. Completely withholding salt from dry cow diets in an effort to prevent udder edema at calving is not a good practice. Maintenance requirements for sodium in nonlactating cows are estimated at 1.5 g/100 kg body wt/day, with gestation requirements

estimated at an additional 1.4 g/day after 190 days of gestation. For large-breed dairy cows, this results in a sodium requirement of ~9–10 g/day. Unsupplemented dry cow diets seldom provide sodium at >3 g/day. Therefore, daily supplementation of dry cow diets with a minimum of 6–7 g of sodium per day (~15–16 g of salt) is important. Additional salt is necessary during heat stress. Although salt should be supplemented to dry cows in required amounts, excessive salt supplementation is unnecessary and may contribute to udder edema at calving.

Supplemental **magnesium** may need to be fed with diets containing high proportions of grass forages, especially those consisting of rapidly growing pasture grasses. Such forages typically have low magnesium concentrations as well as high concentrations of potassium and organic acids, which interfere with the availability of dietary magnesium. Magnesium oxide is the typical magnesium supplement in ruminant diets.

Dairy cattle, like other animals, have no dietary requirement for inorganic **sulfur**. The dietary requirement for sulfur reflects only the dietary requirement for sulfur-containing amino acids. In ruminants, rumen microbes can synthesize sulfur-containing amino acids from nonprotein sources of nitrogen and sulfur. Dairy cow diets most likely to require supplemental sulfur are those with low protein concentrations and those with supplemental nonprotein nitrogen. In general, a nitrogen:sulfur ratio of 15:1 is recommended in ruminant diets.

Recommended dietary concentrations for typical dairy cow diets are: sodium (0.23%), chloride (0.29%), potassium (1.1%), magnesium (0.21%), and sulfur (0.21%).

Trace Minerals: The trace minerals typically supplemented or measured in dairy cow diets include cobalt, copper, iron, manganese, selenium, iodine, and zinc. ● If these, selenium and copper are the trace minerals most likely to be deficient. Several areas of North America, Europe, and other continents are characterized by growing conditions that result in feeds with low selenium concentrations. In these areas, livestock feeds need to be supplemented with selenium. Sources of supplemental selenium include sodium selenite, sodium selenate, and selenomethionine. The latter source is typically referred to as organic selenium.

Selenium deficiency is known to cause myopathies in calves, which may affect

cardiac or skeletal muscle (ie, white muscle disease, *see* p 1172). In adult cattle, selenium deficiency appears to suppress immune function and especially neutrophil function. It also increases the risk of retained placenta, although feeding selenium in excess of requirements does not prevent this condition. Dietary selenium requirements in dairy cattle are estimated at 0.1–0.3 mg/kg diet dry matter. In the USA, 0.3 mg/kg dry matter is the maximum legal concentration of supplemental selenium in dairy cattle diets.

The selenium status of cattle can be accurately assessed from blood or serum concentrations. Whole blood concentrations of 120–250 ng/mL or serum concentrations of 70–100 ng/mL in adult cattle indicate adequate selenium status.

Recommended dietary **copper** concentrations in cattle diets are 10–15 mg/kg diet dry matter; however, the dietary copper requirement depends greatly on the concentration of interfering substances. These include primarily sulfur and molybdenum, but iron, zinc, and calcium may also interfere with copper availability. The adsorption efficiency for dietary copper in ruminants is normally quite low, 4%–5%. However, with increasing concentrations of dietary sulfur and/or molybdenum, absorption efficiency may be reduced to ≤1%.

Copper deficiency is characterized by loss of hair pigmentation, loss of hair around the eyes, anemia, and general ill thrift and suppressed immunity. In severe cases, persistent diarrhea may also occur.

The copper status of cattle can be assessed from liver or serum copper concentrations. Liver concentrations <20 mg/kg dry tissue or serum concentrations <0.5 mcg/mL indicate copper deficiency. Because the liver is a physiologic storage site for copper, copper concentrations in the liver will be reduced before serum concentrations.

Dietary **manganese** deficiencies in dairy cattle are less common than deficiencies of copper or selenium. Signs include poor growth and skeletal deformities in newborn calves and reproductive abnormalities, including anestrus, in adult cows. Recently recommended dietary manganese concentrations for cattle are 15–25 mg/kg; previous recommendations have been as high as 40 mg/kg dry matter.

Recommended **zinc** concentrations in the diets of dairy cattle and calves are 23–63 mg/kg dry matter. Signs of zinc deficiency include reduced feed intake and general ill thrift. Parakeratosis, particularly around the

nostrils and lower legs, and weakening of the hoof horn are signs of prolonged zinc deficiency. Normal concentrations of serum zinc are 0.7–1.3 mcg/mL. Concentrations <0.4 mcg/mL are considered deficient.

Iron deficiency is extremely rare in adult cattle, because iron is ubiquitous in the environment and the endogenous concentrations of iron in most feedstuffs will more than meet requirements. Signs of iron deficiency are primarily anemia and low serum iron concentrations. Adequate serum iron concentrations are 110–150 mcg/dL. However, these concentrations drop quickly in the presence of inflammatory disease, and such changes in serum iron concentrations should not be interpreted as being due to a dietary deficiency. Suckling calves are the only group of cattle generally at risk of iron deficiency and to which supplemental iron need be provided.

Iodine deficiency occurs with some frequency in cattle and is primarily manifest by goiters in newborn calves. The required dietary iodine concentration is generally ~0.2 mg/kg of dietary dry matter. However, dietary iodine concentrations of 0.6 mg/kg are recommended as a safety factor because of the potential presence of goitrogenic substances in common protein supplements.

Vitamins

Vitamin A: Preformed vitamin A, or retinol, does not exist in any plant material, so there is no vitamin A in natural diets for dairy cattle. Vitamin A activity from natural sources comes primarily from β -carotene, which is found in plants and is particularly abundant in fresh forages. β -carotene is labile; its concentrations in forages are not constant but diminish with time in storage. Therefore, measurement of β -carotene concentrations in feeds is not practical and seldom done. Recommended vitamin A consumption rates for various classes of cattle are based on providing supplemental vitamin A, which is derived from commercial sources: for adult cows (lactating and dry)—110 IU/kg body wt, which is ~4,400 IU/kg dry diet; for growing heifers—80 IU/kg body wt, which is ~2,500 IU/kg dry diet. Conditions that can increase dietary vitamin A requirements in adult cows include low forage diets, high corn silage diets, poor quality forages, and infection.

The vitamin A status of cattle may be assessed via serum or hepatic vitamin A concentrations. The liver stores vitamin A for release during periods of insufficient dietary intake, thus making liver the ideal

tissue for nutritional assessment. For adult cattle receiving diets with recommended supplemental vitamin A concentrations, hepatic vitamin A concentrations are 300–1,100 mg/kg dry tissue (expressed as retinol). Clinical signs of vitamin A deficiency do not occur until these reserves have been substantially depleted. Adequate serum vitamin A concentrations in adult cattle are 225–500 ng/mL, with values usually dropping to ~150 ng/mL within 1 wk of calving.

Calves are born with low body stores of vitamin A and depend on colostrum consumption to supply hepatic vitamin A stores. The NRC recommends dietary vitamin A concentrations for young calves at ~9,000 IU/kg diet dry matter. Most milk replacer diets have substantially higher concentrations of vitamin A, possibly because vitamin A requirements may be increased by infectious diseases, especially those affecting the respiratory or enteric epithelium.

Vitamin A deficiency is associated initially with night blindness followed by poor growth, poor hair coats, and suppressed immunity. In adult cattle, vitamin A deficiency is associated with retained placentas and impaired fertility.

Vitamin D: Vitamin D is necessary for the absorption and metabolism of calcium and phosphorus. Recent research suggests that vitamin D may also be necessary for immune cell function. Vitamin D₃ (cholecalciferol) can be formed by the solar irradiation of skin or vitamin D₂ by the solar irradiation of forages. However, reliance on natural vitamin D formation is considered unreliable, and vitamin D requirements are based on recommendations for supplement addition to diets. The recommended rate of vitamin D supplementation for adult dairy cows is 30 IU/kg body wt, which would be supplied by diets with ~1,000 IU/kg dry matter.

Vitamin D status can be assessed via blood serum concentrations of 25-hydroxy-cholecalciferol. Adequate values are 20–50 ng/mL, with concentrations <5 ng/mL indicating deficiency.

Vitamin E: Vitamin E is present in relatively high concentrations in fresh forages. Thus, cattle receiving pasture or fresh-cut forages may require little vitamin E supplement. In contrast, vitamin E degrades in stored forages, so dairy cattle on typical confinement-reared diets require supplemental vitamin E.

Vitamin E functions to protect cellular membranes from oxidative damage. Clinical

manifestations of deficiency include nutritional myopathy (white muscle disease, *see* p 1172) in young calves and diseases in older cattle including retained placenta and increased susceptibility to environmental mastitis.⁵

Recommended rates of vitamin E intake vary based on gestation stage: terminal dry period—1.8 IU/kg body wt, which is ~90 IU/kg dry matter; lactation—0.8 IU/kg body wt, which is ~30 IU/kg dry matter. Much higher concentrations are occasionally supplemented when environmental mastitis is a particular problem. Vitamin E is essentially nontoxic, and there is little risk of oversupplementation.

Vitamin E supplements may be natural or synthetic. Natural sources of vitamin E are derived from plant oils and are designated *RRR*- α -tocopherol or *D*- α -tocopherol, based on stereoisomer characteristics of their chemical structure. Synthetic supplements are designated all *rac*- α -tocopherol, or *DL*- α -tocopherol. The natural-source supplements appear to have much greater biologic activity.

Blood serum vitamin E concentrations may be used to assess vitamin E status in dairy cattle. Serum concentrations of 2–4 mcg/mL are generally adequate. However, in addition to vitamin E nutritional status, these concentrations are influenced by the total concentration of serum lipid, with higher serum lipid concentrations resulting in higher vitamin E concentrations. Serum lipids are generally low in late gestation and high in the period of peak feed intake. To compensate for this fluctuation, serum vitamin E concentrations are sometimes expressed as a ratio, with some serum lipid component, such as cholesterol or triglyceride, used as the denominator.

Other Vitamins: Most ruminant diets provide adequate amounts of vitamin K and the B vitamins, either through natural feedstuffs or synthesis by microbial activity in the rumen. Thus, there are no recommended dietary concentrations of these vitamins for ruminants.

FEEDING AND NUTRITIONAL MANAGEMENT

Three general types of nutritional management systems are typically used in dairy production: confinement systems with totally mixed rations (TMRs), confinement systems in which concentrates and forages are fed separately, and pasture-based systems.

Totally Mixed Rations

TMRs have all dietary components included in a single uniform mixture. TMRs have the nutritional advantage over other types of feeding systems, in that fiber and nonfiber ration components are delivered in uniform proportions throughout the feeding period. This minimizes fluctuations in rumen pH and promotes healthy rumen conditions, even at relatively high rates of energy intake.

Adequate management of TMR systems requires a means of accurately weighing each component of the mixture and a mixer capable of incorporating forages and concentrates into a uniform product. Several types of suitable mixers with self-contained weighing devices are available commercially. Many mixers are limited in their capacity to mix long-stemmed forage into the diet, thus limiting the use of dry hay in TMR diets. This means that maintaining particle size adequate to deliver sufficient effective fiber can be a challenge with TMR diets. Limiting the duration of the mixing process helps maintain sufficient effective fiber if silages have adequate particle length initially and the particles are not further comminuted during the mixing process. Sieves to monitor particle size in TMR mixes are available commercially. See TABLE 32 for recommended particle size distribution in TMR mixes, based on a popular sieving system.

Frequent monitoring of dry-matter concentrations of moist feeds is particularly important in the management of TMR diets. This is because diets are formulated based on the nutrient concentrations of the feeds on a dry-matter basis, but the ingredients are mixed based on their moist weight. Therefore, accurate dry-matter concentration values are critical to ensure the nutrient profile of the final diet is as intended. Routine analysis of the TMR mixture for major nutrient fractions, such as moisture

or fiber, is useful in assuring that the ingredient nutrient profiles and proportions are consistent with the intended diet formulation and are stable over time.

Management of feed delivery and availability is another important aspect in the use of TMR mixes. Cattle should have continuous or nearly continuous access to feed. Adequate bunk space is important, with recommendations for optimal linear space usually 45–60 cm/animal. Bunks should be cleaned daily, and the orts weighed so that daily feed intake for the group may be calculated. To assure optimal feed availability, orts should be 2%–4% of the total amount fed. Particle length of the orts should be measured to assure that sorting of the feed, which usually results in large particles being left behind, is not occurring.

For effective use of TMR diets, cows must be separated into feeding groups: minimally, a lactating and a nonlactating group, and optimally, two or more lactating cow groups and two dry cow groups. One dry cow group should comprise those cows in the first 4–6 wk of the dry period, and the other those in the 2–4 wk before calving. Diets for lactating cow groups should be formulated with a lead factor, meaning the diet should be balanced for more milk production than the average of the group. This is to ensure that the nutrient requirements of the higher-producing cows in the group are met. Optimal lead factors depend on the number of feeding groups and their stage of lactation. When two groups of lactating cows are used, feeding for >20% of the average production is frequently recommended.

Unmixed or Component-fed Rations

Confinement feeding systems in which concentrates are fed separately from forages are traditional in many areas of the world. Advantages of this system relative to the

TABLE 32

PARTICLE SIZE RECOMMENDATIONS FOR TOTALLY MIXED RATIONS^a

	Pore Size ^b (cm)	Particle Size (cm)	Percentage by Weight
Upper sieve	1.9	>1.9	2–8
Middle sieve	0.79	0.77–1.9	30–50
Lower sieve	0.13	0.18–0.77	30–50
Bottom pan		<0.18	≤20

^b Pores are square, so the largest opening is the diagonal.

TMR system include the lack of need for specialized mixing and feed delivery equipment and the ability to adjust concentrate feeding amounts to the needs of individual animals. A major disadvantage is that starch and other nonfiber carbohydrates are generally provided in a small number of meals per day, typically at milking time. Thus, there is the possibility for large fluctuations in rumen pH, which may impair fiber digestion and contribute to poor rumen health. Systems have been developed to avoid large concentrate meals. These include computer-delivered diets in which cows are electronically identified and a computerized feeding apparatus delivers small, individually programmed meals throughout the day.

In addition to the potential for fluctuations in rumen pH, another disadvantage of component feeding systems is the inability to monitor forage intake. This is because there is no direct need to weigh the amount of forage offered if it is not being mixed with other diet components. Thus, there is no means to accurately adjust concentrate intake to match fluctuations in forage consumption. This becomes a particular problem in hot weather during which forage consumption may be reduced substantially while concentrate consumption is less affected. This leads to alterations in the intended proportions of fiber and nonfiber carbohydrates in the diets.

Pasture-based Feeding Systems

Modern means of pasture management have evolved to optimize use of forage resources in pasture systems. Such systems require intensive management of pasture for optimal dry-matter and nutrient yields and for optimal feeding and nutrition of high-producing modern dairy cows. To achieve these objectives, paddocks must be rotated frequently, so forages are consumed at an optimal stage of growth and overgrazing does not occur. Pastures are typically divided into paddocks via the use of easily moved electric fences. Cattle are rotated through paddocks as forages reach stages of growth optimal for both dry-matter yields and nutrient composition.

From a nutritional standpoint, the three major challenges of pasture-based dairy systems are maintaining favorable rumen fermentation conditions, maintaining adequate dry matter intake, and meeting energy and protein requirements. Managing rumen health and dietary fiber adequacy can be as challenging with pasture-based systems as with other dairy feeding systems. Lush, rapidly growing pasture grasses with high energy and protein density typically

have low NDF concentrations. Thus, rumen fermentation conditions, particularly pH, may be a problem. Supplementing the pasture with dry forages to maintain adequate effective fiber concentrations is frequently necessary.

Dry matter consumption in pasture systems may limit nutrient intake because maximal consumption rates are lower than in confinement systems. This will limit energy intake, thus requiring supplemental energy sources to be fed to achieve high milk production. Milk production rates in unsupplemented pasture feeding situations are seldom >25 kg/day. Energy supplements may include starches such as cereal grains or highly fermentable fiber sources such as grain byproducts. Protein, and particularly sources of RUP, may also need to be supplemented. Protein concentrations in pasture grasses may be high but are generally highly rumen degradable.

FEEDING YOUNG CALVES

To assure adequate passive transfer of antibodies, all calves should receive at least 2 L of high-quality colostrum within 6 hr of birth. Colostrum feeding should continue until calves are 3 days old, but the initial feeding of colostrum is critical for passive transfer of immunity.

Traditional System of Replacement Dairy Calf Feeding

After the period of colostrum feeding, the traditional nutritional strategy for raising dairy replacement calves has been to minimize liquid feed consumption, maximize solid feed consumption, stimulate early rumen development, and wean calves at a relatively young age (usually 4–8 wk). Although growth rates are less than maximal, feed costs are minimal. In addition, the risk of enteric disease after weaning is less than during the liquid feeding period, making early weaning beneficial in the management of enteric disease.

Under this system, targeted rates of gain for calves of the large dairy breeds are ~400–600 g/day for the first 3–4 wk of life. This requires a dry-matter intake of 600–750 g/day; ~450 g of this is supplied from liquid feed, which equates to ~4 L of milk or reconstituted milk replacer/day for calves weighing 40–50 kg at birth. This amount should be divided between at least two feedings/day. The remaining dry matter should come from a high-quality calf starter, which is a concentrate mixture specially prepared for young calves. As calves grow,

the amount of liquid feed/day remains constant, and increases in growth rate are accounted for by increases in calf starter consumption.

Liquid feeds for young calves include milk, waste milk, excess colostrum, and milk replacers. Milk and excess colostrum can be high-quality feeds for suckling calves, but adequate biosecurity precautions, such as pasteurization and screening of cows for chronic infectious diseases such as bovine leukosis and Johne's disease, need to be in place.

Milk replacers are designed to mimic bovine milk and thus contain a source of protein, fat, and carbohydrate. Protein concentrations in milk replacers vary from 18% to as much as 30% on a dry-matter basis but typically are 20%–25%. Protein sources in milk replacers vary and may substantially affect the quality of the replacer. Proteins derived from milk sources, such as whey protein isolate, delactosed whey, dried skim milk, and casein, are generally excellent sources of protein, but the quality of even these protein sources may be affected by processing methods. Other animal proteins such as plasma proteins also may be of good quality. Plant protein sources vary in their acceptability, particularly for calves <3 wk old. Appropriately processed plant proteins may be acceptable but are generally less desirable than animal proteins for calves <3 wk old. Plant proteins acceptable for use in milk replacers include soy protein isolate and soy protein concentrate; these proteins may be processed to reduce antigenicity and to remove antinutritional factors such as trypsin inhibitor. The degree of processing varies by manufacturer, and not all milk replacers containing these protein sources are of equal quality. Unprocessed soy flour is an unacceptable protein source for milk replacers.

Fat concentrations in milk replacers vary from 10% to as high as 30%, with most in the range of 15%–20%. Fat sources usually contain some coconut oil and major contributions from tallow, choice white grease, or lard. Lecithin and/or monoglycerides are usually added as emulsifying agents. Fat concentration substantially influences the energy concentration of milk replacer. In cold climates in which high energy consumption is critical for young calves, fat concentration should be $\geq 15\%$. The drawback of higher fat concentrations is that the rate of starter consumption is reduced as replacer fat concentrations increase.

Early introduction of solid feed is important for replacement calf rearing. Solid feed stimulates rumen development. Calves

are born with small, nonfunctional rumens, and rapid rumen development is critical for early weaning. Rumen maturation is stimulated by the presence of fermentation products, particularly butyric acid. Thus, introduction of highly fermentable substrate into the diet is important to rumen development. High-quality calf starters are composed of highly fermentable carbohydrates in a mixture that is coarse in texture, contains few fine or powdery particles, and has a relatively high fiber concentration (~12%–15% NDF). The crude protein concentration should be ~18%–24% on a dry-matter basis. Calves should not be fed hay before weaning. Hay consumption may actually impede rumen development, because hay is less fermentable than concentrate.

A critical factor in stimulating starter consumption is the availability of fresh water. Calves should have readily available fresh water. Water consumption will vary greatly by calf but may be ≥ 4 L/day in addition to milk or milk replacer.

Feeding Calves in Cold Weather

The lower limit of the thermoneutral zone for calves between birth and 3 wk of age is 20° C and for calves >3 wk old, 10° C. Maintenance energy requirements increase as temperatures fall below these values. To compensate for these increased energy requirements, milk replacers with fat concentrations $\geq 15\%$ should be fed in cold weather. Furthermore, the amount of dry powder should be increased by 50 g/day for each incremental decline of 5° C below the thermoneutral zone. For example, if calves <3 wk old are receiving milk replacer powder at 450 g/day at $\geq 20^\circ$ C, the amount should be increased to 650 g/day at 0° C and to 900 g/day at -25° C. The dry powder should be reconstituted with proportionate increases in the amount of water. Feeding this amount of liquid frequently requires more than two feedings per day. In addition to milk or milk replacer, fresh water should be made available at least twice per day.

Feeding Calves with Enteric Disease

Diarrhea is a common condition in young calves and frequently results in life-threatening dehydration. Electrolyte solutions administered orally can be beneficial in supporting hydration and successfully treating calves with diarrhea. To help control and correct dehydration, it may be necessary to reduce milk or milk replacer feeding for a brief period after the onset of diarrhea. Nutritionally, however, the objective is for calves being treated for

diarrhea to be back receiving milk or milk replacer as soon as possible. With appropriate use of oral electrolytes, milk or milk replacer feeding should be reinstituted within 12–24 hr after the onset of diarrhea. Electrolyte solutions can be fed along with milk or milk replacer. Supporting the calf with adequate nutrition speeds restoration of the gut epithelium and generally improves calf health and immunity.

FEEDING CALVES FROM WEANING THROUGH MATURATION

After weaning, calves should receive free-choice calf starter until 3 mo old. If hay is fed during this period, it should be of excellent quality and fed in limited amounts. Energy requirements for adequate growth in calves 3–15 mo old may be derived largely from good quality forage. Meeting protein requirements during this period is challenging, because protein requirements are high relative to energy requirements. This is because in replacement heifers, lean body weight gain is preferred over fattening. For sample diets for large-breed dairy heifers 3–15 mo old, see TABLE 33. The crude protein concentrations of these example diets are high, because there is excess RDP. If rumen bypass (high RUP) ingredients were included, the crude protein concentrations could be lower and still meet the metabolizable protein requirements.

However, such RUP concentrations would be difficult to achieve without inclusion of animal-protein products or specially processed protein supplements. Diets such as those in these examples would best be delivered as TMR.

Heifers of appropriate body weight become sexually mature at ~15 mo old and should be bred at that time. After breeding, requirements for protein and energy during gestation may be met with good quality forages. In general, the feeding of corn silage during this period should be limited to no more than one-half of the diet dry matter, preferably less. This is to prevent fattening, which increases disease risk at calving.

Optimal growth rates of dairy heifers between 2 mo of age and conception are important for dairy herd profitability. Insufficient growth rates result in either an older age at first calving, which increases the cost of heifer rearing, or smaller dams at first calving, which limits milk production and conception rates during the first lactation. Conversely, excessive growth rates, especially those associated primarily with fattening, can adversely affect subsequent milk production and also increase the risk of metabolic problems at calving. Target growth rates between weaning and conception should be 700–900 g/day. As growth rates increase within this range, the proportion of crude protein and RUP in the diet needs to be

TABLE 33

EXAMPLE DIETARY CHARACTERISTICS FOR GROWING REPLACEMENT HEIFERS

	Body Wt (kg)			
	100	150	200	250
DMI (kg/day)	3.1	4.2	5.2	6.1
Concentrates (% of dry matter)	40	20	5	0
Forage (% of dry matter)	60	80	95	100
Crude protein (% of dry matter)	21	20	18.5	18.4
Metabolizable protein (% of dry matter)	11.7	9.6	8.5	7.7
RUP (% of CP)	32%	28%	22%	21%
RDP (% of CP)	68%	72%	78%	79%
ME (Mcal/kg)	2.5	2.4	2.2	2.2

Based on requirements generated by the computer program that accompanies *Nutrient Requirements of Dairy Cattle*, 2001, National Academy of Sciences, National Academy Press, Washington, DC. The crude protein requirements of animals <150 kg are relatively high and could be reduced by the use of protein sources with higher RUP proportions. DMI, dry matter intake; RUP, rumen undegradable protein; RDP, rumen degradable protein; ME, metabolizable energy.

increased to support greater lean body gain and prevent fattening. Weight and height should be measured periodically to check that growth rates and frame development are as intended. The growth response of heifers to apparently similar diets varies greatly among farms, making the monitoring of growth rates particularly important. For target body weight values at a range of age increments for heifers of various mature body sizes, *see* TABLE 34.

The different dietary requirements of calves at various ages dictate that they be kept in separate pens based on their age

and size. Calves between weaning and 5 mo old should be kept in groups of six or less. Older calves may be kept in larger groups, but animal size should be fairly uniform.

ACCELERATED CALF-REARING PROGRAMS

In accelerated calf rearing programs, larger quantities of liquid feeds are fed during the preweaning period, and larger proportions of concentrates are fed during the growing period. Weaning is later, and solid feed

TABLE 34 RECOMMENDED BODY WEIGHTS FOR HEIFERS OF DIFFERENT AGES

Heifer Age (mo)	Approximate Target Body Wt (kg)			
	% of Mature Body Weight	Small Breeds	Medium Breeds	Large Breeds
Birth	6.2	28	34	47
1	9.1	41	50	68
2	12.3	55	68	92
3	16.2	73	89	122
4	20.0	90	110	150
5	23.7	107	130	178
6	27.5	124	151	206
7	31.2	140	172	234
8	35.0	158	193	263
9	38.9	175	214	291
10	42.5	191	234	319
11	46.3	208	255	347
12	49.9	224	274	374
13	53.7	242	295	403

21	83.3	375	458	625
22	87.1	392	479	653
23	90.8	409	499	681

consumption is delayed (relative to traditional programs). After weaning, forage is not offered until heifers are >3 mo old. Dietary protein concentrations during the pre- and postweaning periods are increased (relative to traditional programs) to assure adequate lean gain and to avoid excessive fattening. Rates of gain can be as high as 1 kg/day, with heifers entering the milking herd at 22–23 mo old. Close monitoring is necessary to assure that heifers have adequate frame development and do not become excessively fat.

FEED ADDITIVES

Many non-nutrient feed additives are marketed and approved for use in dairy cattle (*see* TABLE 35).

NUTRITION AND DISEASE

Nutrition has a large effect on the occurrence and severity of many diseases of dairy cattle. *See* TABLE 36 for brief descriptions of nutritionally associated diseases, disease signs, etc.

TABLE 35 FEED ADDITIVES INCLUDED FOR NON-NUTRIENT BENEFITS

Additive	Effect	Feeding Rate
HIGH PROBABILITY OF POSITIVE ECONOMIC RETURN IN GENERAL FEEDING SITUATIONS		
Rumensin	Increased feed efficiency, improved energy metabolism	200–400 mg/day
Sodium bicarbonate and other buffers	Improved feed consumption, stabilization of rumen pH, increased butterfat production	0.75% of dry matter
Yeast culture	Improved feed consumption, improved fiber digestion	Variable, consult manufacturer directions
HIGH PROBABILITY OF POSITIVE ECONOMIC RETURN IN SPECIFIC PROBLEM SITUATIONS		
Strong anion additives for prepartum diets	Improved calcium homeostasis, milk fever prevention	Variable, calculate DCAD ^a , monitor urine pH and dry-matter intake, late gestation only
Propylene glycol	Improved energy metabolism, ketosis prevention	300–500 mL/day, late gestation and early lactation only
Niacin	Improved lipid metabolism, improved rumen fermentation, increased feed efficiency and milk component concentrations	6 g/day, include protected and unprotected sources
Mycotoxin neutralizers	Many products available; effectiveness best demonstrated against aflatoxin; effectiveness against trichothecene toxins including DON ^b or vomitoxin needs further evaluation.	Variable, consult manufacturer instructions
Protected choline	Improved lipid metabolism, fatty liver and ketosis prevention	15 g/day, late gestation and early lactation only

^a DCAD (dietary cation-anion difference)

^b DON (deoxynivalenol)

TABLE 36

DISEASES OR CLINICAL SIGNS IN DAIRY CATTLE THAT MAY BE RELATED TO DIETARY CHARACTERISTICS OR NUTRITIONAL DEFICIENCIES

Sign	Possible Nutrient or Dietary Involvement
Abortion (<i>see</i> p 1333)	Deficiencies of trace minerals or vitamins, especially selenium, vitamin A, or vitamin E
Anemia (<i>see</i> p 7)	Possible copper or cobalt deficiency in adult cattle; iron deficiency in young calves (unlikely in adult cattle)
Blindness and night blindness	May be an initial isolated sign of polioencephalomalacia; may be associated with vitamin A deficiency, with or without signs of corneal opacity
Bloat (<i>see</i> p 227)	Consumption of legume pastures or finely ground, high-starch diets (such as are frequently fed to feedlot cattle) are predisposing; cattle not acclimated to these diets are particularly susceptible
CNS signs	Incoordination, blindness, nystagmus, thrashing, and opisthotonos may be associated with polioencephalomalacia; high-starch diets with microbial inactivation of thiamine and high-sulfur diets such as those associated with heavy feeding of distiller's grains and solubles
Congenital defects	Deficiencies of vitamin A, manganese, or copper
Convulsions	Sign of vitamin A deficiency, particularly if they occur intermittently interspersed with periods of normal activity in growing calves; should be differentiated from nervous coccidiosis
Cystic ovaries (<i>see</i> p 1354)	Energy insufficiency and associated subclinical ketosis in early lactation are predisposing; vitamin E and selenium deficiency speculated to contribute
Diarrhea	Numerous dietary factors, including abrupt changes in diet, especially those associated with increases in dietary nonfiber carbohydrates and dietary rumen fermentability; lush rapidly growing pasture and increased dietary protein or salt concentrations
Displaced abomasum (<i>see</i> p 238)	Both metabolic and nutritional causes; feeding should be to prevent ketosis and stimulate high dry-matter intakes; both pre- and postpartum diets are important in management
Dyspnea	Atypical interstitial pneumonia associated with movement of cattle from poor pasture to lush pasture; associated with ruminal conversion of tryptophan to 3-methyl indole
Fatty liver (<i>see</i> p 1018)	Overfattening in late lactation or during the dry period accompanied by poor feed intake in late gestation and early lactation
Hypomagnesemic tetany (<i>see</i> p 996)	Functional and absolute magnesium deficiency; risk increases with consumption of lush pasture grasses, especially with high potassium concentrations
Inappetence (off feed)	Many nutritional deficiencies (protein, mineral, vitamin) eventually result in reduced feed intake
Incoordination	Blind staggers associated with chronic selenium intoxication; demyelination associated with copper deficiency
Infertility	Energy is the most clearly associated nutrient; insufficiencies of carotene or manganese may affect ovarian function

(continued)

TABLE 36

DISEASES OR CLINICAL SIGNS IN DAIRY CATTLE THAT MAY BE RELATED TO DIETARY CHARACTERISTICS OR NUTRITIONAL DEFICIENCIES (*continued*)

Sign	Possible Nutrient or Dietary Involvement
Ketosis (<i>see</i> p 1024)	Excessive lipid mobilization and insufficient gluconeogenesis; overfattening in late gestation and insufficient feed intake in early lactation are the primary nutritional influences
Laminitis (<i>see</i> p 1082)	Chronic or acute laminitis and their sequelae are thought to result from diets with high concentrations of nonfiber carbohydrate
Milk fever (parturient paresis, <i>see</i> p 988)	Caused by failure of calcium homeostasis rather than dietary calcium deficiency; control by feeding low-calcium diets or acidifying diets prepartum
Pica and dirt eating	Common causes are not well determined; sodium deficiency, potentially phosphorus deficiency, low-fiber diets implicated
Polioencephalomalacia (<i>see</i> p 1281)	Associated with either ruminal destruction of thiamine or with ruminal production of hydrogen sulfide associated with high-sulfur diets; more common in feedlot than dairy cattle
Retained fetal membranes (<i>see</i> p 1381)	Deficiencies of selenium, vitamin A, or vitamin E, but adding these nutrients to adequate diets will not reduce incidence; metabolic problems associated with prepartum negative energy balance may also be predisposing
Rickets and osteomalacia (<i>see</i> p 1051)	Insufficient calcium, phosphorus, or vitamin D consumption
Rumen acidosis, acute clinical	Usually associated with major errors or inconsistencies in feed delivery in which high starch intake occurs in cattle unaccustomed to such diets; associated with formation of lactic acid in the rumen with severe drops in rumen pH
Rumen acidosis, chronic subclinical (<i>see</i> p 225)	Associated with lactation diets with high nonfiber carbohydrate concentrations and low fiber concentrations; also associated with high rumen concentrations of volatile fatty acids and rumen pH values ≤ 5.2
Skin problems	Problems such as dull, brittle hair coats, hypotrichia, easily depilated hair, hyperkeratosis, thin skin, and poor healing may be associated with nutritional problems; deficiencies of vitamin A and zinc, generalized protein-calorie malnutrition
Sudden death	Deficiencies of vitamins A or E, selenium, or copper
Suppressed immunity	Generalized immunosuppression, including both cellular and humoral immunity, may occur due to malnutrition; specific nutrient deficiencies include vitamin A, vitamin E, zinc, copper, and selenium; also generalized protein-calorie malnutrition
Toxicities	Many toxicities associated with feedborne toxicants; including nitrates, cyanide, many mycotoxins, toxic plants
Urolithiasis (<i>see</i> p 1502)	Diets with high phosphorus and low fiber concentrations
Wasting and failure to thrive	Signs of many nutritional deficiencies, as well as of chronic diseases such as internal parasitism; cobalt deficiency is a well-documented cause of ill thrift in cattle; protein-calorie malnutrition should always be evaluated
White muscle disease (<i>see</i> p 1172)	Dietary deficiency of selenium or vitamin E

NUTRITION: EXOTIC AND ZOO ANIMALS

The field of zoo and exotic animal nutrition continues to make advances that result in better diets. Exotic animal nutritionists in zoos and in the feed industry are studying problems and generating information on proper nutritional management for many species.

All animals require nutrients and energy in a metabolizable form. The nutrients and energy must be properly balanced and in the correct form to accommodate particular tastes, digestive systems, and feeding methods. For example, large psittacines typically use their feet to hold food, whereas other species obtain or position food using other appendages (or they do not manipulate food). If a commercial extruded food is fed, the pieces must be large enough for the bird to grasp easily. Diets for exotic and zoo animals have been developed by considering food habits in the wild, oral and GI tract morphology, nutrient requirements established for domestic and laboratory animals and people, nutritional research on exotic species, and practical experience. The ultimate criteria to evaluate the suitability of a diet for a given species are growth, reproductive success, and longevity.

The minimum nutrient requirements established by the National Research Council (NRC) for domestic and laboratory animals can be useful starting points in setting target nutrient levels for an exotic species. For example, the *Nutrient Requirements of Small Ruminants*, published by the NRC in 2007, contains nutritional information on cervids (white-tailed deer, red deer, wapiti, and caribou) and camelids (llamas and alpacas).

For many exotic species that have closely related domestic counterparts, diets can be formulated to contain nutrients that would meet the requirements established for ungulates, mustelids, canids, felids, rodents, primates, lagomorphs, gallinaeous and anseriform birds, and fish. However, nutrient requirements established by the NRC should be used only as guidelines, because the goals of livestock producers in feeding their animals include rapid and efficient gain and high milk yield or egg production—goals that differ from the goals in zoo animal management. In zoos and other exotic animal collections, a maintenance diet should be fed in general, although a breeding or other specific diet

may be needed sometimes, depending on the animal and circumstances.

Although the NRC requirements are less directly applicable to other species, they can still serve as a useful general reference to evaluate the nutritional adequacy for most birds and mammals. The formulation and evaluation of diets for reptiles and amphibians is even more difficult, because there are no domestic animal models and because metabolic rates of poikilothermic animals fluctuate with changes in ambient temperature. Once the nutrient concentrations for the diet have been established, the types and amounts of foodstuffs, methods of presentation, and feeding frequencies should be selected based on the physical and behavioral attributes of the species.

All food should be of good quality. Spoiled or moldy foods, or foods stored for long periods (eg, >1 yr for most bagged feeds and 6–12 mo for most frozen foods) should not be fed. The practice of “topping off” the feed bowl daily or every other day should be discouraged, because uneaten food on the bottom can spoil. Food and water dishes should be thoroughly cleaned before adding food or water. Clean, fresh water should always be available to nonmarine species. Trace mineral salt blocks, bricks, or “spools” are commonly offered to ungulates, psittacine birds, and some rodents.

Cafeteria-style feeding is strongly discouraged, because captive animals rarely select a balanced diet if given a wide selection of foods. Usually, a nutritionally complete commercial product or in-house mixture that cannot be sorted should comprise the bulk of the diet, with components such as meat, fruit, and seeds comprising only a small percentage. Pelleted diets are especially important with psittacines, to avoid self-selection of calcium-deficient seeds.

To improve consumption of pelleted diets, feeding should be done in the morning, with the other food items offered during the day. All diet items to be fed should be weighed, and the actual intake recorded.

Muscle and organ meat, fruit, most grains and seeds, and most insects are poor sources of calcium, and excess consumption can result in calcium deficiency. Calcium gut-loading diets containing at least 12%–15% calcium should be fed to insects.

Dusting with a balanced calcium-phosphorus powder is also a possibility; however, it is doubtful this can add enough calcium to the diet. Other sources of calcium include oyster shell, cuttle bone, and ground calcium carbonate tablets.

Obesity is more common than inadequate nutrient intake. Ungulates, primates, and carnivores can rapidly become overweight when excess amounts of a high-quality diet are offered, particularly when activity is limited. In some birds (eg, ratites, waterfowl), rapid growth rates increase the incidence of leg and wing problems. Both adult and growing animals should be routinely weighed to monitor changes. If weighing four times a year is not possible, a body score index should be performed.

If a dietary change is contemplated because of suspected nutrient imbalances, deficiencies, or toxicities, the diet currently fed should first be computer-analyzed to assess nutrient concentrations. Ingredient or nutrient changes can then be made based on correcting a suspected or confirmed health problem. For captive, exotic animals, establishing and maintaining dietary histories can be particularly helpful in health assessment. Activity patterns of individuals are also important (eg, atherosclerosis is relatively common in obese birds).

Nutritional Supplements: The use of nutritional supplements is popular among animal caretakers. Although many keepers and pet owners use nutritionally complete feeds that require no supplementation, supplements are still often provided. The nutrient content of the current diet should be established or estimated first to determine whether any supplement is needed or whether a supplement should be discontinued. Unfortunately, diets are rarely evaluated first to determine which nutrients (if any) are unbalanced.

If a nutrient is deficient in a diet, a specific supplement in a specific amount should be recommended. Excessive supplementation of some nutrients (eg, some fat-soluble vitamins, selenium, copper) can be just as harmful as not enough because of toxicity and nutrient imbalance. Diets consisting primarily of grain products and cultivated fruits and vegetables may need micronutrient supplementation; however, supplements vary widely in their composition.

Water: Water intake should be assessed routinely but especially in animals with compromised renal function, in lizards or birds prone to gout, and in animals under

conditions of high temperature or low humidity in which evaporative losses can be expected. The salt content of water should be known, because some species are less tolerant than others. Animals fed dry feeds (pellets, extrusions, hay, etc) require more water than those fed succulent feeds. Potable water should be available ad lib.

Many animals in the wild consume much of their water in the foods they eat. When low-moisture foods are consumed (pellets, extrusions, etc), some animals, depending on how water is presented, may not maintain adequate hydration. Many free-ranging small and tropical lizards receive water from foods and from licking drops that accumulate after rainfall. When in captivity, they frequently do not drink readily from containers. In nature, birds of prey do not drink; however, in captivity, they do drink sometimes, depending on the circumstances, so clean drinking water must be available at all times.

Humidity may be especially important to maintain hydration of many reptiles, especially tropical species. Daily misting with warm water is an important source of hydration for some lizards that may not be observed drinking standing water. Eye lesions in semiaquatic turtles (eg, box turtles) and some tortoises may be the result of low environmental humidity (or possibly upper respiratory tract disease) and not vitamin A deficiency. Conjunctivitis may respond better to supportive antibiotic therapy and higher humidity than to supplemental vitamin A. Dietary histories may be especially important in such cases, because many captive turtles are fed commercial food, which is mostly cat food high in vitamin A.

For a discussion of nutrition for orphaned animals, see p 2100.

BIRDS

The exact nutritional requirements for most species of birds are still unknown. The exceptions are birds raised for food or other products, such as poultry, ducks, ostriches, and pheasants. Avian diets for many species are extrapolated from the *Nutrient Requirements of Poultry* published by the NRC.

PSITTACINES

The pet bird population consists largely of psittacine species, primarily passerines and other genera such as those that include toucans. Psittacines eat mainly a plant-based diet and can be classified overall as

florivores. The content of the diet—fruit, nectar, seeds, or a combination—varies by species. Some species ingest a percentage of insects or carrion. Although requirements and dietary sensitivities vary among psittacine species, the pelleted and extruded diets that have been produced for parrots have tremendously improved the nutritional intake and subsequent health and quality of life of these birds. However, pelleted diets differ in content and quality and must be evaluated individually. Extruded pellets in different shapes and sizes are available for maintenance and breeding purposes. Many pellets contain omega-3 fatty acids as well as probiotics.

Psittacine nutrition has been the focus of research throughout the past several decades. Several myths of psittacine nutrition have been debunked during this period. Grit, while probably necessary for some passerines and Columbiformes to aid in mechanical digestion, is not needed by psittacines. If seeds are consumed by psittacines, they are hulled before ingestion. Monkey chow biscuits are nutritionally incomplete, and some brands tend to harbor bacteria or promote excessive gram-negative bacterial growth when included in bird diets. Strictly seed diets, regardless of supplementation, are suboptimal for psittacine species. Deficiencies of vitamin A, protein (the amino acids lysine and methionine, in particular), calcium, and other nutrients are seen in most psittacine species on seed-based diets. Conversely, excessive vitamins, such as vitamin A, are added to some pelleted diets, which can have equally detrimental effects.

Protein: Protein (amino acid) requirements of psittacines have not been well established. The amino acid deficiencies most consistently noted in psittacine birds on seed-based and table-food diets are lysine and methionine. Fiber content must always be considered when determining dietary protein requirements, because increased fiber causes increased fecal protein “loss.” Birds with low-fiber, more readily digestible diets (such as nectar-feeding lorries and lorikeets) may do well on diets with easily digestible protein levels as low as 3%–5%. Adult maintenance levels of protein for budgerigars and cockatiels (7%–12%) are lower than those for African Grey parrots (10%–15%). Protein requirements for growth and for egg-laying hens are higher than maintenance levels in all birds. Periods of heavy molt also greatly increase protein requirements, particularly the need for the sulfur-containing amino

acid cysteine, because feathers average 25% of the total body protein content of birds.

Excessively high dietary protein has the potential to cause renal insufficiency and gout in birds with preexisting renal impairment or a genetic predisposition to gout. Cockatiels with no preexisting renal disease have been shown to tolerate extremely high dietary protein levels (up to 70%) with no renal impairment. A genetic predisposition to renal disease/gout has been documented in some strains of poultry and may be seen in other avian species.

Sudden, dramatic increases in dietary protein may overload the kidneys, producing hyperuricemia and visceral gout. When increased dietary protein is indicated, it should be increased gradually to avoid renal damage.

Fat: Dietary fat provides essential fatty acids, energy, and hormone precursors. It also contributes to egg yolk formation and aids in absorption of fat-soluble vitamins. Diets should contain 5%–12% fat, depending on the species, the general condition of the psittacines, and the physiologic stage and brood condition. At least 1% of the dry diet should consist of PUFA (eg, linoleic acid). Excessive dietary fat leads to obesity, metabolic diseases, cardiac disease, and atherosclerosis (*see also* PET BIRDS, p 1885). The fat requirements of psittacines for reproduction are generally lower than those of poultry, because the psittacines’ altricial young do not require the same quantity of fatty acids as do the precocial young of chickens. However, diets that are borderline deficient often manifest as problems in either the psittacine hen or the chicks during reproduction.

Vitamins: **Vitamin A** is necessary for vision, reproduction, immunologic integrity, and growth, and for the maintenance of epithelial cells in respiratory, GI, and renal tissues. Vitamin A deficiency has historically been noted in psittacines on all-seed diets, so supplementation is commonly recommended. However, indiscriminate supplementation leads to vitamin A toxicosis, as well as to decreased absorption of other fat-soluble vitamins and carotenoids. In nature, psittacines do not consume vitamin A but obtain vitamin A precursors such as carotenoids from various plants. Pelleted diets should contain vitamin A at levels of 5,000–8,000 IU/kg of feed. Higher amounts should be avoided. The source of vitamin A added to bird feed is not regulated, and significant quality control issues have been documented.

Ideally, a quality pelleted diet for psittacines will contain multiple carotenoids and other vitamin A precursors, with a minimum level of vitamin A.

Some **carotenoids** in birds are precursors for the body's formation of vitamin A. Carotenoids also act as antioxidants and are necessary in some species (such as canaries and flamingos) for feather pigmentation.

The primary function of **vitamin D** is to increase absorption of calcium and phosphorus. Vitamin D can be obtained either directly from the diet or from UVB (285–315 nm) light exposure. Vitamin D deficiency is probably rare in nature because of exposure to sunlight. Birds living in polar conditions get their vitamin D during the winter by consuming diets with high amounts of vitamin D (eg, fish, plankton). In the absence of natural sunlight, the minimum oral vitamin D requirement for African Greys is likely to be 500–1,000 IU/kg.

Vitamin D deficiency may be caused by dietary deficiency or lack of exposure to UVB radiation. Limited studies have shown that species variation in psittacines for UVB light requirements exist. Unfortunately, many birds are housed totally indoors, and owners often mistakenly assume either that the birds do not need direct sunlight or that the sunlight the birds receive through glass will supply UVB radiation. Owners of pet birds should be encouraged to expose their bird to direct sunlight (with appropriate cautions regarding excessive heat) or to purchase and properly use UVB bulbs. However, pet bird owners must consider that the further away from the equator, the less UVB is generated, especially in late autumn, winter, and early spring. Some research indicates that UVA and/or UVB can affect vitamin D synthesis in some bird species, the finding of food, well-being, and feather colors. However, more research is needed to determine how much UVA and/or UVB is needed for each bird species.

Vitamin D toxicity is caused by excessive supplementation. Some psittacine species, notably macaws, are sensitive to excessive dietary vitamin D and may develop soft-tissue calcification and renal failure. Toxic levels for psittacines have not been established, but levels that may be toxic for poultry begin at 2,800 IU/kg of feed.

For discussion of **vitamin E**, see p 2291.

PASSERINES

The order Passeriformes contains >5,000 species of birds and includes frugivorous, carnivorous, insectivorous, and granivorous

species. Most passerines maintained as pets (finches and canaries) have historically been fed primarily seed and are considered florivorous to granivorous. Commercial seed mixtures for canaries often contain a mixture of canary, rape, niger, hemp, linseed, and oats. Most of these commercially available seed mixtures are deficient in numerous vitamins and amino acids. The fat-soluble vitamins A, D₃, E, and K are generally low, the calcium:phosphorus ratio is poor, and the amino acids lysine and methionine are insufficient. High amounts of fat in seed-based diets can lead to obesity and to nutritional disorders in the offered food (eg, calcium and vitamin deficiency, as well as an amino acid disorder).

Egg food (hard-boiled egg-based soft food with added vitamins and minerals) has traditionally been fed by canary breeders during the reproductive season, with soaked seed added to increase acceptance. Extruded pellets, such as organic pellets or pellet-based mash, which contains balanced nutrients, are offered by many breeders as a nutritionally consistent alternative. Pellets are fed for maintenance or breeding purposes. Extruded pellets fed for breeding contain 18%–22% crude protein as well as a limited amount of fat (5%–8%), compared with the high amounts of fat in seeds.

Soluble grit (ie, oyster shell, cuttlebone) should be provided to canaries and finches. Sprouts, fruits, and vegetables may be psychologically stimulating and enhance breeding in these passerines.

Plumage colors in canaries partially depend on the pigments in the diet. For example, red-colored canaries are fed canthaxanthins before breeding season. Carotenoids vary in their bioavailability, and there are species differences in the types of carotenoids absorbed and metabolized.

COLUMBIFORMES

(Pigeons and doves)

Most pigeons are either primarily granivorous or frugivorous, with some invertebrates also consumed. Seed-eating pigeons and doves can be fed commercial pigeon pellets (2 mm). These pellets should be comparable in composition to that listed in the NRC requirement of growing chickens 6–12 wk old. Alternatively, psittacine small pellets and mash are accepted by most Columbiformes but, depending on the composition, may have to be supplemented.

Columbiforme parents feed their young with crop milk, which is produced from

desquamated epithelial cells and glandular secretions of the crop. Crop milk is rich in fat and protein, devoid of carbohydrates, has a low pH, and contains several *Lactobacillus* species. Seed-eating pigeons switch in 3–5 days from crop milk production to feeding their young mostly regurgitated seed. Frugivorous pigeon squabs (eg, crowned pigeons) rely on crop milk for at least 30 days.

RAPTORS

Raptors include birds of prey from many genera. Most medium to large raptors consume whole vertebrate prey. Commonly fed items include mice, rats, day-old chicks, quail, and pigeons. Kestrels generally consume insects. Fish are the natural diet of piscivorous raptors such as ospreys and sea eagles. If fish is fed, thiamine supplementation (30–35 mg/kg feed) as well as vitamin E (100 mg/kg) is advised.

Commercial diets for birds of prey are available and consist mostly of a mash of several different prey items with a specific amount of vitamins and minerals.

Small raptors (100–200 g) eat as much as 20%–25% of their body wt/day; raptors weighing 200–800 g eat 15%, raptors weighing 800–7,000 g eat 6%–10%, and raptors >7,000 g eat 3.5% of their body wt/day. Captive raptors should be weighed regularly, and food volume adjusted as needed to prevent emaciation as well as obesity. If weighing is not possible, the breast-comb can be checked: if sharp, the animal is emaciated; if fat, it is obese.

The best food for birds of prey is mice and rats; however, day-old chicks and other whole birds or mammal species also are an adequate feed. The egg yolk of day-old chicks should not be removed when fed, because it contains a considerable amount of vitamins and minerals. It is advised not to feed animals from the wild (eg, rats, pigeons, rabbits) because of potential diseases, toxins, and poisonings.

Although whole prey, including their organs, should be a complete nutrient sufficient feed, it is advised to add a small amount of a balanced vitamin and mineral supplement, especially when the birds are under stress. Prey with relatively large bones must be avoided because of obstructions in the gizzard, which prevent casting. Birds <12 days old should not be fed too many bones, because they cannot digest them, and metabolic bone diseases can result. Metabolic bone diseases can also result when a chick is growing too fast. Birds of prey should not be fed before travelling. If

an organ meat-based diet is fed, vitamins and minerals should be supplemented; calcium supplementation should be 10 g of calcium carbonate/kg of fresh meat.

PISCIVOROUS BIRDS

Penguins, pelicans, and other fish-eating species in the wild feed primarily on fish, crustaceans, and squid. These food sources vary in their fatty acid, vitamin, and carbohydrate contents. In captivity, squid, smelt, herring, mackerel, and whiting fish are commonly available. One of the most important aspects of feeding piscivorous birds is fish quality (see p 2297). It is advised to feed several fish species, although in some cases one species of fish has been fed for a lifetime. Captive seabirds develop strong preferences for a particular fish if it is fed exclusively for prolonged periods, which can lead to both nutritional deficiencies and inanition if the feeder fish becomes unavailable.

Supplements commonly given to captive penguins include vitamins A, D, B₁, and E. The need for these and the quantity that must be supplemented depends on the quality and content of the primary diet. Supplements can be added to the fish as tablets, as a gel, or as a liquid to be injected in the fish.

Dietary salt (NaCl; 0.5–1 g salt/bird/day) is often provided to birds in freshwater exhibits to help maintain proper functioning of the salt glands.

Thiamine: The process of thawing fish in running water depletes them of water-soluble vitamins. Additionally, several fish species contain thiaminase, leading to thiamine (B₁) deficiency during the defrosting process.

Supplementation of thiamine is recommended at 30–35 mg/kg fish, daily.

Vitamin E: Most fish are deficient in vitamin E. Clinical signs of vitamin E deficiency in piscivorous birds include weakness and inability to stand or hold the wings in normal posture. Severe generalized myopathy with muscle atrophy, degeneration and necrosis, and replacement with fibrous connective tissue can occur with chronic pronounced vitamin E deficiency. Supplementation with 100 IU vitamin E/kg fish has been proposed. However, oversupplementation (vitamin E at 500–10,500 IU/kg food) may result in decreased growth and coagulation disorders, possibly from creating vitamin K deficiency rather than directly from vitamin E toxicity.

Hand feeding of species and individuals of concern will ensure that each bird receives the proper amount of food and supplement. Some piscivorous species will accept commercial bird-of-prey diets, trout pellets, and/or mice in the diet, as well as fish.

WATERFOWL

The order Anseriformes includes ducks, geese, and swans. These waterfowl vary from strictly herbivorous (swans, most geese, most ducks) to highly piscivorous (marine ducks, mergansers). Commercial duck or game-bird pellets should contain 14%–17% protein and 3%–6% fat with an adequate vitamin mineral supplement. During breeding season, the amount of protein can be increased to 16%–18%. In winter in colder areas, more fat can be added by adding 20% of corn to the diet. Piscivorous waterfowl consume mostly a fish-based pellet containing 25%–40% protein and 5%–10% fat. Some breeders prefer to feed a “sinking” or “floating” waterfowl pellet in the water. However, pellets fed in water should not be allowed to dissolve before consumption.

Swans and geese are fed the same diet as herbivorous ducks. Although waterfowl can live on only nutrient adequate pellets, usually some lettuce is also fed.

Diets of little lettuce and corn, which are unfortunately often provided, lead to protein and multiple vitamin deficiencies. These often manifest as poor plumage, swollen joints, and pododermatitis.

As is true for most bird species, young waterfowl should be fed starter pellets with higher fat (5%–8%) and protein (16%–20%) content. However, excessively rapid growth of large waterfowl must be avoided to prevent bone and joint deformities, such as angel wing and perosis.

GALLINACEOUS BIRDS

Many gallinaceous birds are omnivorous. Commercial diets for domestic fowl, domestic turkeys, and Japanese quail are available. During nonbreeding periods, a maintenance diet can be offered two or three times daily and generally should contain <20% crude protein. During the breeding season, food should be offered free choice and contain a higher protein content (20%–25% crude protein).

Most quail are primarily seed-eaters and are easy to feed. Some Old World quail species are insectivorous and must be provided a diet with specific protein requirements. Peafowl in general (*Pavo*

spp) consume invertebrates, mollusks, beetle larvae, and in the case of the Indian blue peafowl, even the venomous cobra. Other gallinaceous birds consume almost exclusively vegetable material. The tragopans (*Tragopan* spp), some pheasants (*Symaticus* spp), and several species of grouse are largely vegetarian. Tragopans consume sprouts, grasses, mosses, berries, and a few insects. In captivity, tragopans can be fed lucerne, grasses, cucumbers, apples, and different kinds of berries. Grouse are noted for their ability to feed on plants containing quinones, which are not consumed by other animals. Captive grouse should receive natural foods or at least large amounts of leaves, grass, and berries supplemented with a limited quantity of pellets and grain. Feeding these largely herbivorous species with game bird or domestic fowl commercial diets will result in suboptimal fertility and health.

Coccidiostats are added to some poultry feeds. Monensin is commonly used and is toxic for guinea fowl. All gallinaceous birds should have access to grit. Poultry pellets generally contain adequate calcium and vitamins, and additional supplementation should be done only when a deficiency exists.

RATITES

See also RATITES, p 1960.

Ratites are flightless birds and do not require the high-energy diets of flighted birds. Ostriches, rheas, and emus consume low-quality roughage in nature, which is fermented in their intestinal tract. The nutritional requirements of juveniles are much higher in protein and calcium than those of adults. Breeders have even higher calcium requirements (see TABLE 37).

In most parts of the world, the commercial breeding market for ratites is declining; however, in some areas significant numbers of ostriches and nandus are being kept. Ratite production for meat and leather has necessitated the development of diets to maximize growth and minimize cost. Bringing an animal to market in minimal time is financially advantageous, but excessively rapid growth can lead to angular deformities of the legs.

Cassowaries are rainforest ratites and are primarily frugivorous. They are not raised commercially, and their nutritional requirements are not documented. Adult birds often consume 3–5 kg of food/day. Diets fed in zoos include fruits and vegetables such as bananas, apples, tomatoes, papaya, watermelon, grapes, mangoes, plums, nectarines, cherries, kiwi fruit, figs, sweet

potatoes, and carrots. These are commonly supplemented with animal protein (eg, day-old chicks, mice, dry dog food).

MYNAHS

Mynah birds of the family Sturnidae are omnivorous. Preferred food items in the wild include fruits, a variety of insects, and small reptiles and amphibians. In captivity, a low-iron pelleted diet to prevent iron storage disease (≤ 100 ppm iron) and fruit are generally fed. Fruits high in vitamin C should be avoided, because these facilitate iron absorption.

During breeding, insects such as mealworms are preferred by the parents for feeding their young. Calcium gut-loading or dusting of insects with calcium powder will help prevent hypocalcemia in the chicks.

TOUCANS

In nature, toucans (*Ramphastos* spp) eat mostly fruit but also consume insects, rodents, and invertebrates. Like mynahs, toucans are susceptible to iron storage disease. Their basic diet should be a low-iron pellet with a variety of fruits (apples, banana, grapes) offered daily. If the bird picks the fruit preferentially over the large toucan pellets, the pellets can either be crushed, or very small low-iron pellets can be mixed with the fruit, so the pellets adhere to the fruit and are ingested. These long-beaked birds may have difficulty drinking water and may become dehydrated if not provided a large enough drinking pan.

MANAGING AVIAN ZOOLOGICAL COLLECTIONS

When working with large zoological collections containing disparate species, a

team approach is critical to improve nutrition for multiple species. The keepers' experience regarding the birds' habits and preferences, combined with input from the curator, veterinarian, and outside nutritional consultants are all necessary. Input from other institutions where a given species has a history of longevity and successful reproduction can be invaluable. In large collections, decreasing waste, spoilage, overfeeding, and excessively time-consuming diet preparation must be considered along with improvement of the birds' nutritional intake.

MAMMALS

HANDREARING ZOO MAMMALS

Successful nutrition of handreared mammals requires 1) selecting a formula that will support adequate growth and not cause GI upset; 2) offering it at proper intervals, in proper amounts, and in the proper way to ensure acceptance and prevent overfeeding, underfeeding, or aspiration into the lungs; and 3) keeping all feeding utensils clean and disinfected. If success is judged in terms of survival and not in comparison with maternal-raised growth and health, most precocial species maintained in captive collections have been handreared successfully. Handrearing more altricial species (eg, marsupials, rodents, rabbits) is generally less successful unless the young have been dam-raised to a more advanced stage.

Whenever possible, data on milk composition and handrearing case histories should be consulted before attempting to bottle-raise a species for the first time. Extensive books with general information on handrearing birds and handrearing wild

TABLE 37 SELECTED NUTRITIONAL REQUIREMENTS FOR RATITE PRODUCTION^a

Diet	Age (mo)	Estimated Body Wt (kg)	Crude Protein (%)	Calcium (%)	Fiber (%)

and domestic mammals are available. However, most milk composition data are not available for most species, and some of the published data are of dubious value. Lactose content of milk varies widely between different species.

Animals (eg, pinnipeds, rabbits) that normally consume milk low in lactose generally produce little lactase and often develop severe GI problems and diarrhea when fed a high-lactose milk, eg, bovine. Similarly, adding sucrose to milk formulas is often contraindicated, because many neonates produce little sucrase. Many species have been raised using diluted evaporated milk or commercial calf, lamb, foal, or doe milk replacers (eg, most ungulates), commercial dog milk replacer (eg, canids, procyonids, bears, bats, edentates, mustelids, rabbits, rodents), commercial cat milk replacer (eg, felids), human infant formulas in general (eg, most primates), and soybased human infant formulas in particular (eg, rabbits, some marsupials). In some cases, these basic formulas can be modified to better suit the needs of a particular species by adding ingredients such as egg yolk, butterfat, cream, and casein. Supplementation with vitamin and mineral products may be warranted. Some companies offer a range of products with different amounts of protein and fat, so the desired amount of protein or fat can be provided in the formula. *See* TABLE 38.

It is preferred that some species (eg, ungulates, marsupials, mink) receive colostrum within 12–48 hr of birth to acquire immunoglobulins necessary for survival. Including some colostrum in the diet of ungulates for up to 2–3 wk after birth may

provide additional local gut protection. Colostrum from domestic cows has proved satisfactory for many exotic ruminants and can be stored frozen. When colostrum is fed, the best way to do so is to offer it from the dam or from a similar species from the same stable. Studies suggest that conspecific serum, collected aseptically, can be given PO or SC as a substitute for colostrum.

Frequency of feeding and the amount fed depends on natural nursing behavior, formula composition, and the desired rate of gain as well as practical labor restrictions. The stomach capacity of most species can be estimated at 50 mL/kg. Overfilling the stomach leads to GI upset, decreased transit time, and diarrhea. Daily intake, as a rule, should not exceed 20% body wt/day and should be divided into frequent feedings that do not exceed 35–40 mL/kg. In general, most newborns should be fed every 2–4 hr, and daily metabolizable energy intake (kcal) should be $\sim 210 \times \text{body wt (kg)}^{0.75}$. Appetite, condition of feces, and general health should be monitored closely. Pulmonary aspiration is the main problem during bottle feeding. Body weights should be recorded at frequent intervals. Smaller, more altricial species often must be fed by stomach tube.

See also CARE OF ORPHANED NATIVE BIRDS AND MAMMALS, p 2100.

BATS

Captive insectivorous bats frequently are fed diets consisting primarily of mealworms. Crickets, fruit flies, blowfly larvae, and other insects also are commonly offered. Because insects typically are low in calcium, they should be maintained on a

TABLE 38 NUTRIENT REQUIREMENTS FOR HANDREARING SELECTED ZOO MAMMALS

Animal	Dry Matter	% of Dry Matter		
		Protein	Fat	Carbohydrates/Lactose
Horses, rhinos	8–12	15–20	2–15	59–75
Primates	2–14	7–15	25–35	50–60
Elephants, ruminants, pigs	12–23	21–27	30–45	20–37
Rodents, carnivores, deer	18–34	28–42	32–55	5–25
Rabbits, bears	30–40	25–45	40–50	5–10
Seals	41–61	10–20	74–82	0–2
Marsupials	23–28	—	—	1

calcium-enriched diet so that the bat will consume the insect's high-calcium gut contents. A suitable mealworm diet can be formulated using 35% wheat middlings, 35% ground dry dog or cat food, and 30% ground calcium carbonate, which should be fed at least 3 days. Gels containing water and a calcium solution can also be fed. Frugivorous bats should be fed a diet that contains a low amount of iron to prevent iron storage disease. The diet could contain a low-iron pellet for birds mixed with apples, bananas, and oranges.

Often, captive insectivorous bats must be fed by hand when flying insects are not available. Some bats can be trained to

accept insects from a food dish by being placed directly on the live food.

Many insectivorous bats can be maintained successfully in captivity using artificial liquid or solid diets (see TABLE 39). Liquid diet can be placed in shallow plastic trays positioned near wire or branches for the bats to land on and hang from while feeding. Leftover liquid diet should be replaced daily. Solid diets usually include bananas as the major ingredient. Additional ingredients frequently offered include papaya, apple, pear, melon, grape, and cooked carrot and sweet potato. Canned cat or dog food, chopped eggs, and mealworms also have been fed with the fruit.

TABLE 39 DIETS OF SELECTED MAMMALS

Freshwater Otter Diet	Percent (%)
Ground horse or cow meat	38
Ground beef heart	20
Ground dry cat food	13
Beet pulp	2.9
Mirra-Coat®	1.9
Calcium carbonate	0.8
Poultry fat	4.9
Water	16.9
Lactose	0.04
Yogurt	0.72
Mineral-vitamin mix	0.84

All ingredients should be combined in a large mixer, divided into daily portions, and frozen. Lactose for lactobacilli can be added in yogurt to help maintain freshness. Lactose and yogurt are optional.

Liquid Diet for Bats	Percent (%)
Dry mix:	
Mixed baby cereal	20.7
Wheat germ	4
Nonfat dried milk powder	9
Calcium caseinate	15.8
Sugar	45.5
Protein supplement (casein-based)	3
Mineral-vitamin mix	2

The dry mix (100 g) should be mixed with canned peach nectar (540 mL), water (260 mL), and corn oil (6 mL), and fed with peeled bananas.

(continued)

TABLE 39 DIETS OF SELECTED MAMMALS (continued)

Large Herbivore Pellet for Grazers	Percent (%)
Wheat middlings	30
Alfalfa hay, sun-cured, ground (16% crude protein)	22
Corn grain, ground	19.1
Soybean meal without hulls (48% crude protein)	11.4
Alfalfa meal, dehydrated (17% crude protein)	10
Sugarcane molasses	5
Soybean oil	1
Phosphorus supplement	0.8
Sodium chloride	0.5
Mineral premix ^a	0.1
Vitamin premix ^b	0.1
Calculated composition (dry-matter basis): 89% dry matter, 19% crude protein, 4.3% fat, 16% acid detergent fiber, 12% crude fiber, 0.75% calcium, 0.7% phosphorus	

^a Mineral premix (mg/kg of premix): 75,000 Zn, 50,000 Fe, 30,000 Mn, 10,000 Cu, 800 I, 200 Se, and 100 Co

^b Vitamin premix (per kg of premix): 5,000,000 IU vitamin A, 400,000 IU vitamin D₃, 200,000 mg vitamin E, 500,000 mg choline, 40,000 mg niacin, 20,000 mg pantothenic acid, 4,000 mg riboflavin, 20 mg vitamin B₁₂

CARNIVORES

Most zoos in the USA use nutritionally complete commercial diets to feed exotic felids, canids, mustelids, and viverrids rather than attempt to prepare diets in-house. In other parts of the world, a whole or partial carcass (eg, of cows or horses) may regularly be fed. Other prey animals, such as rabbit and chicken, are also regularly offered. A supplement containing at a minimum calcium, vitamin A, iodine, taurine, and some B vitamins should be added to the meat diet. Feeding a complete mixed diet greatly reduces incidence of nutritional problems in captive exotic carnivores; however, such a diet regularly causes fecal problems. Most commercial diets are based on horsemeat and its byproducts, but diets based on beef and poultry are also available. Typical lesser ingredients include fish meal, soybean meal, beet pulp, and ground corn, as well as mineral and vitamin supplements.

Exotic feline diets are usually higher than canine diets in fat, protein, and vitamin A. A diet suitable for most cat species contains 45%–50% protein, 30%–35% fat, 3%–4% crude fiber, 1.2%–1.5% calcium, 1%–1.2% phosphorus, and 20,000–40,000 IU of vitamin A/kg

diet (dry matter basis). Apparently, exotic cats, like domestic cats, are unable to convert carotene to vitamin A, tryptophan to niacin, and linoleic acid to arachidonic acid. They also probably cannot synthesize adequate taurine (a taurine deficiency has been reported in leopards) and would be susceptible to ammonia toxicity if fed an arginine-deficient diet. Therefore, these nutrients should be considered dietary essentials for all felids.

Frozen and canned cat foods usually are more palatable than dry ones to exotic cats. Many zoos prefer to use frozen diets over canned products, because generally they are less expensive and large quantities are easier to feed. The soft, hamburger-like consistency of commercial diets can result in excess calculus deposits and periodontal disease if hard or unprocessed items are not also provided. All cats fed a soft diet should receive bones with some meat intact twice weekly. Horse or beef shank bones are suitable for large cat species; oxtails, rib bones, or whole rodents can be used for smaller cats. Mice, rats, and chicks are frequently included in the diets of smaller cats. Rodents, poultry, fish, and organ and chunk muscle meats can be offered as occasional treat items to administer medica-

tion or to stimulate appetite, but generally they are not required as dietary staples for large cats fed commercial diets.

Canids can be fed frozen, canned, or dry canine diets. Although most canids are less particular than cats, frozen and canned foods are generally preferred over dry ones. Bones should be included in the diet when soft foods are fed. Canids can also be fed meat, with the right amount of vitamins and minerals added, varied with small prey animals like rats, mice, rabbits, and chicken. Small amounts of fruits and vegetables can be included in the diets of foxes and coyotes.

Most mustelids and viverrids do well on frozen feline diets or canned cat foods; a meat-based diet supplemented with the right amount of vitamins and minerals is also appropriate. Many species readily accept small amounts of fruits, vegetables, and cooked egg. Mice, fish, and chicks can be offered as occasional treat items and to stimulate appetite and activity. Rib bones can be given twice weekly to promote dental health. Canned foods may be more palatable but are not recommended as a base diet, because ferrets may not be able to eat enough to meet their needs for calories and protein. *See* TABLE 39 for a diet used successfully for freshwater otter species.

Procyonids can be fed diets similar to those offered to small canids, or an adequate meat diet can be fed. Feeding a good-quality dry dog food along with apple, banana, and carrot is satisfactory for raccoons and helps minimize obesity problems that commonly result when frozen or canned diets are fed. The red or lesser panda has been maintained successfully on commercial high-fiber primate biscuits and bamboo. The herbivorous food habits of the giant panda require large amounts of bamboo supplemented with high-fiber primate biscuits.

Bears can be fed meat supplemented with vitamins and minerals, frozen canine diet, dry dog food, fish, and commercial omnivore biscuits. Polar and Kodiak bears do well on a diet of 25% frozen canine diet, 25% fish (eg, smelt), 15% dry dog food, 15% omnivore biscuits, 10% bread, and 10% apples. Commercial diets formulated especially for polar bears are available. Other bear species can be fed less fish and more omnivore biscuits, bread, and produce. Bananas and green vegetables can be included in the diet of sun, sloth, spectacled, and black bears. Food intake of captive bears varies widely with the season. Intakes generally are maximal during summer and early fall and minimal during winter. It is advisable to feed extra cod oil

(0.5–1 L) to polar bears before their hibernation starts.

INSECTIVORES, EDENTATES, AND AARDVARKS

Most shrews, hedgehogs, tenrecs, and moles can be fed frozen cat food supplemented with mealworms, earthworms, crickets, and mouse pups. Ground meat fortified with minerals and vitamins, canned dog food, cooked egg, and small amounts of fruits and vegetables also are readily accepted by many species. Bacterial hazards have been associated with the feeding of raw, meat-based diets to some species. Carnivorous and insectivorous small mammals appear particularly susceptible, and septicemia and deaths have been reported. Canned, meat-based products are a safer alternative.

Armadillos will eat frozen feline diet, moistened dry cat food, canned dog food, or ground meat fortified with minerals and vitamins. Milk, chopped egg, cooked sweet potato, diced banana, and other fruits also are consumed. Vitamin K supplementation of armadillos has been recommended to help prevent hemorrhages: 5 mg of menadiolone sodium bisulfite/kg dry diet should be adequate. Sloths can digest fiber, but if they are kept in an environment that is too cold, their digestion rate will be very slow. Their diet should consist of a mixture of primate and high-fiber primate diets and some green, diced vegetables and preferred leaves. Food pans should be placed in such a way that the animal can hang from a perch while feeding.

In captivity, aardvarks, lesser anteaters, and giant anteaters readily accept semiliquid diets instead of termites, ants, and other natural foods. Artificial diets typically consist of milk, water, ground meat, and/or meat-based product such as frozen feline diet, mink chow or dry dog food, hardboiled egg, protein powder, baby cereal, and a mineral-vitamin supplement. All ingredients are mixed in a blender to the consistency of a thick gruel. For adult giant anteaters, a commercial diet is available. Loose feces may develop when a semiliquid diet is fed. If this occurs, milk and water can be withdrawn gradually from the formula. As a precaution, vitamin K often is added to all edentate diets.

MARINE MAMMALS

See also MARINE MAMMALS, p 1856.

Fish are the primary food of captive marine mammals except for the herbivorous sirenians. The purchase and subse-

quent proper storage and handling of high-quality fish are the most important aspects of feeding cetaceans and pinnipeds.

On receipt, fish should always be inspected for quality. The following are useful for evaluation: 1) The boxes should be checked to see whether catch dates are indicated. 2) Overall appearance of the fish should be good. 3) Gills should be red (light pink gills indicate considerable time may have elapsed before the fish were frozen after being caught). 4) Eyes should not be sunken, indicating dehydration. 5) Flesh of thawed fish should be firm, skin should be intact and not discolored, and there should not be a bad odor. 6) There should not be excess water and blood pooled on the bottom of frozen cases, which indicates the fish have thawed and been refrozen. 7) Ideally, the lenses of frozen fish should be cloudy, which indicates the fish have been properly stored at or below -30°C before purchase (higher temperatures often result in clear lenses).

To minimize peroxidative damage and nutrient destruction, fish should be stored at or below -25°C . Most fish species should not be stored >6 mo if at all possible. A maximum of 3–4 mo is recommended for fatty fish such as mackerel; lean fish such as smelt may remain in good condition for up to 9 mo. Ideally, fish should be thawed overnight under refrigeration. If this is not possible, thawing at room temperature is preferable to thawing in water, which can cause significant nutrient leaching. Thawing temperature should not be $>10^{\circ}\text{C}$. Individually quick frozen fish are preferred by many zoos, because proper quantities can be thawed without waste.

As a general rule, marine mammals should be given marine fish. Composition of marine fishes can vary greatly between species and even within species depending on age, season, and catch location. Fish that have been used successfully include Atlantic and Pacific herring; Atlantic, Pacific, and Spanish mackerel; bluerunner; capelin; and anadromous smelt. Squid are readily consumed by many pinnipeds, and clams can be included in walrus diets. No commercial substitute for fish has been developed that will be accepted by cetaceans, but such products have been used with some success for pinnipeds. The regular diet of any marine mammal should consist of two or more fish species to help ensure a balanced diet. It is not recommended to feed fish that are threatened in the wild. For example, Marine Stewardship Council (MSC) fish can be fed.

Thiamine should be added (at 30–35 mg/kg fish, as fed daily) to any marine mammal feeding program because of the possibility of thiamine destruction by thiaminases found in several fish species. Supplemental vitamin E helps compensate for oxidative destruction of natural vitamin E in fish during storage and helps protect against the deleterious effects of peroxides formed in stored fish. Oily fish such as mackerel, which are high in unsaturated fatty acids, are particularly susceptible to vitamin E destruction and peroxidative damage. Vitamin E at 100 IU/kg fish, as fed per day, is generally recommended whenever fish are fed.

Although subject to some debate, salt (NaCl) supplementation of pinnipeds maintained in freshwater is sometimes recommended to prevent hyponatremia; 3 g salt/kg fish should be adequate. Although supplemental vitamin C is frequently given to captive cetaceans, there is no conclusive evidence it is beneficial. Evidence indicates hepatic vitamin A levels in captive dolphins are often much lower than in their wild counterparts. Although specific recommendations cannot be made, vitamin A supplementation of some captive cetacean diets may be desirable.

Food intake in marine mammals varies considerably, depending on fat content of fish, water temperature, and activity. Performing Atlantic bottlenose dolphins generally eat 7–10 kg fish/day. Adult seals and sea lions consume ~5%–8% of their body wt in fish/day. Captive sirenia can be maintained on a diet of lettuce, cabbage, alfalfa, and aquatic plants (eg, water hyacinth).

MARSUPIALS

Most didelphid marsupials can be fed dry or canned dog or cat food. Smaller species can be fed canned primate diet. Hard-boiled egg, green vegetables, carrot, sweet potato, apple, and banana can also be offered. Dasyurids (eg, marsupial "nice," native cats, Tasmanian devils) and bandicoots can be fed canned or frozen feline diet. In addition, crickets, mealworms, and mouse pups can be given to smaller species; larger species can be given mice and shank or rib bones. Wombats and the larger macropod marsupials can be fed a combination of large herbivore pellets, rabbit pellets, or special kangaroo pellets. Rat kangaroos will eat a combination of mouse pellets and rabbit pellets. To prevent lumpy jaw, the diet of marsupials should contain at least 200 mg of vitamin E and 0.2 mg of selenium/kg dry matter.

Green vegetables, carrot, sweet potato, apple, and banana can be offered to all herbivorous and omnivorous marsupials. For herbivores, greens and vegetables should be added in limited amounts; these marsupials should be fed a good-quality hay that has not too long stems. Currently, captive koalas can be fed successfully only on leaves of certain species of eucalyptus. Special pellets for koalas are being tested and may be available in the future.

PRIMATES

In general, primates can be fed a diet based on commercial monkey biscuits or canned primate diet. Marmosets should be fed a marmoset diet. Moderate amounts of assorted carrot, sweet potato, apple, banana, and orange also can be offered; however, it is advised to feed greens and green vegetables, which are more comparable to the natural diet. Monkey biscuits and the canned products should comprise 20% of the dry-matter intake of gorilla and orangutan diets; fruits and treat items should comprise $\leq 20\%$. Green vegetables and browse should be at least 40% of the diet, depending on the species.

Feeding only greens and vegetables, with vitamin and mineral supplements, is being tested in several species of primates. Diets should be developed and offered in such a way that enrichment is supported.

Dietary crude protein ranges for Pongidae such as gorillas are 14%–16% and for New World primates such as pinches 18%–22%. The unsaturated fatty acid composition should be at least 2.5% ($\% n-6$ fatty acids). Neutral detergent fiber in the dry matter ranges from at least 10% in macaques, to 10% in marmosets, 30% in Howlers and langurs, and 20% in lemurs, chimpanzees, and gorillas. Acid detergent fiber ranges from 5% in macaques, to 5% in marmoset and tamarins, 10% in lemurs and Pongidae, and 15% in Howler and langur diets. For all primates, the diet should contain 0.8% calcium and 0.6% phosphorus. Primate diets should contain 5,000–8,000 IU vitamin A and 800–1,500 IU vitamin D, except diets for squirrel monkeys and marmoset/tamarin should contain 2,400 IU vitamin D. The vitamin C level should be at least 200 mg/kg dry matter. The maintenance metabolic rate (kcal/day) is for Pongidae (gorillas, orangutans), 3,621; baboons, 1,099–1,324; langurs, 632–637; Rhesus macaques, 567–1146; marmoset, 31–76; and tamarin, 57–105. Obesity should be prevented; therefore, it is important to weigh animals

regularly or to perform body condition scoring.

Monkey biscuits containing high-quality protein (18%–22.5% crude protein) should be fed to New World primates to ensure that their higher protein requirements are met. Regular monkey biscuits can be fed to Old World species depending on other components in the diet, although many larger Old World species such as gibbons, orangutans, chimpanzees, and gorillas also need high-fiber products. Laboratory primate biscuits are typically formulated with very low fiber levels (eg, 5%). Because many of the natural foods consumed by these species appear to contain very high fiber levels (eg, $>20\%$), increasing the dietary fiber intakes of larger primate species is widely practiced. High-fiber biscuits should comprise at least 50% of the dietary dry matter, and browse should be at least 40% of the diet fed. Most of the time, however, these amounts are not available, and greens and vegetables can be a replacement for the browse.

Cultivated fruits should be used sparingly for great apes and leaf-eating species because, compared with cultivated green vegetables, they are typically high in sugars and simple carbohydrates and low in protein and calcium. Monkey biscuits can be made more palatable for some species by soaking them in water or fruit juice. To prevent leaching of nutrients, the biscuits should be placed in a thin film of liquid so that the liquid is drawn up into the biscuit.

Other items commonly included in primate diets include hard-boiled egg (if cholesterol is not a concern), yogurt, and bread. Grapes, raisins, peanuts, crickets, and mealworms are treat items well liked by most species. However, these items should be fed two or three times a week at the most, not every day. The energy amount of these enrichment items should not exceed 5%–10% of the energy consumed by the animal.

Mouse pups are favored items for many smaller primates. However, callitrichid hepatitis in tamarins and marmosets has been associated with the feeding of newborn mice infected with lymphocytic choriomeningitis virus. Most zoos have discontinued the feeding of mouse pups to these New World primates. Sunflower seeds, instant rice, cracked corn, and shredded coconut can be scattered around the exhibit or holding areas to promote foraging activity. The amount of energy used for these enrichment feeds should not exceed 5%–10% of planned dietary energy. Hay should be provided for nesting

materials and diversion, and it can act as a foraging substrate.

Many zoos offer meat to their great apes; although meat is often relished by the animals, there is no evidence it is necessary if the diet is properly balanced. Because hypercholesterolemia is seen in many captive gorillas, the feeding of meat may be contraindicated. For most primates, meals should be offered at least twice daily. Smaller species may benefit from even more frequent feedings.

New World primates use vitamin D₂ poorly. It is particularly important that these species receive an adequate source of stabilized vitamin D₃ (cholecalciferol) in their diet if they are not exposed daily to direct sunlight. Marmosets require up to four times the amount of vitamin D₃ required by other New World primates. Because of potential vitamin D toxicity, commercial marmoset diets should be fed only to marmosets. In noncommercial mixtures for smaller primates (mixtures of cut apples, bananas, and cereal products with vitamins and minerals added), vitamin D₃ should be included; however, care should be taken to prevent vitamin D toxicity.

Several cases of rickets in some Old World species at weaning have been reported. This may be because barred, outdoor primate exhibits have been replaced with indoor, albeit more naturalistic, exhibits. Although most free-ranging primate species probably satisfy their requirement for vitamin D by exposure to ultraviolet B (UVB) from sunlight, captive animals may rely entirely on a dietary source. Infants at weaning appear to be particularly at risk because milk levels of vitamin D are probably quite low, and many foods the young begin to eat are not fortified with this vitamin. Exposing the infant or juvenile to natural sunlight may be the best solution, because assuring that a dietary supplement is consumed by a young primate may not be possible.

The amount of UVB from sunlight is the highest in and around the equator; in regions at latitudes farther away from the sun the amount of radiated UVB, particularly in autumn, winter, and spring, is not enough. Lights that emit energy in the UVB range can be practical for use with primates, provided precautions are taken to prevent the primates from being able to touch the UVB lamp.

All primates require a source of vitamin C, which is added to commercial monkey biscuits. Most of the time, stable vitamin C is added to the pellet, meaning it will not undergo significant destruction within 6 mo

of milling. Supplementation is done, because the amount of vitamin C consumed via green vegetables, oranges, multiple vitamins, chocolate, fruit juice, or fruit-juice powders may not be sufficient.

Members of the subfamily Colobinae are perhaps the greatest challenge in proper feeding of captive primates. Pregastric fermentation, similar to that in ruminants, occurs in the complex stomach of these species. In the wild, leaves and high-fiber fruits and nuts form a major part of the diet of most colobines. Therefore, natural diets are high in fiber, and animals spend much time foraging. Offering a rich, rapidly consumable diet of monkey biscuits and fruit (easily digestible sugars and starches) in captivity presents a situation quite different from that typically found in the wild, and it may frequently cause GI problems. In addition, some evidence suggests that a high percentage of colobus monkeys may be sensitive to starch and gluten.

Commercial, preferably gluten-free, high-fiber monkey biscuits (25%–50% neutral detergent fiber and up to 15%–35% acid detergent fiber) have been developed to feed captive colobines. A diet consisting of 30% of a palatable high-fiber biscuit and ≥70% green vegetables and fresh browse is recommended for most colobines. Only a high-fiber primate biscuit and browse is the preferable food for colobines. If the biscuit is not readily accepted, adding a limited amount of applesauce or banana flavor can increase palatability. Also, alfalfa pellets and a good-quality alfalfa hay can be provided in limited quantities. If a gluten-sensitive enteropathy is suspected, any product that contains wheat, barley, rye, or oats should be removed from the diet. In colobines, dietary changes always should be made gradually to allow their gastric microflora time to adapt.

RODENTS AND LAGOMORPHS

Most rodent and lagomorph species do well on diets based on commercial laboratory rodent pellets or rabbit pellets. Rabbits, hares, pikas, marmots, and prairie dogs can be maintained on rabbit pellets, alfalfa or grass hay, and a limited amount of assorted vegetables. Most other sciurids can be fed rat pellets and a limited mixture of sunflower seeds, millet, corn, and rolled oats. Ground squirrels can also be offered a limited amount of green leafy vegetables, carrot, and apple. Most murids, cricetids, gophers, dormice, and jerboas do well on rat pellets; for smaller species, mouse

pellets, a seed and grain mix, green leafy vegetables, carrot, and apple can be fed.

Hay should be made available to voles and lemmings. Captive voles may be difficult to manage unless a high-fiber rabbit pellet is used. Muskrats, agoutis, and capybaras will eat a combination of rat and rabbit pellets along with alfalfa hay, carrot, and apple. Porcupines can be fed rat pellets, rabbit pellets, and dry dog food in equal portions along with some apple, carrot, and bread; evergreen (willow) branches should be made available whenever possible. It is also advised to provide bones for gnawing. Beavers will eat a combination of rabbit pellets, large herbivore pellets, and dry dog food, regularly augmented with willow, poplar, aspen, or alder branches.

Guinea pigs can be offered commercial guinea-pig pellets, which are rabbit pellets with vitamin C added, along with greens and carrot. Although guinea pigs and cavies are the only rodents known to require a dietary source of vitamin C, lagomorphs and rodents may benefit from it.

SUBUNGULATES AND UNGULATES

Hay comprises the bulk of the diet for most ungulates in captivity and should be available for most of the day rather than fed at intervals as meals. In general, a leafy legume hay, eg, alfalfa, should be used for species that are primarily browsers (eg, Giraffidae, Cervidae, sitatunga, bongo, duiker, tapir), whereas a good-quality grass hay is satisfactory for most grazers or bulk feeders (eg, zebra, elephant, bison, buffalo, wildebeest, camel). Legume hays are higher in nitrogen and calcium and, if of good quality, are more digestible than grass hays. Hay should be leafy and green, free of mold, dirt, excess weeds, and other foreign matter, and should not be overmature. Several zoos are test-feeding hay and alfalfasilage. In general, palatability is good.

Hay analysis can be very useful to evaluate quality and design proper feeding programs. "Poor" hay will have a good fiber percentage, but the protein quality can be low and poor, and the mineral status, especially of calcium, can be too low. Low levels of calcium can cause poor bone calcification and also affect the calcium level in the blood, which can cause birth problems.

Precautions should be taken if feeding silage products. If the silage was not processed or stored properly or contaminated by animal or meat products, it may

contain fungi or bacteria (eg, *Clostridium botulinum*) that can produce lethal toxins.

In addition to hay, a pelleted diet that contains protein, minerals, and vitamins in concentrations adequate to meet the needs of domestic species and those wild species for which data are available (eg, white-tailed deer) should be offered. See TABLE 39 for composition of a sample pellet for large herbivores. In the frequent situation in which animals are fed as a group rather than as individuals, it is preferable to use a pelleted diet that is not excessively high in digestible energy (~3 kcal DE/g dry matter is suggested) and that contains sufficient fiber to support proper rumen or colon function. This precaution reduces the possibility of untoward effects (eg, rumen acidosis, colic, obesity) caused by overconsumption of concentrates. Depending on the nutritional status of the animal, ~0.5–1.5 kg should be fed per animal. Overfeeding can result in obesity. Animals should be weighed regularly, or body condition scoring performed.

A specialized pellet with high amounts of neutral detergent fiber (NDF) and acid detergent fiber (ADF) is recommended for browsers (eg, giraffe, kudu, okapi, reindeer), and a pellet with moderate amounts of NDF and ADF is recommended for grazers (eg, elephant, bison, banteng, addax antelope). The intermediate feeding animals should get an equal mix of the browser and grazer pellets. Preferably, the diet of browsers should consist of equal parts of browser pellets, good palatable alfalfa, and browse. Diets for grazers and browsers should contain high amounts of vitamin E and biotin to prevent muscle dystrophy and hoof problems.

A pellet size of $\frac{3}{16}$ in. is satisfactory for most artiodactyls, whereas a pellet or cube size of $\frac{1}{2}$ in. (~13 mm) helps minimize waste when fed to larger perissodactyls and subungulates. Commercial cattle products should not be fed to zoo herbivores because of palatability problems and low vitamin E levels, and some products may contain nonprotein nitrogen sources such as urea that are not tolerated by hindgut-fermenting species (eg, equids). Also, the amount of easily digestible energy may be high, leading to obesity. Tapirs should get a mixture of grazer and browser pellets combined with some greens, alfalfa, and browse.

In general, most large ungulates (>250 kg) consume 1.5%–2% of their weight in dry matter daily. Smaller species (<250 kg) generally consume 2%–4%. Offering a pelleted diet at 10%–15% of the dry-matter intake is adequate for most grazers if

good-quality hay is fed. The amount of minerals and vitamins should be balanced in the pellets in such a way that the total diet (including greens, browse, and hay) should be adequate. When hay quality declines, or for more delicate species, the percentage of high-fiber pellets should be increased. Ungulates and subungulates should always have salt blocks available, preferably with a balanced vitamin and mineral supplement. However, excessive licking can become a neurotic behavior and should be prevented.

Elephants should receive extra calcium, because mostly poor hay with a low level of calcium is fed. Because of the sensitivity to hemosiderosis, black rhinos should be fed a diet with a low level of iron (<100 mg/kg dry matter). Browse can contain significant amounts of iron; however, rose leaves contain low amounts. It is speculated that other ungulate species may also get hemosiderosis. It is advised that all ungulates be exposed to UVB from sunlight, because it has been suggested that oral supplementation of vitamin D in some cases is not sufficient (elephant, kudu).

Hay should be fed from a rack rather than off the ground for most species (elephants are an exception). Hay racks should be located at eye level for tall browsers such as giraffes and gerenuks. Pellets can be offered from a covered trough or (rubber) feed pans. Regularly feeding the pelleted diet in an animal's holding area can facilitate close observation and easy capture. If possible, animals should be fed separately to ensure that each individual receives a similar amount of food. If feeding separately is not possible, at least two widely separated feeding stations may be necessary to reduce conflict and to ensure that subordinate animals obtain their share of food.

In addition to hay and pelleted diet, assorted fruits and vegetables often are fed to exotic ungulates. For most species, these items usually are not necessary except as an occasional treat; the amount should be limited to <10% of the total diet. The exception might be for those species that regularly feed on fruits and succulents in the wild. It may be advisable to include some greens and vegetables (~0.5 kg/100 kg body wt) in the diet of species such as okapi, duikers, dik diks, bongo, and tapirs. Fresh, frozen, or dried browse is consumed avidly by most captive ungulates and subungulates and should be offered to browsers if possible *ad lib*, because it improves rumen function.

REPTILES

See also REPTILES, p 1967.

Appropriate husbandry of reptiles is as important as providing adequate nutrients. Photoperiod, temperature, humidity, substrate, and cage "furniture" can affect feeding behavior and, thus, nutrient intake. Temperature and humidity gradients within a reptile enclosure allow the animal to select warm, dry spots or cooler, moist areas. Competition for preferred sites and for food pans in an enclosure with multiple animals should also be assessed. Sufficient numbers of warm spots, UVB exposure spots, and food pans should be available for all animals within an enclosure. Visual barriers may be useful to reduce competition for preferred sites or food dishes.

Prey such as rabbits, rats, or mice should come from commercial breeding centers and be offered dead to prevent injury to the reptile and for welfare reasons of the offered prey. Although it is not common, prey have been known to attack predators and can inflict serious bites. Offering dead prey can also reduce the chance of injury to the predator caused by striking the walls of the enclosure. However, some reptiles may initially need the stimulation of live prey, particularly if they are not adapted to captivity. The possibility of disease or parasite transmission from prey to predator should be considered.

Vertebrate prey should be fed nutritionally complete diets appropriate for the species (eg, mouse diet, rabbit diet, rat diet, etc). The nutrient content of the prey depends on what it is fed (eg, mice raised on a diet deficient in vitamin A have decreased liver storage of this essential nutrient). Additionally, if frozen mice or rats are routinely used to feed carnivorous reptiles, freezer storage conditions should be optimal (eg, ≤6 mo and in thick, plastic bags to retard deterioration). Methods of thawing that minimize water loss are also important. Because many carnivorous reptiles rely on their prey not only as sources of nutrients but also as sources of water, the state of hydration of the prey can be very important.

Familiarity with a species' food habits in the wild is essential if appropriate foods and nutrient levels are to be offered. Common practice has been to offer two or more different prey species, because differences in nutrient content exist among vertebrate and invertebrate prey. Reduced dependence on a single food or prey species is also desirable, because some prey items may be

periodically difficult to obtain. Dependence on a single prey item is frequently seen in snakes and may be unavoidable.

Many commercial diets for reptiles are marketed. Products for carnivorous, herbivorous, and omnivorous reptiles are now available in frozen, freeze-dried, canned, extruded, pelleted, or sausage forms. Acceptability may be better when the commercial diets are offered to reptiles when they are young. Appropriately formulated, manufactured diets for reptiles are a potentially simpler and more economical alternative to feeding fresh produce or live prey. However, some of these diets may not be formulated rationally, and frequently little information concerning micronutrient concentrations is provided by the manufacturers. When selecting a commercial product, the buyer should obtain accurate information about

product formulation and specific nutrient concentrations. Unfortunately, little controlled research has been conducted on nutrient requirements of reptiles, and claims of product superiority may not have a scientific justification.

Herbivorous reptile pellets should make up 25%–50% of the diet of herbivorous reptiles. Animals should be fed 1%–4% of their body weight on a dry-matter basis. Vegetables with a low amount of oxalate should be fed to prevent kidney stones. A good quality grass hay or a so-called herbs-hay should be fed. No more than 50% of the diet should consist of fresh greens, fruits, and vegetables. The amount of fruit should be no more than 5%. In Europe, often herbs and dandelions are fed to herbivorous reptiles. Fresh, clean water must be available at all times.

See TABLE 40 for recommended nutrient concentrations for reptiles.

TABLE 40

RECOMMENDED NUTRIENT CONCENTRATIONS FOR REPTILES

Nutrient ^b	Concentration ^a		
	Carnivorous Reptiles	Omnivorous Reptiles	Herbivorous Reptiles
Crude protein ^c	30%–50%	20%–25%	18%–22%
Fat		3%–6%	
Crude fiber		20%–35%	
Arginine	1.0%	1.8%	
Isoleucine	0.5%	1.3%	
Lysine	0.8%	1.5%	
Methionine	0.4%	0.4%	
Methionine + cysteine	0.75%	0.75%	
Threonine	0.7%	1.0%	
Tryptophan	0.15%	0.3%	
Linoleic acid ^d	1.0%	1.0%	
Calcium	0.8%–1.1%	1.0%–1.5%	1.4%–2.0%
Phosphorus	0.5%–0.9%	0.6%–0.9%	0.8%–1.0%
Potassium	0.4%–0.6%	0.4%–0.6%	
Sodium	0.2%	0.2%	
Magnesium	0.04%	0.2%	
Manganese	5 ppm	150 ppm	
Zinc	50 ppm	130 ppm	
Iron	60–80 ppm	200 ppm	

(continued)

TABLE 40

RECOMMENDED NUTRIENT CONCENTRATIONS FOR REPTILES (continued)

Nutrient ^b	Concentration ^a		
	Carnivorous Reptiles	Omnivorous Reptiles	Herbivorous Reptiles
Copper	5–8 ppm	15 ppm	
Iodine	0.3–0.6 ppm	0.4 ppm	
Selenium	0.3 ppm	0.3 ppm	
Riboflavin	2–4 ppm	8 ppm	
Pantothenic acid	10 ppm	60 ppm	
Niacin	10–40 ppm	100 ppm	
Vitamin B ₁₂	0.020 ppm	0.025 ppm	
Choline	1,250–2,400 ppm	3,500 ppm	
Biotin	70–100 ppb	400 ppb	
Folacin	200–800 ppb	6,000 ppb	
Thiamine ^c	1–5 ppm	5 ppm	
Pyridoxine	1–4 ppm	10 ppm	
Vitamin A ^f	5,000–10,000 IU/kg	15,000 IU/kg	
Cholecalciferol (vitamin D ₃) ^g	500–1,000 IU/kg	500–1,000 IU/kg	
Vitamin E ^h	200 IU/kg	200 IU/kg	

^a Nutrient concentrations are recommended minimums for carnivorous reptiles and averages for omnivorous reptiles.

^b Nutrient levels expressed on a dry-matter basis.

^c Taurine requirements have not been determined for reptiles (the requirement for cats is 400–500 mg of taurine/kg dry diet).

^d A dietary source of arachidonic acid at 200 mg/kg dry diet may be necessary.

^e Thiamine concentrations should be increased to 10–20 mg/kg if frozen, thawed fish constitute >25% of the diet offered.

^f A source of preformed vitamin A may be required because it is not known if reptiles can convert carotenes to retinol (vitamin A), although it is likely that herbivorous reptiles can.

^g Requirements for vitamin D may be partially or totally satisfied by exposure to sunlight or appropriate sources of artificial ultraviolet light. These suggested concentrations are not sufficient to prevent signs of vitamin D deficiency in green iguanas.

^h 300 IU/kg dry matter is advisable if the diet is high in fat, especially unsaturated fat.

Ulcerative Stomatitis: Vitamin C synthesis has been reported in many reptile species. It has been suggested that ulcerative stomatitis seen in snakes and lizards may be associated with a vitamin C deficiency, although there is no supportive evidence. In controlled studies with garter snakes (*Thamnophis* sp) fed supplemental vitamin C, tissue levels and body stores remained stable, although synthesis by the snakes was reduced.

Gout: Although most reptiles excrete nitrogen primarily as uric acid, aquatic reptiles typically excrete excess nitrogen as urea or ammonia. The relative proportions of various nitrogenous wastes may depend on the amount and composition of feed, frequency of feeding, and state of hydration. The excessive precipitation of urate crystals in joints, kidneys, or other organs (gout) can be a common condition in some species of captive reptiles. The etiology is not clear, but

it is commonly thought that diets high in protein may predispose reptiles to gout. Impaired renal function and dehydration have also been suggested as possible causes.

If poor-quality protein is fed (unbalanced amino acids) or when tissue is catabolized for energy, uric acid excretion increases. Although gout in some reptiles is associated with increased circulating levels, postprandial transient increases in circulating uric acid may be seen in some species and confound the diagnosis. Assuring an adequate state of hydration in a susceptible animal may help prevent uric acid precipitation in joints and organs. Feeding diets low in protein to carnivorous reptiles is unwise, because they are adapted to feeding on high-protein prey.

Vitamin D and Ultraviolet Light: Most vertebrates can either absorb vitamin D from the diet or synthesize it in the skin from 7-dehydrocholesterol using energy from ultraviolet (UVB) light of certain wavelengths (290–315 nm) in a temperature-dependent reaction. Thus, vitamin D is required in the diet only when endogenous synthesis is inadequate, as develops when animals are not exposed to UV light of appropriate wavelengths.

Many captive basking species appear susceptible to rickets or osteomalacia. Bone fractures, soft-tissue mineralization, renal complications, and tetany can develop. Reptiles frequently show few premonitory signs, although lethargy, inappetence, and reluctance to move are commonly reported. Serum calcium concentrations may not be diagnostically useful. Although blood levels of vitamin D can be measured, normal values for most species are not known. Supplementation with injectable calcium and vitamin D may provide some short-term relief. However, exposure to UV light, or lack of it, may be an important, yet often overlooked, factor in the differential diagnosis. Complicating the diagnosis may be soft-tissue mineralization, seen radiographically or at necropsy.

In green iguanas, metastatic calcification may not result from vitamin D toxicity. Iguanas with both fractured bones and extremely low or undetectable levels of circulating 25-hydroxycholecalciferol also had calcified soft tissues. The etiology of the metastatic calcification is not understood and is contrary to conventional understanding of the signs of vitamin D deficiency and toxicity in domestic species. Dietary sources of vitamin D may not be sufficient to prevent rickets and osteomalacia. Diets

with as much as 3,000 IU vitamin D/kg did not prevent bone fractures and cortical thinning in green iguanas. Bulbs emitting UVB placed over the lizards at ~12–18 in. for 12 hr/day appeared to reverse the signs in the least severely affected lizards.

Because some lizards seek a warm spot to increase body temperature, placement of a warming bulb, usually incandescent, adjacent to a UVB bulb helps ensure adequate exposure to UVB light. Exposure to unfiltered natural sunlight, depending on latitude, during warmer months and use of UVB bulbs during the rest of the year usually eliminate the risk of bone disease caused by insufficient absorption of calcium (due to a vitamin D deficiency).

Some lizard species may be unable to absorb sufficient dietary vitamin D,₃ although the reason is poorly understood. New World primates are believed to have exceptionally high dietary requirements for vitamin D, which may be related to lower numbers of vitamin D cellular receptors than are present in Old World primates. Similar metabolic differences may exist in some basking lizard species, although this has not been established. UVB bulbs are sold in pet stores, but label claims may not be reliable.

UVB Lighting: Three types of UVB lighting are on the market: fluorescent tubes, compact fluorescent lamps, and mercury lamps. Fluorescent tubes supply a diffuse light with a low amount of visible light. Heat radiation is low, and the UVB gradient is fairly uniform. The light from fluorescent tubes resembles more or less the natural UVB in the shade of a sunny day spread over a relatively large area. Compact fluorescent lamps provide a more intensive UVB gradient focused on a small area. These lamps are characterized by fairly low intensity visible light and little heat. Mercury lamps (vapor spot and narrow spots) produce an intensive UVB gradient on a smaller area, producing heat and an intense light.

Mercury lamps can become very hot. Reptiles must be prevented from getting burned during UVB basking. It is important to recognize that when a UVB lamp is added to a terrarium, the emission of UVB drops with the square of the distance; this explains the low exposure level of UVB at the level of the reptile when the lamp has been hung too high.

The radiation of UVB declines during the lighting time. In general, UVB lamps should be replaced once a year. However, it is best to regularly measure the amount of UVB

with meters used in the artificial sunbath industry. A "D3 Yield Index" that compares the vitamin D₃-producing ability of the lamp with the sun is under development.

How long and how much exposure to UVB is needed in reptiles is not exactly known. In general, reptiles that need UVB must be exposed to 30 min to 2 hr of UVB each day. However, there can be exceptions. For example, bearded dragons do not develop metabolic bone diseases if they are exposed only a few times a week to UVB for a limited time.

Enlisting the assistance of a specialist is advised, because there is no ideal UV bulb (see p 1969).

CROCODILIANS

Captive alligators and crocodiles are usually fed a combination of rodents, poultry, fish, and meat-based diets. A varied diet is recommended. Diets consisting primarily of fish should include three or more different species of fish and should be supplemented with 30–35 mg of thiamine and 100 IU vitamin E/kg of fish, as fed. Signs of vitamin E deficiency (eg, steatitis) have been reported in crocodilians fed fish inadequately supplemented with vitamin E. Although previously reported otherwise, alligators can digest some carbohydrate; however, the total carbohydrate in the diet should not exceed 20%. Commercial, dry alligator diets are being marketed, largely to reduce the cost and to improve nutrient intakes of farmed alligators; their use is still uncommon in zoos.

SNAKES

Snakes feed almost exclusively on vertebrate or invertebrate prey. A few species are specialized egg feeders. Most boas, pythons, vipers, colubrids, crotalids, and elapids are fed mouse pups, mice, chicks, hamsters, rats, guinea pigs, chickens, ducks, or rabbits. Frozen, thawed prey are usually used in zoos; thawing under refrigeration is recommended. After thawing, prey should not be fed cold but at room temperature, or preferably warmer. Some species (eg, king cobra, hognose snake, garter snake) feed primarily on other poikilotherms in the wild. Some of these species can be switched, at least in part, to homeothermic prey, which is often more available and less expensive.

Minced prey is sometimes fed in agar, gel, or sausage form. Advantages include the ability to formulate and feed a nutritionally complete diet, to add a balanced vitamin

and mineral mixture, and, if needed, to add antibiotics or coccidiostats. Mostly a complete diet is fed in a sausage; however, tests are also being done with gel feeding to reptiles.

The scent of preferred foods can be rubbed on the new item. Alternatively, the preferred foods can be inserted into, or attached to, the new food. Anoles, yellow rat snakes, frogs, and smelt, depending on natural feeding habits, can be fed when homeotherms are not accepted. Prey size is usually proportional to snake size and should not be much larger in diameter than the snake's head. Snakes that are routinely handled can be fed in a separate tank to reduce biting. To reduce the chance of regurgitation, snakes should not be handled for 3 days after feeding.

Most species should be fed every 1–2 wk. Some large, less active snakes may typically go 6 wk between feedings. Force-feeding should be used only if necessary. Animals can be force-fed whole prey lubricated with egg white by gently inserting the food a few inches down the throat using forceps. Tube feeding is also possible using ground (homogenized) prey.

TURTLES

Many freshwater turtles in the wild eat primarily animal matter but also consume some plant material. Some species may be carnivorous when young and shift to omnivorous or herbivorous feeding patterns as adults. Most aquatic turtles cannot be considered strict carnivores, because they consume at least some plant material. Commercially available turtle feeds are available from many manufacturers, although nutrient content can vary widely. These products are usually manufactured as extruded or pelleted diets and are typically 30%–50% protein. Such diets may be appropriate for carnivorous and omnivorous turtles, although the more omnivorous species would benefit from the addition of some fruits or vegetables.

A sample diet for carnivorous and omnivorous turtles consists of the following feed items: water (272 g), gelatin (unsweetened or dry, 34 g), corn oil (11 g), spinach (23 g), cooked sweet potato (23 g), Vionate® (a vitamin/mineral supplement, 5 g), trout pellets (50 g), and vitamin E at 50 IU/g (1 g). This diet contains on a dry-matter basis 47% protein, 14% fat, 1.5% calcium, 0.55% phosphorus, vitamin A at 10,000 IU/kg, vitamin D₃ at 1,000 IU/kg, vitamin E at 279 IU/kg, and vitamin C at 280 mg/kg.

TORTOISES

Tortoises are herbivorous and, like herbivorous lizards (*see below*), must consume plant material to maintain healthy gut physiology. Microbial fermentation of plant fiber can be a significant source of nutrients for tortoises. Diets of tortoises in the wild often contain >15% protein (dry-matter basis) in plant materials consumed, because natural vegetative materials are usually high in protein in the pre-seed stage, although a part of that protein is indigestible. Although small tortoises consuming pelleted diets can use plant fiber effectively, they should be fed more frequently than larger animals. Small and large tortoises can be maintained on appropriately formulated, extruded, pelleted, or coarsely ground tortoise diets.

Larger tortoises, such as Aldabra or Galapagos tortoises, can consume grass or alfalfa hay along with a complete pelleted food formulated for tortoises or exotic herbivores. Hay should be cut short, because the mouth shape of these tortoises makes it impossible for them to chew long hay. A vegetable mix consisting of broccoli, green beans, leafy greens (eg, romaine, green leaf lettuce, endive), kale, and shredded carrots may be fed as a supplement to a formulated tortoise diet. Such mixes contain adequate protein, calcium, and micronutrients; only limited vitamin and mineral supplements should be added. Cultivated fruits are typically poorer sources of protein, calcium, and micronutrients and, if fed in significant amounts, vitamins and minerals should be added. Some herpetologists offer oyster shell and pea gravel to tortoises, because "mining" activity has been seen in free-ranging animals.

Shell deformities in tortoises have been thought to result from rapid growth associated with consumption of high-protein diets. Humidity and temperature also may influence shell deformation.

LIZARDS

The feeding patterns of lizards are extremely diverse. Lizards may be insectivorous (eg, day and leopard gecko, whiptail lizard, anole, chameleon), carnivorous (eg, varanids such as monitor lizard, Gila monster, Mexican bearded lizard), omnivorous (eg, many iguanid and agamid species), or herbivorous (eg, iguanid species, prehensile-tailed skink).

Insectivorous lizards in captivity are usually fed diets of mealworm larvae or crickets. Because calcium concentrations

in these, and in most insects, are extremely low (0.03%–0.3% calcium with 0.8%–0.9% phosphorus), the inverse calcium:phosphorus ratio must be corrected before the insects are fed to lizards. A diet with a balanced vitamin and mineral mixture and containing 12% calcium as calcium carbonate can be fed to crickets or mealworm larvae 3 days before the insect is fed to the lizard. However, this diet should not be used to maintain a cricket colony. Within 2 days of feeding the high-calcium diet, the gut of the insect is filled with calcium, raising the calcium concentration of the insect to ~0.8%–0.9% and resulting in a calcium:phosphorus ratio of ~1.2:1. A satisfactory high-calcium diet for crickets can be inexpensively made by using 29% wheat middlings, 10% corn meal, 40% ground dry cat or dog food, and 21% ground oyster shell or calcium carbonate (*see also* BATS, p 2294, for mealworm diet). Larger insectivorous lizards may also consume mouse pups and earthworms.

Carnivorous lizards may be offered mouse or rat pups, adult mice and rats, chickens, and eggs. The size of prey should be appropriate for the lizard species. Omnivorous lizards are usually fed a combination of foods, including insects, vertebrate prey, and a chopped vegetable mixture (*see* TORTOISES, p 2307, for vegetable mix). Most lizards should be fed daily (juveniles and small species) or at least every other day. Large carnivorous species should be fed once or twice a week.

Herbivorous lizards are adapted to ferment plant fiber in enlarged hindguts. The microbes in the cecum and colon digest plant fiber that the lizard could not otherwise use. As with tortoises, herbivorous lizards should be fed plant-based diets to assure healthy gut function. The use of insects, vertebrate prey, or diets high in fruits is not advised, because these feeds are low in fiber and are inappropriate for herbivores. Diets for lizards may be commercial preparations formulated for herbivorous reptiles, or vegetable mixes (*see* p 2307).

FISH

Knowledge of fish nutrition is increasing, but it has been mostly focused on commercial fish and not on specific fish held in cold or warm freshwater or seawater tanks. Pellets and flakes are available; some claim to be especially developed for specific species, but detailed nutritional information is not always available. Pellets fed in water should not be allowed to dissolve before eating to prevent pollution of the water.

Marine fish can be herbivorous, carnivorous, or omnivorous. Grazing or herbivorous fish eat plant materials from the rocks of the sea and need more fiber than carnivorous fish. This can be accomplished by feeding plant material in a basket in the water or by feeding an herbivorous fish pellet. Carnivorous fish should be fed a diet with high amounts of protein and fat, which can be a pellet or different fish species. Nonpelleted food for fishes can consist of artemia, algae, squid, herring, mackerel, whiting, sprat, bream, and shrimp. It is important to know the origin of the food, because threatened fish or fish harvested in areas or ways that negatively affect the environment should not be fed. Moreover, the fish should not be contaminated with

heavy metals or organic components such as PCB and DDT.

Vitamins should be added to fish diets, including vitamins E and B₁, and stabilized vitamin C. Iodine should be added to prevent struma in sharks and rays. Some zoos also add glucans. Vitamins and minerals can be injected into the fed fish. Alternatively, tablets can be added just behind the gills of the fed fish.

Fish products or pellets should contain the right amount and type of feed. Regularly checking whether the fish are too fat or too thin is an important factor in proper feeding. In a mixed exhibit, the feeder should ensure that all fish get the right amount and type of food. If possible, sharks should be fed individually.

See also NUTRITIONAL DISEASES OF FISH, p 1798.

NUTRITION: GOATS

Although goats and sheep have several similarities, their nutrient requirements differ in several ways. Goats exhibit significant differences from sheep in grazing habits, physical activities, feed selection, milk composition, carcass composition, and metabolic disorders. Goats browse more than sheep, whereas sheep tend to be true grazers. Still, many of the principles useful for sheep feeding and nutrition are applicable for goats. The basic assessment for nutritional well-being should be body condition or body fat covering. Goats in good flesh, or with normal fat scores, are usually being fed a diet with adequate energy and to a lesser extent, protein. (*See also* NUTRITION: SHEEP, p 2345.)

NUTRITIONAL REQUIREMENTS

Water: Goats should be provided unlimited access to fresh, clean, nonstagnant sources of freely accessible water. Goats are among the most efficient of domestic animals in their use of water; however, only ~10% of body water loss may prove fatal. They appear to be less subject to high temperature stress than other species of domestic livestock. In addition to a lesser need for body water evaporation to maintain comfort in hot climates, goats can conserve body losses of water by decreasing losses in urine and feces. Factors affecting water

intake in goats include lactation, environmental temperature, water content of forage consumed, amount of exercise, stage of production (growth, maintenance, lactation, etc), and salt and mineral content of the diet. Goats grazing lush pastures may consume much lower quantities of water than those feeding on dry hay. Still, it is imperative to allow free access to water for all goats regardless of age, breed, purpose, stage of life cycle, or environment.

Energy: Energy limitations may result from inadequate feed intake or from poor diet quality; excessive water content of the feedstuffs also may become a limiting factor. Energy requirements are affected by age, body size, body condition, stage of production (growth, maintenance, pregnancy, and lactation), and concurrent medical conditions (eg, parasitism, dental disease, arthritis). Energy requirements also may be affected by the environment, hair growth, activity, and relationship with other nutrients in the diet. Increased temperature, humidity, sunshine, and wind velocity may decrease energy requirements. Shearing mohair from Angora goats and pashmina from Cashmere goats decreases insulation and results in increased energy needs (at least in colder environments).

Goats exhibit a wide range of grazing activity, ranging from light activity for goats

under intensive management, through moderate activity on semiarid land, to high activity for goats grazing on sparsely vegetated grassland and on mountainous pastures that necessitate long-distance travel daily.

The best assessment of energy intake adequacy in goats is proper body condition or fat covering the loin, brisket, inner thigh, and ribs. Using herd/individual medical record systems, a standardized body condition score (1–5, with 1 being extremely thin, to 5 being extremely obese) should be used to monitor body fat changes and make less subjective decisions with respect to longterm dietary energy adequacy. If animals are parasite- and disease-free, yet underconditioned, then they are usually being fed an energy-deficient diet; the reverse is true for obese animals. The energy values required for growth and lactation are very comparable to the numbers used for sheep and cattle, respectively. Therefore, sheep nutrition principles from an energy standpoint will probably suffice when dealing with all classes of goats, except for lactating dairy goats.

Protein: Protein is required for most normal functions of the body, including maintenance, growth, reproduction, lactation, and hair production. Protein deficiencies in the diet deplete stores in the blood, liver, and muscles and predispose animals to a variety of serious and even fatal ailments. Feed intake and dietary digestibility are reduced if dietary crude protein is <6%, further compounding an energy-protein deficiency; thus, for maintenance of mature, healthy animals, the diet should have a minimum of 7% crude protein. Dietary crude protein requirements are higher for growth, gestation, and lactation.

Most forages contain adequate amounts of dietary protein for maintenance, but lactating, growing, sick, or debilitated animals may require diets fortified with legumes or protein supplements (eg, soybean meal, cottonseed meal, etc). Feeding adequate to slightly greater amounts of protein than required appears to aid in the control (both resistance and resilience) of internal nematode parasites.

Minerals: Requirements for minerals have not been established definitively for goats at either maintenance or production levels. Research has been conducted with goats in mineral metabolism studies, especially with calcium and phosphorus. In general, these data support assumptions that several

mineral requirements for goats are similar to those for sheep. (For detailed nutrient requirements for goats, refer to the most current *Nutrient Requirements of Small Ruminants*, published by the National Research Council [www.nap.edu].) Feeding to meet the goat's needs will maximize its production, reproduction, and immune system. The addition of specific minerals (phosphorus for dry winter forages, selenium in deficient areas, etc) to salt (NaCl), preferably in granular form and offered free choice, helps prevent most mineral deficiencies and improves performance.

Calcium requirements are generally met under grazing conditions with either Angora or meat-type goats, but levels should be checked in high-producing dairy goats because a deficiency can lead to reduced milk production. Adequate levels of calcium for lactating goats are necessary to prevent parturient paresis (milk fever). In browsing or grain-fed goats, the addition of a calcium supplement (dicalcium phosphate, limestone, etc) to the feed or to a salt or trace mineral-salt mixture usually meets calcium requirements. Legumes (eg, clover, alfalfa, kudzu) are also good sources of calcium.

Phosphorus deficiency results in slowed growth, unthrifty appearance, and occasionally a depraved appetite. Goats can maintain milk production on phosphorus-deficient diets for several weeks by using phosphorus from body reserves, but during long periods of phosphorus deficiency, milk production was shown to decline by 60%. The calcium:phosphorus ratio should be maintained between 1:1 and 2:1, preferably 1.2–1.5:1 in goats because of their predisposition for urinary calculi. Phosphorus deficiency in grazing goats is more likely than a calcium deficiency. In cases of struvite calculi, the ratio should be maintained at 2:1.

Magnesium deficiency is associated with hypomagnesemic tetany (grass tetany), but ordinarily this condition is less common in grazing goats than it is in cattle. Goats do have marginal ability to compensate for low magnesium by decreasing the amount of magnesium they excrete. Both urinary excretion and milk production are reduced in a magnesium deficiency.

Salt (NaCl) is usually recognized as a necessary dietary component but is often forgotten. Goats may consume more salt than is required when it is offered ad lib; this does not present a nutritional problem but may depress feed and water intakes in some arid areas where salt content of the drinking

water is quite high. Salt formulations are used as carriers for trace minerals, because goats have a clear drive for sodium intake.

Potassium has an important role in metabolism. However, forages generally are quite rich in potassium, so a deficiency in grazing goats is extremely rare. Marginal potassium intake is seen only in heavily lactating does fed diets composed predominately of cereal grains. Excessive potassium intake (particularly in late gestation) may be associated with hypocalcemia in dairy goats. If hypocalcemia is a herd problem, attention should be paid to reducing or monitoring potassium-rich feedstuffs (eg, alfalfa).

Iron deficiency is seldom seen in mature grazing goats. Such deficiency might be seen in young kids because of their minimal stores at birth, plus the low iron content of the dam's milk. This is more commonly seen in kids fed in complete confinement and heavily parasitized animals. Iron deficiency can be prevented by access to pasture or a good quality trace mineral salt containing iron. In severe cases, and for kids reared in confinement, iron dextran injections at 2- to 3-wk intervals (150 mg, IM) for the first few months may be curative. In the cases of mixed iron/selenium deficiencies, caution should be used when injecting iron dextrans until the selenium deficiency is also corrected.

Iodine deficiency in the soil, and in the crops produced thereon, is seen in some areas of the USA. Therefore, iodine should be provided in stabilized salt. Conditional iodine deficiency may develop with normal to marginal iodine intake in goats consuming goitrogenous plants. Marked deficiency of iodine results in an enlarged thyroid; poor growth; small, weak kids at birth; and poor reproductive ability.

Zinc deficiency results in parakeratosis, stiffness of joints, smaller testicles, and lowered libido. A minimal level of 10 ppm of zinc in the diet, or a trace mineral salt mixture of 0.5%-2% zinc, prevents deficiencies. Excessive dietary calcium (alfalfa) may increase the likelihood of zinc deficiency in goats.

Copper deficiency may result in microcytic anemia, poor production, lighter or faded hair color, poor fiber quality, infertility, poor health and slowed growth, some forms of metabolic bone disease, diarrhea, and possibly a greater susceptibility to internal parasites. Copper deficiency in a diet may be caused by inadequate copper intake, a lowered copper-molybdenum ratio, or excessive dietary sulfur. Goats

appear to be much more resistant to copper toxicity than sheep.

Selenium deficiency in the diet is usually associated with nutritional muscular dystrophy, retained placentas and metritis, poor growth, weak or premature kids, and mastitis.

Vitamins: Recommendations for vitamin requirements of goats are even more sparse than for mineral requirements. At best, almost all vitamin recommendations for goats must be based on those for sheep (*see* p 2345).

HERBAGE AND BROWSE UTILIZATION

In contrast to other farm animals, except llamas, goats prefer shrubs and tree leaves, whether deciduous or evergreen. Because of this preference, goats have been used to control encroaching shrub-type growth in pastures. Goats consume approximately the same weight of forage as do sheep of similar size. Goats tend to select highly digestible portions of most forages and show a preference to browse along fence lines and rough areas. Goats usually perform on improved pastures and prefer browse to grass (a diet of >80% browse).

Browse (leaves and twigs of trees and shrubs) generally contain higher levels of crude protein and phosphorus during their growing season than do grasses. However, some palatable browse species are limited in value because of one or more inhibitors that may bind or otherwise prevent use of nutrients contained in the plants. One such inhibitor is lignification of woody twigs and tree leaves, which physically binds (or encapsulates) the desirable nutrients. Certain oils (terpene-based compounds) are present in relatively high concentrations in some range shrubs and apparently inhibit growth of rumen bacteria. High concentrations of tannins are present in certain browse plants and depress digestion of feedstuffs by binding enzymes or by inhibiting enzymatic activity. Excessive tannins may also increase sulfur requirements, which may be more critical for hair-producing goats. However, in spite of these potential problems, when given the opportunity to choose, goats appear to be able to select more digestible and beneficial browse. Grazing or browsing tannin-containing plants may help control many species of internal nematode parasites.

For sample rations for kids and goats, *see* TABLE 41.

TABLE 41 SAMPLE RATIONS FOR GOATS^a

For a 30-kg (66-lb) goat in a nonproductive state, minimal activity, maintenance only:

Chickpea straw 630 g (1.4 lb)

Alfalfa, fresh 95 g (0.20 lb)

For a 50-kg (110-lb) goat in a nonproductive state, minimal activity, maintenance only:

Wheat straw 716 g (1.6 lb)

Alexandrian clover, fresh 333 g (0.73 lb)

For a 20-kg (44-lb) kid gaining 50 g/day, minimal activity:

Alfalfa hay, full bloom 80 g (0.18 lb)

Corn grain 360 g (0.79 lb)

For a 30-kg (66-lb) kid gaining 150 g/day (0.33 lb):

Chickpea straw 500 g (1.1 lb)

Corn grain 400 g (0.88 lb)

Linseed meal 65 g

For a 40-kg (88-lb) doe in late gestation with minimal activity:

Johnsongrass hay 960 g (2.11 lb)

Sorghum grain 350 g (0.77 lb)

For a 70-kg (154-lb) doe producing 5 kg (11 lb) of milk testing 3.5% butterfat:

Corn silage (dough stage) 1,000 g (2.2 lb)

Alfalfa hay, full bloom 500 g (1.1 lb)

Corn grain 1,365 g (3.00 lb)

Soybean meal 280 g (0.62 lb)

^a Dry-matter basis

NUTRITIONAL DISEASES

Enterotoxemia: This feed related malady causes almost sudden death due to a toxin produced by *Clostridium perfringens* type D and sometimes type C. The organism appears to be widespread in nature. Under conditions of high carbohydrate consumption or high intake of immature succulent forage, the causative bacteria multiply rapidly and produce an ϵ toxin that increases intestinal permeability. (See also ENTEROTOXEMIAS, p 609.) Some cases of enterotoxemia are seen in goats, usually those fed diets with high concentrations of carbohydrates. Diarrhea, depression, lack of coordination, digestive upsets, coma, and death may be seen after excessive carbohydrate feeding of both baby kids and mature goats. The best method to prevent enterotoxemia in stable-fed goats is frequent, small-volume feeding of milk, grain, and forage. Large meals fed once a day should be avoided. Acute indigestion and a rumen pH of <4.8 indicates lactic acidosis,

which can lead to the secondary complication of enterotoxemia.

Polioencephalomalacia: Clinical signs include disorientation, dullness, aimless wandering, loss of appetite, circling, progressive cortical blindness, extensor spasms, and occasionally head pressing. Some animals become recumbent and may eventually die without treatment. Diets that produce a low rumen pH or that are high in grain and low in forages predispose ruminants to polioencephalomalacia. Such dietary conditions can result in depressed production of thiamine, the production of thiamine antimetabolites, or the production of thiaminases in the rumen.

Affected animals can usually be treated successfully with thiamine (200–500 mg, IV, IM, or SC). Although response is dramatic and almost immediate, if significant brain damage has occurred, animals rarely return to a satisfactory level of production. Therefore, prompt treatment is critical.

The diet should be modified to reduce grain and increase forage intake. During times of stress, or when predisposing diets are unavoidable, the inclusion of thiamine mononitrate in the diet may aid in prevention. (See also POLIOENCEPHALOMALACIA, p 1281.)

Pregnancy Toxemia: Seen in late pregnancy, pregnancy toxemia is much more common in dams carrying multiple fetuses. Clinical features include abnormally increased blood levels of ketone bodies with concurrent hypoglycemia. Affected animals exhibit many of the signs described for enterotoxemia (see above). During late gestation, the developing fetuses have high demands for glucose; in an attempt to meet the glucose needs, the dam begins to metabolize adipose tissue (fat). The ability of the liver to metabolize this extra fat load is compromised, with a subsequent increase in the release of ketone bodies into the bloodstream. Signs include depression, dullness, opisthotonos, and eventually death.

In early stages of the disease, when signs first appear, a drench of 200–300 mL of propylene glycol or glycerol can be used as an energy source for the dam to prevent so much body fat from being metabolized. However, the administration of glucose (5% dextrose or 50–120 mL of 23% calcium borogluconate solution into a liter of 5% dextrose IV) is the treatment of choice.

Prevention should be aimed at maintaining a proper body condition score, identifying females with twins and triplets and feeding accordingly, reducing the incidence of chronic disease, shearing long-fibered does in late gestation, and possibly including niacin (1 g/day in the diet during late gestation) in the diet. Ensuring adequate winter feedstuffs while monitoring body condition changes throughout gestation will help reduce the incidence of this condition. (See also PREGNANCY TOXEMIA IN EWES AND DOES, p 1021.)

Urinary Calculi: Calculi result from mineral deposits in the urinary tract.

Difficult and painful urination is evidenced by straining, slow urination, stomping of the feet, and kicking at the area of the penis. Blockage of the flow of urine generally is seen only in intact or castrated males. The blockage may rupture the urinary bladder, resulting in a condition known as waterbelly, and cause death. It is common when diets with high concentrations of cereal grains are fed (feedlot lambs, pet goats, etc). Affected animals excrete an alkaline urine that has a high phosphorus content.

The incidence of urinary struvite calculi can be reduced by lowering phosphorus consumption to minimal levels and maintaining a calcium:phosphorus ratio >2:1 (with the phosphorus content <0.45% of the diet). The use of anionic salts such as ammonium chloride (0.5% of the complete diet), dietary tetracycline, adequate vitamin A (or β -carotene) intake, increased dietary intake of NaCl, reducing grain intake, minimizing use of pelleted cereal grains, and ensuring an adequate source of fresh, clean, palatable water free choice have proved beneficial. Affected animals drenched with ammonium chloride (7–14 g/day for 3–5 days) may show a good response. In range sheep and goats, the disease is associated with consumption of forages having a high silica content. (See also NONINFECTIOUS DISEASES OF THE URINARY SYSTEM IN LARGE ANIMALS, p 1502.)

White Muscle Disease: White muscle disease is caused by low levels of selenium and possibly vitamin E. It seems to develop less frequently in goats than in sheep. Signs include stiffness (especially in the hindquarters), tucked-up rear flanks, arched backs, pneumonia, and acute death. On necropsy, white striations are found in cardiac, diaphragmatic, and skeletal muscles. Levels of AST and lactic dehydrogenase are increased, indicating muscle damage. Blood levels of the selenium-containing glutathione peroxidase are reduced. (See also NUTRITIONAL MYODEGENERATION, p 1172.)

NUTRITION: HORSES

Horses are maintained for a much longer time than most farm animals and have more varied uses as athletes and service and companion animals. Feeding programs, therefore, must sustain a long, productive, and athletic life. The feeding recommenda-

tions given below are based on both practical experience and scientific research. Detailed recommendations can be found in *Nutrient Requirements of Horses*, 6th Ed, published in 2007 by the National Research Council (NRC).

NUTRITIONAL REQUIREMENTS

Horses can use hay and other roughages as nutrient sources much more efficiently than other nonruminants such as poultry or pigs, although utilization is less efficient than in ruminants. Traditionally, it was stated that a good source of roughage should comprise at least 50% of the total equine ration by weight. Current recommendations are that horses receive at least 1.5%–2% of their body weight in forage or forage substitutes such as hay cubes or other high-fiber source daily. The average maximum daily dry matter intake is 2.5%–3% body wt (although some breeds and age groups, notably ponies and weanlings, can exceed those maximums if on good pastures); therefore, forage or forage substitutes should be the major components of an equine ration. The main sites of fermentation in horses are in the cecum and large colons, where products of microbial fermentation, such as volatile fatty acids, amino acids, and vitamins, are also absorbed. Microbial fermentation also occurs in the stomach and small intestine to lesser degrees, depending on the type of feed. Enzymatic digestion of carbohydrates, protein, and fats occurs only in the duodenum and jejunum. Any of these nutrient sources that escape small-intestinal digestion/absorption are passed on for microbial degradation in the large intestine, where their fermentation will alter pH and microbial activity, both acutely and longterm.

Water: Water requirements depend largely on environmental conditions, amount of work or physical activity being performed, type and amount of feed, and physiologic status of the horse. The minimal maintenance daily water requirement of a sedentary adult horse in a thermoneutral environment is 5 L/100 kg body wt/day, assuming the horse is consuming at least 1.5% of its body wt in feed dry matter. However, a 500-kg horse will usually drink 21–29 L of water per day when fed a mixed hay/grain ration or pasture. If fed only dry hay, water intake will almost double. Lactation or sweat losses also increase the needs by 50%–200%. A 500-kg horse exercising for 1 hr in a hot environment will need to drink 72–92 L of water to replace sweat and evaporative losses. Lactating mares need 12–14 L per 100 kg body wt to sustain good health and milk production.

Unlimited free access to clean water is usually recommended, although horses can easily adapt to only periodic access throughout the day if the amounts offered

during the watering sessions are not limited. Inadequate water access will reduce feed intake and increase the incidence of impaction colic, anhidrosis, and other metabolic disorders.

Energy: Energy requirements may be classified into those needed for maintenance, growth, pregnancy, lactation, and work. Equations to estimate energy requirements at any state of performance or production have been derived primarily from studies of light horse breeds (see TABLES 42 and 43). However, the need for energy differs considerably among individuals; some horses require much greater amounts of feed than others (“hard keepers”), and others are much more efficient at feed digestion/utilization (“easy keepers”). Digestibility of feedstuffs also often differs significantly from published values. Therefore, the caloric recommendations provided herein should be considered only a starting point to determine the actual energy needs of a given horse.

Amounts fed should be adjusted to maintain a body condition score between 4 and 6 (see TABLE 44). Emaciated and very thin horses have decreased stress and cold tolerance and increased susceptibility to infections. Obese horses have decreased tolerance of exercise and heat, increased risk of laminitis and lipoma strangulation colic, and if fasted, hyperlipidemia and hypertriglyceridemia. Obesity is also associated with insulin resistance and glucose intolerance.

Maintenance: For maintenance of body weight and to support normal activity, the daily digestible energy (DE) requirement (in Mcal) of the nonworking adult horse in good body condition is estimated to be on average 33.3 kcal/kg body wt, with a minimum requirement of 30.3 kcal/kg for easy keepers or draft/warmblood types of horses and 36.3 kcal/kg for hard keeper adult horses. For obese or emaciated horses, the estimated ideal body weight in kg should be used in the equation rather than current body weight. For weight gain, it is estimated that 1 unit of change in body condition score takes 16–20 kg body wt gain and that each kg of gain requires 20 Mcal DE above maintenance requirements. Caloric intake in obese horses should not be restricted severely for prolonged periods of time because of the risk of hyperlipidemia, especially in ponies and donkeys.

Cold weather increases the energy requirement by 0.00082 Mcal DE/kg body wt for each degree Celsius drop below the

TABLE 42

ESTIMATED DAILY NUTRIENT REQUIREMENTS OF GROWING HORSES AND PONIES

Age (mo)	Body Weight (kg)	Daily Gain (kg)	Daily Nutrients Per Animal ^a				
			Digestible Energy (Mcal)	Crude Protein (g)	Ca (g)	P (g)	Vitamin A ^b (IU)
ADULT WEIGHT 200 KG (PONIES)							
4	67	0.34	5.3	268	15.6	8.7	3,000
6	86	0.29	6.2	270	15.5	8.6	3,900
12	128	0.18	7.5	338	15.1	8.4	5,800
18	155	0.11	7.7	320	14.8	8.2	7,000
24	172	0.07	7.5	308	14.7	8.1	7,700
ADULT WEIGHT 500 KG (AVERAGE HORSES)							
4	168	0.84	13.3	669	39.1	21.7	7,600
6	216	0.72	15.5	676	38.6	21.5	9,700
12	321	0.45	18.8	846	37.7	20.9	14,500
18	387	0.29	19.2	799	37.0	20.6	17,400
24	365	0.18	18.7	770	36.7	20.4	19,300
ADULT WEIGHT 900 KG (DRAFT HORSES)							
4	303	1.52	23.9	1,204	70.3	39.1	13,600
6	389	1.30	28.0	1,217	69.5	38.7	17,500
12	578	0.82	33.8	1,522	67.8	37.7	26,000
18	697	0.51	34.6	1,438	66.7	37.1	31,400
24	773	0.324	39.2	1,492	66.0	36.7	34,800

^a Assumes good-quality forage with or without additional concentrates. Maximal daily intake is estimated to be 2.5%–3% body wt in dry matter.

^b ● 1 mg of β -carotene equals 400 IU of vitamin A for the horse.

Adapted from *Nutrient Requirements of Horses*, 2007, National Academy of Sciences, National Academy Press, Washington, DC.

lower critical temperature (LCT) of the animal. However, the LCT of cold-adapted adult horses in Canada was estimated to be -15°C , whereas donkeys acclimatized to summer temperatures in Nevada had an LCT of 26°C . Wind, precipitation, and body condition also affect LCT. Therefore, LCT must be estimated based on regional average temperatures and conditions and perhaps type of horse. For example, draft breeds with thick hair coats would tolerate lower temperatures than a thin-haired, thin-skinned Thoroughbred.

Growth: For growth, the daily DE requirement of light horse breeds is estimated to be maintenance DE Mcal/day =

$(56.5X^{-0.145})/1,000$ times body wt in kg plus the caloric requirements for growth = $(1.99 + 1.21X - (0.021X^2)) \times \text{ADG}$, using the above equation(s) for the maintenance DE, and X as the age in months and ADG as the desired average daily gain in kg. This equation will give an estimate of caloric requirements; intakes should be adjusted to maintain body condition scores of 5 or 6 in growing horses. Warmblood, draft, and draft-cross breeds may require 10%–20% less than calculated by the equations above to sustain rapid growth and avoid obesity.

Pregnancy and Lactation: During pregnancy, if the mare is not exercised or exposed to extreme weather conditions,

TABLE 43

ESTIMATED AVERAGE DAILY NUTRIENT REQUIREMENTS OF MATURE HORSES AND PONIES

Daily Nutrients Per Animal ^a						
Body Weight (kg)	Digestible Energy (Mcal)	Crude Protein (g)	Ca (g)	P (g)	Vitamin A ^b (IU)	Daily Milk Production (kg)
MAINTENANCE

^a Assumes good-quality forage with or without additional concentrates. Maximal daily intake is estimated to be 2.5%–3.0% body wt in dry matter. Ranges are given for requirements that change with time of pregnancy/lactation.

^b One mg of β -carotene equals 400 IU of vitamin A for the horse.

Adapted from *Nutrient Requirements of Horses*, 2007, National Academy of Sciences, National Academy Press, Washington, DC

maintenance DE intakes are usually adequate until the last 90 days of gestation. Energy requirements during months 9, 10, and 11 of gestation are estimated by multiplying estimated maintenance requirements by 1.11, 1.13, and 1.20, respectively. Voluntary intake of roughage decreases as the fetus gets larger, and it may be necessary to increase the energy density of the ration by using supplemental concentrates in late pregnancy.

To support lactation, the NRC has estimated that 792 kcal of DE/kg of milk produced per day (see TABLE 43) should be added to the increased (36.3 kcal/kg body wt) maintenance needs. Lactating light horses (eg, Thoroughbred, Quarter horses) maintained body weight when fed 28–31 Mcal DE/day. Draft mares may require as much as 43 Mcal/day. However, this recommended level of energy intake has increased body weight gain in lactating

TABLE 44 BODY CONDITION SCORES FOR HORSES

Score	Description
Emaciated	Spinous processes, ribs, tailhead, tuber coxae, and ischii prominent. Bone structure of neck, withers, and shoulders easily visible. No fat palpable over lumbar vertebral transverse processes.
2 Very thin	Slight fat covering spinous processes and tailhead. Transverse processes slightly rounded. Ribs, tailhead, and tuber coxae and ischii prominent. Bone structure of neck, withers, and shoulders faintly discernible.
3 Thin	Fat buildup halfway on spinous process and tailhead; both prominent, but individual vertebrae in tailhead not visible. Transverse processes cannot be felt. Slight fat buildup over ribs and tuber coxae but easily visible. Tuber ischii not discernible. Withers, neck, and shoulder accentuated, but bone structure not visible.
4 Lean	Slight ridge visible over loin, faint outline of ribs visible. Tailhead prominence depends on conformation, but fat palpable around it. Tuber coxae not visible. Withers, shoulder, and neck not obviously thin.
5 Moderate	Loin is flat (no crease or ridge). Ribs not visible but easily felt. Fat around tailhead is spongy, withers rounded over spinous process, and shoulders and neck blend smoothly into body.
6 Moderately fleshy	May have slight crease down loin, ribs barely palpable with light pressure, and fat around tailhead soft. Some fat palpable on side of withers, neck, and behind shoulder.
7 Fleshy	May have crease down loin, and ribs difficult to feel. Fat deposited along withers, behind shoulder, and along neck.
8 Fat	Crease down loin. Ribs very difficult to feel; fat around tailhead very soft. Fat filling area over withers and behind shoulder with noticeable thickening of neck.
9 Obese	Obvious crease down loin. Patchy fat deposits over ribs. Fat bulging around tailhead, along withers, behind shoulders, and along neck. Flank filled with fat (no abdominal tuck).

pony mares, indicating that it may exceed the needs of some breeds or individuals. The mare's body condition should be evaluated on a regular basis and maintained in the range of 5 to 7 using the body condition scores of 1 to 9 (described above) throughout pregnancy and lactation. Mares should be maintaining or gaining in condition to optimize reproductive success during the breeding season, even if lactating at the same time.

Work: The energy requirements of work are influenced by many factors, including type of work, condition and training of the horse, fatigue, environmental temperature, and skill of the rider or driver. As the duration of exercise increases and level of activity is maintained, the DE requirement per unit of time worked actually decreases.

For these reasons, DE recommendations for various activities of light horses (*see* TABLE 45) should be adjusted to meet individual needs and to maintain body condition scores between 4 and 6 for optimal athletic performance.

Protein and Amino Acids: Although some amino acid synthesis and absorption occurs in the cecum and large intestine, it is not sufficient to meet the amino acid needs of growing, working, or lactating horses; therefore, the protein quality of the feed provided to these classes of horses is important. Weanlings require 2.1 g, and yearlings 1.9 g, of lysine/Mcal DE/day. Requirements for other dietary amino acids have not been well established; however, the crude protein recommendations given

TABLE 45

ENERGY REQUIREMENTS OF WORK FOR LIGHT HORSES^a AND DESIRABLE BODY CONDITION SCORES

Activity	DE (Mcal/day)	Body Condition Score
Idle (maintenance)	$0.033 \times \text{body wt (kg)}$	4–6
Halter competition, pleasure trail riding	$1.20 \times \text{DE for maintenance}$	5–6
Performance/show (park, English, and Western pleasure, youth activity), equestrian instruction	$1.4 \times \text{DE for maintenance}$	5–6
Ranch work, frequent strenuous show (cutting and roping, barrel racing), endurance trail ride, lower level 3-day event (hunt course, stadium jumping, dressage), polo	$1.60 \times \text{DE for maintenance}$	4–5
Race training, elite 3-day event	$1.9 \times \text{DE for maintenance}$	4–5

^a 200–600 kg body wt

in TABLES 42 and 43 should be adequate if good quality forages and concentrates are used in the ration. The amino acid balance in alfalfa and other legumes such as soybeans appears to be better than that found in cereal grains or some grass hays. This should be considered when formulating rations, especially for rapidly growing young horses.

Growing horses have a higher need for protein (14%–16% of total ration) than mature horses (8%–10% of total ration). Aged horses (>20 yr old) may require protein intakes equivalent to those for young, growing horses to maintain body condition; however, hepatic and renal function should be assessed before increasing the protein intake of old horses. Fetal growth during the last third of pregnancy increases protein requirements somewhat (10%–11% of total ration), and lactation increases requirements still further (12%–14% of total ration). Work apparently does not significantly increase the protein requirement, provided that the ratio of crude protein to DE in the diet remains constant and the increased energy requirements are met.

Minerals: Because the skeleton is of such fundamental importance to performance of the horse, calcium and phosphorus requirements deserve careful attention (TABLES 42 and 43). Excessive intakes of certain minerals may be as harmful as

deficiencies; therefore, mineral supplements should complement the composition of the basic ration. For example, if the horse is consuming mostly roughage with little or no grain, phosphorus is more likely to be in short supply, especially for growth, than calcium. However, if more grain than roughage is being fed, a deficit of calcium is much more common. The total mineral contribution and availability from all parts of the ration (forages and roughages, concentrates, and all supplements) should be considered when evaluating the mineral intake. However, aside from actual feeding trials, no suitable test for availability of dietary minerals exists. Blood concentrations do not reflect dietary intake adequately for any of the macrominerals, especially calcium.

Calcium and Phosphorus: Requirements for calcium and phosphorus are much greater during growth than for maintenance of mature animals. The last third of pregnancy and lactation also appreciably increase the requirement. Aged horses (>20 yr old) may require more phosphorus than is required for adult maintenance (0.3%–0.4% of total ration). Excess calcium intake (>1% of total ration) should be avoided in aged horses, especially if renal function is reduced.

For all horses, the calcium:phosphorus ratio should be maintained at >1:1. A desirable ratio is ~1.5:1, although if adequate phosphorus is fed, foals can apparently

tolerate a ratio of up to 3:1 and young adult horses a ratio even higher. Work does not appreciably increase calcium or phosphorus requirements as a portion of diet.

Salt: Salt (NaCl) requirements are markedly influenced by sweat losses. It is recommended that horse rations contain 1.6–1.8 g salt/kg feed dry matter, although there are limited data on the precise requirements. Sweat losses may cause NaCl losses >30 g (1 oz) in only 1–2 hr of hard work, and feed concentrations of salt for working horses are recommended to be at least 3.6 g NaCl/kg feed dry matter. The upper limit for salt inclusion in the ration of even hard-working horses is recommended at 6% of the total ration. However, NaCl is the only mineral for which horses are known to have true “nutritional wisdom.” Horses voluntarily seek out and consume salt in amounts to meet their daily needs if given the opportunity. Salt or salt blocks should be available free choice. Supplemental salt may be provided by oral dosing or added to feed or water in addition to free-choice salt to replace acute losses during hard work, but prolonged, excessive, forced supplementation will enhance excretion, which will reduce the ability to adjust to acute losses in the future. Forced oral administration of concentrated salt pastes (electrolytes) to dehydrated horses can cause abdominal malaise. Some horses, usually those confined to stalls, will ingest excessive amounts of salt, possibly due to restricted feed intake and/or boredom. This will not cause health problems as long as adequate water is available, although it will increase water intake and urination. Salt poisoning is unlikely unless a deprived horse is suddenly allowed free access to salt, or if water is not available to horses force-fed salt (eg, electrolyte mixtures given PO during competitions). Excessive salt content of feed or water will limit voluntary intakes, precluding toxicity but putting the horse at risk of energy deficits.

The most satisfactory method to provide supplemental calcium, phosphorus, and salt is to furnish a mixture of one-third trace mineral or plain salt and two-thirds dicalcium phosphate free choice. Trace mineral salt blocks do not contain additional calcium or phosphorus.

Magnesium: The daily magnesium requirement for maintenance has been estimated at 0.015 g/kg body wt based on limited studies. Working horses are estimated to require 0.019 to 0.03 g/kg body wt for light to strenuous exercise, respectively, due to sweat losses. The requirements

for growth have not been well established but have been estimated to be 0.07% of the total ration. Most feeds used for horses contain 0.1%–0.3% magnesium. Although deficiencies are unlikely, hypomagnesemic tetany has been reported in lactating mares and stressed horses. The upper limit of recommended intake is estimated to be 0.3% of ration dry matter based on data from other species, but adult horses have been fed rations with higher magnesium content without apparent adverse effects. Anecdotally, high magnesium intake has a pharmacologic calming effect on horses, but large doses of magnesium sulfate (ie, Epsom salts) are also laxative.

Potassium: The recommended potassium intake for maintenance in adult horses is 0.05 g/kg body wt. Most roughages contain >1% potassium, and a ration containing ≥50% roughage provides more than sufficient potassium for maintenance animals. Working horses, lactating mares, and horses receiving diuretics need higher potassium intakes because of sweat, milk, and urinary losses. Hard work may increase intake needs by a factor of 1.8. It has been proposed that rations fed to hard working horses should provide 4.5 g potassium/Mcal DE. Potassium chloride is the most common salt used to supplement rations. However, upper safe limits have not been established, and although excesses are usually efficiently excreted by the kidneys in healthy horses, acute hyperkalemia caused by the rapid absorption of concentrated salt mixtures can induce potentially fatal cardiac arrhythmias. Forced oral supplementation with large doses of potassium salts should be avoided, even in hard working horses.

Iodine: Iodized salts used in salt blocks or commercial feeds easily fulfill the dietary iodine requirement (estimated to be 0.35 mg/kg feed dry matter), as do forages grown in iodine replete soils. Late pregnant mares may require slightly higher intakes (0.4 mg/kg feed dry matter), but iodine toxicity has been noted in pregnant mares consuming as little as 40 mg of iodine/day. Goiter due to excess iodine intake has been well documented in both mares and their foals, and several cases were associated with large amounts of dried seaweed (kelp) in the diet. Except in regions where the soils are known to be severely iodine deficient, iodine supplementation should not be necessary for horses.

Copper: The dietary copper requirement for horses is probably 8–10 ppm, although

many commercial concentrates formulated for horses contain >20 ppm. The presence of 1–3 ppm of molybdenum in forages, which interferes with copper utilization in ruminants, does not cause problems in horses. However, excessive iron supplementation (fairly common, especially in performance horses [see below]) may inhibit adequate absorption. Copper deficiency may cause osteochondritis dissecans in young, growing horses and is associated with a higher risk of aortic or uterine artery rupture in adults. Copper deficits may also cause hypochromic microcytic anemia and pigmentation loss. Horses are extremely tolerant of copper intakes that would be fatal to sheep. However, excessively high copper intakes potentially reduce the absorption and utilization of selenium and iron, and should be avoided.

Iron: The dietary maintenance requirement for iron is estimated to be 40 mg/kg feed dry matter. For rapidly growing foals and pregnant and lactating mares, the requirement is estimated to be 50 mg/kg feed dry matter. Virtually all commercial concentrates formulated for horses and most forages contain iron well in excess of the recommended concentrations. Only horses with chronic bloodloss (eg, parasitism) should be considered to be at risk of iron deficiency. Excess iron intake potentially interferes with copper utilization. The presence of anemia (low PCV or red cell volume) alone is not sufficient indication for iron supplementation in horses.

Zinc: The zinc requirement is estimated to be 40 mg/kg feed dry matter, although there is evidence that this recommendation may be as much as twice the actual requirement to prevent signs of deficiency in most horses. This mineral is relatively innocuous, and intakes several times the requirement are considered safe, although intakes >1,000 ppm have induced copper deficiency and developmental orthopedic disease in young horses.

Selenium: The dietary requirement for selenium is estimated to be 0.1 mg/kg feed dry matter in most regions. However, there are regions of the world (including the lower Great Lakes, the Pacific northwest, the Atlantic coast, and Florida in the USA, as well as parts of New Zealand) where soils are profoundly deficient in this important but potentially very toxic trace mineral. In other areas (including parts of Colorado, Wyoming, and North and South Dakota), forages may contain 5–40 ppm of selenium,

which is sufficient to produce clinical signs of toxicity (see p 3085). Exercise increases glutathione peroxidase (selenium-containing enzyme) activity and may increase need for supplementation in heavily exercised horses. No more than 0.002 mg/kg body wt should be supplemented on a daily basis; toxicity has been seen with as little as 5 mg selenium/kg feed dry matter.

Other Minerals: The requirement for **sulfur** in horses is not established. However, sulfur-containing amino acids (methionine) and vitamins (biotin) are essential for healthy hoof growth. If the protein requirement is met, the sulfur intake of horses is usually ~0.15% dry-matter intake—a concentration apparently adequate for most individuals. Sulfur deficits may contribute to poor hoof quality.

The dietary requirement for **cobalt** is apparently <0.05 ppm. It is incorporated into vitamin B₁₂ by microorganisms in the cecum and colon and, therefore, is an essential nutrient per se only if exogenous sources of B₁₂ are not incorporated into the ration. The upper limit of intake is estimated to be 25 mg/kg feed dry matter based on data from other species.

Manganese requirements for horses have not been well established; amounts found in the usual forages (40–140 mg/kg dry matter) are considered sufficient.

Rock phosphates, when used as mineral supplements for horses, should contain <0.1% **fluorine**. Fluorine intake should not exceed 40 mg/kg feed dry matter. Excessive ingestion can result in fluorosis, although horses are more resistant to fluorine excesses than are ruminants.

Although **molybdenum** is an essential cofactor for xanthine oxidase activity, no quantitative requirement for horses has been demonstrated. Excessive levels (>15 mg/kg feed dry matter) may interfere with copper utilization.

Vitamins:

Vitamin A: The vitamin A requirement of horses can be met by β -carotene, a naturally occurring precursor, or by active forms of the vitamin (eg, retinol). Fresh green forages and good-quality hays are excellent sources of carotene, as are corn and carrots. It is estimated that 1 mg of β -carotene is equivalent to ~400 IU of active vitamin A. However, because of oxidation, the carotene content of forages decreases with storage, and hays stored >1 yr may not furnish sufficient vitamin A activity. Horses consuming fresh green forage for 3–4 mo of the year usually have sufficient stores of

active forms of vitamin A in the liver to maintain adequate plasma concentrations for an additional 3–6 mo. Rations for all classes of horses should provide a minimum of 30 IU active vitamin A/kg body wt (whether as β -carotene or an active synthetic form such as retinyl acetate). Prolonged feeding of excess retinyl or retinol compounds (>10 times recommended amounts) may cause bone fragility, bone exostoses, skin lesions, and birth defects such as cleft palate and microphthalmia (based on data from both horses and other species). The proposed upper safe concentration for chronic administration is 16,000 IU of the active form of the vitamin per kg feed dry matter. There is no known toxicity associated with β -carotene in horses.

Vitamin D: Horses exposed to ≥ 4 hr of sunlight per day or that consume sun-cured hay do not have dietary requirements for vitamin D. For horses deprived of sunlight, suggested dietary vitamin D₃ concentrations are 800–1,000 IU/kg feed dry matter for early growth and 500 IU/kg feed dry matter for later growth and other life stages. Vitamin D toxicity is characterized by general weakness; loss of body weight; calcification of the blood vessels, heart, and other soft tissues; and bone abnormalities. Dietary excesses as small as 10 times the recommended amounts may be toxic and are aggravated by excessive calcium intake.

Vitamin E: No minimal requirement for vitamin E has been established. However, it has been established that selenium and vitamin E work together to prevent nutritional muscular dystrophy (white muscle disease, *see* p 1095), equine degenerative myeloencephalopathy, and equine motor neuron disease. Evidence of vitamin E deficiency is most likely to appear in foals nursing mares on dry winter pasture or horses fed only low-quality hay unsupplemented with commercial concentrates. Horses forced to exert great physical effort and/or fed high-fat (>5%) rations may have increased needs for vitamin E. However, if selenium intakes are adequate, it is likely that 50 IU vitamin E/kg feed dry matter is adequate for most stages of the life cycle and moderate activity. Supplementation with 500–1,000 IU vitamin E may be necessary for horses working hard and/or fed high-fat (>7%) rations. Excessive supplementation (>5,000 IU/day for an average adult horse) results in decreased vitamin A absorption and should be avoided.

Vitamin K: Vitamin K is synthesized by the microorganisms of the cecum and colon in sufficient quantities to meet the normal requirements of horses. However, consumption of moldy sweet clover hay may induce vitamin K-dependent coagulation deficits (*see* p 3156). The synthetic form of vitamin K (menadione) is nephrotoxic if administered parenterally to dehydrated horses.

Ascorbic Acid: Mature horses synthesize adequate amounts of ascorbic acid for maintenance from glucose in the liver. Some horses may need supplemental ascorbic acid (0.01 g/kg body wt/day) during periods of severe physical or psychologic stress, eg, prolonged transportation or weaning. Oral availability is variable. Ascorbyl palmitate is reportedly more readily absorbed than ascorbic acid or ascorbyl stearate. Prolonged supplementation to nonstressed horses may reduce endogenous synthesis and/or enhance excretion, resulting in deficiencies if supplementation is abruptly discontinued.

Thiamine: Although thiamine is synthesized in the cecum and colon by bacteria and ~25% of this may be absorbed, thiamine deficiency has been reported in horses fed poor-quality hay and grain. Although not necessarily a minimum value, 3 mg thiamine/kg ration dry matter has maintained peak food consumption, normal gains, and normal blood thiamine concentrations in skeletal muscle in young horses. As much as 5 mg/kg feed dry matter may be necessary for horses exercising strenuously, although verifiable deficits have not been recorded. Occasionally, horses are poisoned by consuming plants that contain thiaminases, which results in acute deficits (*see* p 3089).

Riboflavin: Riboflavin deficits have not been documented in horses. Previous correlations with low riboflavin intake and recurrent uveitis in horses have not been substantiated. However, there is no evidence of toxic effects as a result of supplementing this water-soluble vitamin, and daily intakes of 0.04 mg riboflavin/kg body wt are recommended.

Vitamin B₁₂: Intestinal synthesis of vitamin B₁₂ is probably adequate to meet ordinary needs, provided there is sufficient cobalt in the diet. Deficiencies of cobalt in horses have not been reported. Vitamin B₁₂ is absorbed from the cecum, and feeding a ration essentially devoid of vitamin B₁₂ for 11 mo had no effect on the normal hematology or apparent health of adult

horses. Vitamin B₁₂ injected parenterally into racehorses and foals is rapidly and nearly completely excreted via bile into the feces.

Niacin: Niacin is synthesized by the bacterial flora of the cecum and colon and is synthesized in the liver from tryptophan. There is no known dietary requirement for niacin in healthy horses.

Other Vitamins: **Folacin, biotin, pantothenic acid, and vitamin B₆** probably are synthesized in adequate quantities in the normal equine intestine. However, biotin supplementation (15–25 mg/day) has been documented to improve hoof quality in adult horses with soft, shelly hoofwalls.

FEEDING PRACTICES

Ideally, horses should be given free access to hay and/or pasture forages with salt and water ad lib. Horses should not be offered >0.5% of their body weight in high starch/sugar grain-based concentrates (eg, textured grain, pellets, or extruded feed) in a single feeding. More than this in a single meal reduces digestive efficiency and predisposes to problems such as gastric ulcers, insulin resistance, laminitis, and colic. If large amounts of grain-based concentrates are being fed (>0.4% body wt/day), the total amount offered daily should be divided into two or more feedings. Most horses fed good-quality forages require little to no concentrate supplementation. Exceptions are hard-working horses or those with limited access to good-quality forage (<2% body wt in feed dry matter).

It has been well documented that feeding >50% of the total ration in the form of grain-based concentrates increases the risk of colic and laminitis in adult horses. High starch/sugar intake also has been correlated to increased incidence of insulin resistance in both adult and young growing horses. Large (>0.25% body wt) meals of grain-based concentrates should not be offered <1 hr before strenuous exercise, transport, or other stress, or to exhausted horses with poor gut motility.

Because horses are particularly sensitive to toxins found in spoiled feeds, all grains and roughages offered should be of good quality and free of mold. Grains should be stored at a moisture content of <13%. In warm, humid areas, mold inhibitors may help reduce feed spoilage. In contrast, excessively dry, dusty feeds tend to initiate or aggravate respiratory problems. Dampening or soaking such feeds in water

before feeding can help alleviate this problem.

Feeds

Pasture: Good pasture provides both an excellent source of nutrients and the opportunity to exercise. The pasture should be kept as free of weeds as possible by regular mowing or clipping. A legume-grass mixture offers the advantages of good nutrient supply, persistence, and durability. Ideal mixes vary with region, and local recommendations from specialists should be followed. However, some forages should not be used for horse pastures. Alsike clover (*Trifolium hybridum*) and kleingrass (*Panicum coloratum*) are potentially hepatotoxic to horses, and Johnson grass (*Sorghum halepense*) and Sudan grass (*S. sudanense*) contain cyanogenic glycosides. Buffel (*Cenchrus* spp), panic (*Panicum* spp), pangola (*Digitaria decumbens*), kikuyu (*Pennisetum* spp), and *Setaria* spp grasses all contain potentially harmful concentrations of oxalates. None of these forage species should be used for horse pastures.

In sandy areas, horses should be provided with supplemental hay when pasture is short (ie, overgrazed) to prevent sand ingestion and subsequent colic. The hay should be offered in feeders or on a platform to reduce sand ingestion. The use of psyllium products to enhance the elimination of sand from the equine GI tract can be expensive, and efficacy has not been well documented. Supplemental hay is also recommended in any situation when the pasture is limited in quality (lots of weeds, undesirable weeds) or quantity to avoid weed ingestion and preserve the pasture cover.

Hay: Common types of hay used to feed horses include both grass hays, such as timothy, brome, coastal Bermuda, or orchard, and legumes such as alfalfa or clover. Legume-grass mixtures are generally high-yielding and contain considerably more protein, minerals, and vitamins than do grasses alone. However, they may be more difficult to cure in a warm, humid climate and more prone to mold. Coastal Bermuda grass has been associated with an increased risk of impaction colic, especially when harvested late. Alfalfa may be contaminated with blister beetles and also tends to be more allergenic than grass hays or clover. ●**Mat** hay has been used in some regions and, if properly harvested and baled, is roughly equivalent to good-quality

grass hays. Teff grasses are used in some regions of the world but may be deficient in calcium and should be used with caution (or only if an accurate nutrient analysis is done), especially for growing, pregnant, or lactating horses.

The form in which harvested forages are provided to horses is of concern. High-moisture haylages and silages made from whole corn plants should be used with caution as forage sources for horses because of the risk of molds. Moldy corn silage especially can cause fatal leukoencephalomalacia. Feeding large round bales of hay in pastures can be economically advantageous if feeders that reduce waste are used, but it has been documented to increase the risk of botulism. Cubed or chopped forages are often recommended as substitutes for long-stem hay or pasture and for horses that have trouble chewing. Forage-based cubes may need to be soaked in water to decrease the risk of choke, at least initially.

Concentrates and Other Supplements:

Concentrates include all grains and byproduct feeds high in energy and/or protein (eg, wheat bran, soybean meal, rice bran). Processing grains before feeding is often desirable to improve nutrient availability. However, cracked or rolled grains are more susceptible to mold. Because of differences in density, grains should be measured by weight, not volume.

Oats, one of the most traditional grains for horses, may be fed whole, rolled, or crimped. Processing increases the bulk 20%–30% and improves digestibility by ~10%. “Hulled” or “naked” oats are more energy dense than regular oats and should be introduced slowly to reduce the risk of founder or colic.

Barley is a good grain for horses. It is higher in energy than regular oats but lower than corn. It may be fed as the only grain to horses that have a high energy need. Barley should be rolled or crimped to improve digestibility. Palatability, however, is not as high as that of oats or corn.

Corn (maize) is a high-energy feed, useful for horses that are working hard or in need of extra weight gain. However, the starch in corn is less digestible than that of oats and can more easily bypass small-intestinal digestion, resulting in colic and/or laminitis if suddenly fed in large amounts. To maximize digestibility, shelled corn may be cracked or rolled, but the moisture level should be low enough to avoid spoilage during storage. Moldy corn can cause fatal leukoencephalomalacia.

Sorghum grain (milo) and **wheat** should be fed with care. These grains must be cracked or rolled if fed to horses. They are not commonly used in horse rations.

Other concentrate sources of energy/protein used in various regions of the world include dried peas (Great Britain), sugar cane pulp (Brazil), fava beans (Middle East), and bread (note that additives such as sesame or chocolate might cause positive drug-test reactions).

Other Supplements: **Wheat bran** and **rice bran** are byproduct supplements commonly fed to horses. However, both are very high in phosphorus (>1.2%), and the proper calcium:phosphorus ratio should be maintained when any form of bran is added to the diet. Wheat bran is not laxative, contrary to popular belief, but is extremely palatable to horses and often used as a wet “mash” to increase water intake or mask the flavor of other supplements. Because of its high phosphorus content, wheat bran is not recommended as a major or daily component of the ration unless the calcium intake is carefully balanced. Rice bran is a high-fat product added to rations of horses that need extra calories. Many rice bran products have added calcium to offset the high phosphorus content but still are designed to be fed in only limited (<1 kg/day) amounts.

Beet pulp, a byproduct of the sugar beet industry, is added to horse rations as both a source of calories and fiber. It contains moderate amounts of calcium and protein and can be safely fed on a daily basis in larger amounts than the bran products. Shredded beet pulp usually should be soaked in water before feeding to horses. Beet pulp pellets do not require presoaking and are often included in concentrate mixes.

Edible oils and fats may be added to rations to increase the energy density. Normal horse rations contain only 3%–4% fat, but horses can easily tolerate up to 10% fat if it is introduced slowly and they are given 3–4 wk to fully adapt to the change. Corn and vegetable oils are commonly used. Edible oils should be introduced slowly to the ration to avoid diarrhea. Although highly digestible, animal fat is not commonly used in horse rations.

Soybean meal is a palatable protein supplement with good amino acid balance for use in concentrate mixes. It may be fed when pastures or hay are low in protein and are of poor quality or when protein requirements are greatest, such as during early growth or lactation. **Linseed meal** or **cottonseed meal** should not be used as a

protein supplement for young, growing horses because of their low lysine content, but they are adequate for adult horses.

Cane molasses is frequently added to grain mixtures (sweet feeds). It is highly palatable, minimizes separation of “fines,” and reduces dustiness of concentrate mixtures. It is also high in potassium. The readily fermentable carbohydrates and moisture that cane molasses contains may increase mold growth in hot weather and freeze solid in cold winter weather. High sugar/starch (>30% nonstructural carbohydrate) rations have been documented to induce relative insulin resistance in horses and are associated with increased incidence of vices such as wind sucking and wood chewing.

Limestone of a high grade (38% calcium) may be used as a supplemental source of calcium. When both supplemental calcium and phosphorus are needed, dicalcium phosphate, steamed bone meal, or defluorinated rock phosphate is recommended. Dicalcium phosphate is particularly good because the cost per unit of phosphorus is low, the elements are quite available, and it is fairly palatable.

Salt (NaCl) should be provided in a block or in granular form free choice to all horses. Salt content of forages in some regions (notably the southwestern USA) and many commercial feeds may reduce the need for supplemental salt but, because of variable losses in sweat, exact needs are hard to estimate. Horses, if given the opportunity, will voluntarily consume sufficient salt to meet their longterm needs for maintenance, even in hot climates. For maintenance, in horses that do not have high mineral needs, trace mineralized salt that contains added iodine, iron, copper, cobalt, manganese, zinc, and selenium is often used. The need for these additional minerals varies with the locality.

Exercise- and/or heat-induced sweat losses can cause acute sodium/chloride/potassium deficits that must be replaced more rapidly than voluntary homeostatic mechanisms can accommodate. It is common in these circumstances (eg, performance horses) to give oral electrolyte drenches before, during, and/or after strenuous activities.

Feeding Rates

Individual differences in the need for energy and nutrients and gross variations in nutrient contents of feedstuffs make it difficult to generalize about the amount of feed to provide. The amounts given in TABLES

46 and 47 can be used as guidelines, but body condition should be monitored and amounts adjusted accordingly. The maximal dry matter intake in 24 hr is only 3%–3.5% of a horse's body wt, and many horses voluntarily consume <2.5% of their body wt in dry matter in 24 hr. Feed intake should therefore be monitored.

The need for concentrate supplementation while on pasture depends on pasture quality but is more important for young horses and lactating mares. If the pasture is of good to excellent quality, no supplementation other than water and salt are needed by most adult horses at maintenance or in light work. It is desirable to creep-feed nursing foals at the rate of 0.5%–1% body wt with concentrates formulated specifically for growth. Good-quality hay may be needed even when on pasture, especially in winter.

Forage-based total mixed rations and “complete” feeds, which may have concentrates added, have been developed for horses. These can be textured, pelleted, cubed, or extruded products. They have the advantage of uniform quality, complete control over nutrient intake, suitability for horses with bad teeth, less dustiness (which reduces respiratory problems), and reduced bulk for storage and transport. Disadvantages include an increased risk of choke and increased wood chewing, especially with the pelleted and extruded feeds fed as the sole source of nutrition. Most, however, are sufficiently high calorie that they need to be limit fed (<2.5% body wt/day). Wood chewing and boredom can be minimized by feeding long-stem hay with these products or by dividing the total daily allotment into multiple small feedings. Damage to stables and fences can be reduced by treating wood with foul-tasting substances or by covering or replacing wood with metal in vulnerable areas.

NUTRITIONAL DISEASES

Reports of uncomplicated nutrient deficiencies in horses are rare. The nutrients most likely to be deficient are caloric sources, protein, calcium, phosphorus, copper, sodium chloride, and selenium, depending on age and type of horse and geographic area. Signs of deficiency are frequently nonspecific, and diagnosis may be complicated by deficiencies of several nutrients simultaneously. The consequences of increased susceptibility to parasitism and bacterial infections may be superimposed over still other clinical signs. Simple excesses are more common. Nutrients most commonly given in excess of needs, leading

to toxicity or induced deficits of other nutrients, are energy, phosphorus, iron, copper, selenium, and vitamin A.

Energy Deficiency: Many nonspecific changes found in horses with caloric deficiency can result from inadequate intake, maldigestion, or malabsorption. Weight loss is the cardinal sign of inadequate energy intake. In partial or complete starvation, most internal organs exhibit some atrophy.

The brain is least affected, but the size of the gonads may be strikingly decreased, and estrus may be delayed. The immune system is adversely affected, resulting in increased risk of viral diseases. The young skeleton is extremely sensitive, and growth slows or may completely stop. A decrease in adipose tissue is an early and conspicuous sign and is seen not only in the subcutis but also in the mesentery; around the kidneys, uterus, and testes; and in the retroperitoneum. Low-fat

content of long bone marrow is a good indicator of prolonged inanition. The ability to perform work is impaired, and endogenous nitrogen losses increase as muscle proteins are metabolized for energy, causing muscle wasting.

Energy Excess: Overfeeding high-calorie feeds results in obesity in horses and may contribute to developmental orthopedic disease in growing horses. However, some horses, especially those that are sedentary, can become obese on only good-quality hay or pasture. Obesity increases the risk of laminitis (presumably associated with relative insulin resistance) and colic, due to strangulation of the small intestine by pedunculated mesenteric lipomas. Obese horses and ponies have reduced heat and exercise tolerance.

Protein Deficiency: A deficiency of dietary protein may be caused by either inadequate intake of high-quality protein or

lack of a specific essential amino acid. The effects of deficiency are generally nonspecific, and many of the signs do not differ from the effects of partial or total caloric restriction. In general, the horse will have poor quality hair and hoof growth, weight loss, and inappetence. In addition, there may be decreased formation of Hgb, RBCs, and plasma proteins. Milk production is decreased in lactating mares. The following liver enzymes have shown decreased activity: pyruvic oxidase, succinoxidase, succinic acid dehydrogenase, D-amino acid oxidase, DPN-cytochrome C reductase, and uricase. Corneal vascularization and lens degeneration have been noted. Antibody formation is also impaired.

Mineral Deficiencies and Excesses:

Nutritional Secondary Hyperparathyroidism (Bighead, Bran disease): Horses of all ages feed grass hay or pasture and supplemented with large amounts of

TABLE 47

CONCENTRATES SATISFACTORY FOR USE WITH HAYS AS INDICATED IN TABLE 46

Ingredient ^a	Formula A	Formula B
Corn ^b or sorghum grain, rolled or cracked	45	55
Oats ^b , rolled or crimped	24	24
Soybean meal (44% crude protein)	20	10
Cane molasses ^c	8	8
Limestone (34% Ca)	0.5	0.5
Calcium phosphate, monobasic (16% Ca, 22% P)	1.5	1.5
Trace mineral salt ^d	1	1
	100%	100%
Analysis		
Digestible energy (Mcal/kg)	3.2	3.2
Crude protein (%)	16	12
Digestible protein (%)	12	8.5
Calcium (%)	0.60	0.58
Phosphorus (%)	0.67	0.62

^a Except for the cane molasses, all figures are on a 90% dry-matter basis.

^b Barley may be used to replace the corn or sorghum and the oats, by using weights of barley equal to the combined weights of the grains replaced.

^c Cane molasses is not an essential part of a concentrate mixture, but it may help to minimize separation of "fines" and reduce dustiness.

^d Providing NaCl, Fe, Cu, Mn, Co, I, Zn, and Se (from sodium selenite) to provide 0.2 mg selenium/kg concentrate.

grain-based concentrates or wheat bran are most likely to develop relative or absolute calcium deficiencies leading to nutritional secondary hyperparathyroidism. Excess phosphorus intake (Ca:P ratio <1) causes the same clinical signs. Blood concentrations of calcium do not reflect intake because of homeostatic mechanisms, although blood inorganic phosphorus may be increased because of mobilization of bone mineral content. Serum alkaline phosphatase activity is usually increased, and clotting time may be prolonged slightly. Young, growing bone is frequently rachitic and brittle. Fractures may be common and heal poorly. Swelling and softening of the facial bones and alternating limb lameness are frequently reported. (*See also OSTEOMALACIA*, p 1052.)

Phosphorus Deficiency: Phosphorus deficiency is most likely in horses being fed poor-quality grass hay or pasture without grain. Serum inorganic phosphorus concentrations may be decreased, and serum alkaline phosphatase activity increased. Occasionally, serum calcium

levels may be increased. An insidious shifting lameness may be seen. Bone changes resemble those described for calcium deficiency. Affected horses may start to consume large quantities of soil or exhibit other manifestations of pica before other clinical signs are apparent.

Salt Deficiency: Horses are most likely to develop signs of salt (NaCl) deficiency when worked hard in hot weather. Sweat and urinary losses are appreciable. Horses deprived of salt tire easily, stop sweating, and exhibit muscle spasms if exercised strenuously. Hemoconcentration and acidosis may be expected. Anorexia and pica may be evident in chronic deprivation, although these are not specific signs of salt deficiency. In lactating mares, milk production seriously declines. Polyuria and polydipsia secondary to renal medullary washout may be seen in prolonged deficits.

Potassium: Chronic dietary deficiency of potassium results in a decreased rate of growth, anorexia, and perhaps hypokalemia.

However, most forages contain more than sufficient potassium for the average horse. Acute deficits due to sweat losses are more likely and may cause muscle tremors, cardiac arrhythmias, and weakness. Excess potassium intake, especially if given as a bolus PO or IV, also will induce cardiac arrhythmias such as atrial fibrillation.

Magnesium: Foals fed a purified diet containing magnesium at 8 mg/kg (3.6 mg/lb) exhibited hypomagnesemia, nervousness, muscular tremors, and ataxia followed by collapse, with increased respiratory rates, sweating, convulsive paddling, and death after a few weeks. However, most commonly used feeds contain magnesium well in excess of the 70–100 mg/kg dry ration currently recommended. Oversupplementation of this mineral is more likely. Although the effects of excessive magnesium intake in horses have not been determined, based on data from other species, it may cause clinical signs of calcium deficiency.

Iron: Iron deficiency may be secondary to parasitism or chronic blood loss and results in microcytic, hypochromic anemia. However, it is highly unlikely that even anemic horses are iron deficient. Iron excess interferes with copper metabolism and also causes microcytic, hypochromic anemia. Blood transferrin concentrations are the most reliable method to determine the iron status of a horse.

Zinc: Zinc deficiency in foals causes reduced growth rate, anorexia, cutaneous lesions on the lower extremities, alopecia, decreased blood levels of zinc, and decreased serum alkaline phosphatase activity. Excesses (>1,000 ppm) were associated with developmental orthopedic disease in young horses. The effects of excesses or deficits of zinc have not been documented in adult horses.

Copper: An apparent relationship between low blood copper concentrations and uterine artery rupture in aged parturient mares suggests reduced copper absorption with age or reduced ability to mobilize copper stores. Dietary deficiency may cause aortic aneurysm, contracted tendons, and improper cartilage formation in growing foals. Excessive copper intake may interfere with selenium and/or iron metabolism.

Selenium: Selenium deficiency results in reduced serum selenium, increased AST activity, white muscle disease, and perhaps rhabdomyolysis in working horses. (See **also** NUTRITIONAL MYOPATHIES, p 1185.)

Selenium excesses of as little as 5 ppm in the ration cause loss of mane and tail hairs and sloughing of the distal portion of the hoof.

Vitamins: A **vitamin A** deficiency may develop if dried, poor-quality roughage is fed for a prolonged period. If body stores of vitamin A are high, signs may not appear for several months. The deficiency is characterized by nyctalopia, lacrimation, keratinization of the cornea, susceptibility to pneumonia, abscesses of the sublingual gland, incoordination, impaired reproduction, capricious appetite, and progressive weakness. Hooves are frequently deformed, with the horny layer unevenly laid down and unusually brittle. Metaplasia of the intestinal mucosa and achlorhydria have been reported. Genitourinary mucosal metaplasia may be expected. Bone remodeling is defective. The foramina do not enlarge properly during early growth, and skeletal deformities are evident. The latter may be seen in foals of vitamin A-deficient mares.

Vitamin E is very labile and quickly lost with storage in both hays and commercial feeds. It is an important antioxidant, and deficiency has been reported to be associated with an increased incidence of rhabdomyolysis, impaired immune function, reproductive failure, and ocular lesions. Some prolonged, aggressive antibiotic treatments, such as recommended for equine protozoal myelitis, have also been reported to induce vitamin E deficits. Fresh forages, however, are excellent sources of vitamin E, and horses with free access to good pasture rarely need supplementation.

If sun-cured hay is consumed or the horse is exposed to sunlight, it is doubtful a **vitamin D** deficiency will develop. Prolonged confinement of young horses offered only limited amounts of sun-cured hay may result in reduced bone calcification, stiff and swollen joints, stiffness of gait, irritability, and reduced serum calcium and phosphorus. Clinical signs are easily reversible with supplementation or exposure to sunlight.

Signs of experimental **thiamine** deficiency include anorexia, weight loss, incoordination, decreased blood thiamine, and increased blood pyruvate. At necropsy, the heart is dilated. Similar signs have been seen in bracken fern poisoning (see p 3089). Under normal circumstances, the natural diet plus synthesis by microorganisms in the gut probably meet the need for

thiamine. However, needs may be increased by stress.

Although natural feeds plus synthesis within the gut normally provide adequate **riboflavin**, limited evidence indicates an occasional deficiency when the diet is of poor quality. The first sign of acute deficiency is catarrhal conjunctivitis in one or both eyes, accompanied by photophobia and lacrimation. The retina, lens, and ocular fluids may deteriorate gradually and result in impaired vision or blindness. Equine recurrent uveitis (*see* p 508) has been linked to riboflavin deficiency but may be a sequela of leptospirosis or onchocerciasis.

The normal feedstuffs of horses generally contain very little **vitamin B₁₂**. However, horses can synthesize this vitamin in the gut, from which it is absorbed.

FEEDING THE SICK HORSE

Nutrition is an important part of the management and treatment of sick horses. Stresses (eg, surgery, severe orthopedic problems, or infection) can significantly increase caloric needs due to an increase in catabolism. In addition, anorexia or dysphagia can lead to inadequate intake of the proper nutrients. The consequences of not providing proper nutrition include impairment of the immune system, delayed wound and fracture healing, hypoproteinemia, muscle wasting, and weakness. Generally, supportive nutritional therapy should be considered if an adult horse has been hypophagic for 23 days. Neonatal foals require some energy source within 24 hr of decreased intake.

The order of nutrient priorities is water, energy, electrolytes, and protein. Some water-soluble vitamins are poorly stored in the body and should be supplemented. The basal energy requirement (BER) in kcal/day can be calculated by the following formula: $BER = 70 (\text{body wt in kg})^{0.75}$. For example, BER is ~6,800 kcal/day for a 450-kg horse and 1,300 kcal/day for a 50-kg foal. Severe illness or trauma (eg, barn fire burns) significantly increase these needs.

There are several methods to provide nutritional support to a sick horse. The simplest method is to encourage the horse to eat on its own. Unusual feed preferences may be seen. Offering a variety of feeds and letting the horse choose can best determine what is most palatable to the animal. Many horses will eat fresh, green grass even though they refuse other feeds. Alfalfa hay is more palatable than grass hays. Whole oats and sweet-feed mixtures of rolled grains and molasses are the most appetizing

of grains. Bran mashes are usually palatable, but the addition of molasses, applesauce, and salt may increase their acceptance in anorectic horses.

When horses experience pain or fever, analgesics can improve food intake; NSAIDs, such as dipyrone, flunixin meglumine, meclofenamic acid, and phenylbutazone, can be used. Prolonged use of phenylbutazone should be avoided because of the adverse effects of gastric and small-intestinal ulceration and renal papillary necrosis.

Tube feeding is a second way to provide nutrition to horses that will not (or cannot) eat voluntarily. A normal stomach tube may be passed several times a day or may be sutured to the nostril and left as an indwelling feeding tube. This is an effective method to provide nutrients to sick neonates. It is also an inexpensive method to replace fluid and electrolyte losses. Enteral nutritional supplements used in human medicine are particularly useful to provide sufficient caloric intake to adult horses. These products have a known caloric content, which facilitates calculation of the animal's needs. Soaking a complete pelleted feed in water can make a slurry for tube feeding; however, when feeding a slurry in this manner, the stomach tube may clog with feedstuff.

The third method to provide energy and protein to sick horses is through use of total or partial parenteral nutrition (TPN or PPN). Fluid administration (IV) can maintain hydration in horses unable either to drink or absorb fluids. Common replacement solutions include sodium chloride, lactated Ringer's, and 5% dextrose. The nutritional value of these fluids is insignificant. Fat and amino acid solutions are also available. The components of parenteral nutrition are glucose, amino acids, lipid, trace minerals, and multivitamins. The resultant solution is hypertonic and is delivered by constant infusion through a jugular catheter. Delivery is optimized through use of a fluid pump. Blood and urine glucose should be monitored twice daily to regulate the rate of infusion. TPN is costly and requires intensive care and monitoring, which limits its usefulness in adult horses.

Nutrition for Specific Diseases/Problems: Horses with recurrent airway obstruction (*see* p 1455) are frequently sensitive to the dust and molds found in normal hay. They often improve when hay is removed from their diet and they are placed on a complete ration that is pelleted or contains a roughage source such as beet pulp. They do best on pasture. Another source of dust-free roughage is haylage.

Diarrhea in horses is primarily a colonic disease. Traditionally, affected horses are fed less grain and more hay. This increase in dietary fiber can bind water and may result in better formed feces. If weight loss is a concurrent problem, it may be better to maintain grain intake. Grain is digested mainly in the small intestine, and hay in the large intestine. Unless the small intestine is also affected, feeding grain helps maintain body mass. (See also COLIC IN HORSES, p 248, and INTESTINAL DISEASES IN HORSES AND FOALS, p 281.)

The role of nutrition in horses with **hepatic disease** (see p 329) is to provide adequate energy, thus easing the liver's role in energy production and decreasing the amount of metabolic waste to which the liver is exposed. Parenteral or enteral glucose administration may be important as an energy source in anorectic horses. In horses that are eating, cereal grains should provide adequate carbohydrates. Corn is the grain of choice because of its low-protein, high-carbohydrate content. High-protein feeds, such as alfalfa hay, should be avoided.

Horses excrete significant amounts of calcium in their urine. In cases of **renal disease**, low-protein, low-calcium diets should be fed. Corn and grass hay are the feeds of choice.

FEEDING THE AGED HORSE AND THE ORPHAN FOAL

Aged horses often lose weight because of dental wear. Their teeth lose the grinding surface, which results in poor mastication of food. Aged horses also may have reduced protein, fiber, and phosphorus digestion. Feeding a moistened, complete pelleted ration designed for aged horses may improve the horse's well-being.

If an **orphan foal** has not received colostrum from its dam, it must receive either colostrum from another mare or frozen-stored colostrum within 24 hr of

birth—preferably within the first 3–12 hr. Antibody-rich plasma-replacement products for IV administration are available but are expensive and provide protection of questionable duration.

A nurse mare, preferably with a good disposition, is best for the overall care of an orphan foal. The amnion and/or placenta of a mare who has lost a newborn foal can be placed over the orphan foal to increase the mare's acceptance of the foal. The mare and foal should not be left unattended until the mare has accepted the orphan; physical or chemical restraint of the mare may be required initially and repeated on several occasions before she will accept the new foal.

If a nurse mare is not available, a lactating dairy goat (positioned on a stand or bale of hay or straw) may serve as an alternative. Constant monitoring is necessary, because the foal should be fed every 4 hr.

Artificial mare's milk diets and goat's milk have also been used successfully to feed orphan foals. Foals should be fed every 1–2 hr for the first 1–2 days of life, then every 2–4 hr for the next 2 wk at the rate of 250–500 mL per feeding, using a warmed milk container and an artificial nipple. Of the various artificial nipples available, those designed for use by lambs are best suited for foals. The feeding intervals may be lengthened gradually after 2 wk; however, the amount per feeding also should be increased so that the foal consumes 10%–15% of its body wt/day.

A foal should be encouraged to drink freshly prepared milk out of a bucket, ad lib, early in life. After 1 mo, the foal can be encouraged to eat grain mixes (with ≥18% crude protein designed for growing foals) and good-quality hay in addition to the milk or milk replacer. The foal can be weaned off the milk replacer at 3 mo of age. Fresh water should be available to the foal at all times from birth. (See also PERINATAL MARE AND FOAL CARE, p 2159.)

NUTRITION: PIGS

NUTRITIONAL REQUIREMENTS

Pigs require a number of essential nutrients to meet their needs for maintenance, growth, reproduction, lactation, and other functions. The National Research Council (NRC), in its publication, *Nutrient Requirements of Swine* (updated in 2012),

provides estimates of the amounts of these nutrients for various classes of swine under average conditions. However, factors such as genetic variation, environment, availability of nutrients in feedstuffs, disease levels, and other stressors may increase the needed level of some nutrients for optimal performance and reproduction.

The NRC uses a modeling approach to take some of these factors into consideration in its estimates of requirements for energy, amino acids, calcium, and phosphorus, but requirements for other minerals and vitamins are estimated strictly from empirical data.

Although the NRC addresses factors such as lean growth rate, gender, energy density of the diet, environmental temperature, crowding, parity, stage of gestation, and various measures of sow productivity when estimating nutrient requirements, nutritionists, feed manufacturers, veterinarians, or swine producers may wish to include higher levels of certain nutrients than those listed by the NRC to ensure adequate intake of nutrients and for insurance purposes. Any negative effects from oversupplementing diets are generally minimal except in cases of extreme imbalance.

Swine require six general classes of nutrients: water, carbohydrates, fats, protein (amino acids), minerals, and vitamins. Energy, although not a specific nutrient, is an important nutritional component and is

primarily derived from the oxidation of carbohydrates and fats. In addition, amino acids (from protein) that exceed the animal's requirements for maintenance and tissue protein synthesis provide energy when their carbon skeletons are oxidized. Antibiotics, chemotherapeutic agents, microbial supplements (prebiotics and probiotics), enzymes, and other feed additives are often added to swine diets to increase the rate and efficiency of gain, to improve digestibility, and for other purposes, but they are not considered nutrients.

The NRC estimates of nutrient requirements for various body weight groups of pigs from 5–135 kg body wt, expressed as dietary concentrations, are shown in TABLE 48. Requirements for gestating and lactating sows, expressed as dietary concentrations, are shown in TABLE 49. The dietary concentrations listed in the NRC tables are based on a given amount of feed intake; if intake is less than the amount listed, the dietary concentration may need to be increased to ensure an adequate daily intake of the nutrients.

TABLE 48

DIETARY NUTRIENT REQUIREMENTS OF GROWING PIGS ALLOWED AD LIB FEED (90% DRY MATTER)^{a,b,c}

	Body Weight (kg)

^a Adapted, with permission, from *Nutrient Requirements of Swine* (2012), National Research Council, National Academies Press, Washington, DC.

^b Estimates of nutrient requirements are for the midpoint of the weight range as determined by the NRC growth model for pigs of mixed gender (1:1 ratio of barrows and gilts) with high-medium lean growth rate (mean whole body-protein deposition of 135 g/day) from 25–125 kg body wt.

^c Estimates of amino acid, calcium, and phosphorus requirements differ for barrows, gilts, and intact boars, for pigs with differing lean growth rates, for pigs fed ractopamine, and for boars immunized against gonadotropin-releasing hormone. For additional information, see *Nutrient Requirements of Swine* (2012), National Research Council, National Academies Press, Washington, DC.

^d NE = net energy, DE = digestible energy, ME = metabolizable energy. Dietary energy contents relate to corn and soybean meal-based diets. DE and ME are calculated from NE.

^e Assumes 5% feed wastage.

^f Total amino acid requirements apply to corn-soybean meal-based diets. For 5- to 25-kg pigs, lysine percentages are estimated from empirical data, and the other amino acids are based on the ratios of amino acids to lysine based on amino acid requirements for maintenance and growth. The requirements for 25- to 135-kg pigs are estimated from the NRC growth model.

^g The calculated crude protein levels are based on corn-soybean meal diets containing 0.1% supplemental lysine and 3% minerals and vitamins. In addition, specialty ingredients (lactose, dried whey, dried blood plasma, dried blood cells, etc) are included in diets for 5–11 kg pigs.

^h STTD = standardized total tract digestible, ATTD = apparent total tract digestible, ATTD phosphorus and total phosphorus requirements apply to corn and soybean meal-based diets.

ⁱ Conversions: 1 IU vitamin A = 0.30 mcg retinol or 0.344 mcg retinyl acetate; 1 IU vitamin D₂ or D₃ = 0.025 mcg cholecalciferol; 1 IU vitamin E = 0.67 mg of α -tocopherol or 1 mg of DL- α -tocopherol acetate.

^j The niacin in corn, grain sorghum, wheat, and barley is unavailable. Similarly, the niacin in by-products made from these cereal grains is poorly available unless the by-products have undergone fermentation or wet-milling process.

Water: Pigs should have free and convenient access to water, beginning before weaning. The amount required varies with age, type of feed, environmental temperature, status of lactation, fever, high urinary output (as from high salt or protein intake), or diarrhea. Normally, growing pigs consume ~2–3 kg of water for every kg of dry feed. Lactating sows consume more water because of the high water content of the milk they produce. Water restriction

reduces performance and milk production and may result in death if the restriction is severe.

Water quality is important. Water should be relatively free of microbial contamination; if not, chlorination may be necessary. Excessive minerals in water may create problems. Water should have <1,000 ppm of total dissolved solids (TDS). Higher levels of TDS (2,000–5,000 ppm) can cause diarrhea or temporary water refusal, TDS levels of

5,000–7,000 should be avoided for breeding animals, and TDS levels >7,000 ppm are unfit for pigs. Pigs tolerate moderate levels of sulfates in water, but high levels (>3,000 ppm) of sulfates should be avoided.

Energy: Energy requirements are expressed as kilocalories (kcal) of digestible energy (DE), metabolizable energy (ME), or net energy (NE). DE and ME values are used most commonly, but

TABLE 49

REPRODUCTIVE MEASURES AND DIETARY NUTRIENT REQUIREMENTS OF GESTATING AND LACTATING SOWS^{a,b}

	Gestation				Lactation (21-day)

^a Adapted, with permission, from *Nutrient Requirements of Swine* (2012), National Research Council, National Academies Press, Washington, DC.

^b Estimates of amino acid, calcium, and phosphorus requirements during gestation differ for parity 1, 2, 3, and 4+ sows, stage of gestation, body weight at breeding, anticipated litter size, and other factors. Requirements for these nutrients during lactation differ for parity 1 and 2+ sows, body weight after farrowing, litter size, and other factors. For additional information, see *Nutrient Requirements of Swine* (2012), National Research Council, National Academies Press, Washington, DC.

^c NE = net energy, DE = digestible energy, ME = metabolizable energy. Dietary energy contents related to corn and soybean meal-based diets. DE and ME are calculated from NE.

^d Assumes 5% feed wastage.

^e Total amino acid requirements apply to corn-soybean meal-based diets.

^f The calculated crude protein levels are based on corn-soybean meal diets containing 0.1% supplemental lysine and 3% minerals and vitamins.

^g STTD = standardized total tract digestible, ATTD = apparent total tract digestible, ATTD phosphorus and total phosphorus requirements apply to corn and soybean meal-based diets.

^h Conversions: 1 IU vitamin A = 0.30 mcg retinol or 0.344 mcg retinyl acetate; 1 IU vitamin D₃ or D₃ = 0.025 mcg cholecalciferol; 1 IU vitamin E = 0.67 mg of D- α -tocopherol or 1 mg of DL- α -tocopherol acetate.

ⁱ The niacin in corn, grain sorghum, wheat, and barley is unavailable. Similarly, the niacin in by-products made from these cereal grains is poorly available unless the by-products have undergone fermentation or wet-milling process.

there is a trend in the industry to formulate diets on the basis of NE. The NRC determines energy requirements on the basis of NE, and then DE and ME are estimated from NE. Energy requirements of pigs are influenced by their weight (which influences the maintenance requirement), their genetic capacity for lean tissue growth or milk production, and the environmental temperature at which they are housed. The amount of feed consumed by growing pigs allowed to consume feed ad lib is controlled principally by the energy content of the diet. If the energy density of the diet is increased by including supplemental fat, voluntary feed consumption decreases. Pigs fed such a diet generally will gain faster, and efficiency of gain will improve, but carcass fat may increase. If the diet contains excessive amounts of fiber (>5%-7%) without commensurate increases in fat, the rate—and especially the efficiency—of gain are decreased.

Protein and Amino Acids: Amino acids, normally supplied by dietary protein, are

required for maintenance, muscle growth; development of fetuses and supporting tissues in gestating sows, and milk production in lactating sows. Of the 22 amino acids, 12 are synthesized by the animal; the other 10 must be provided in the diet for normal growth. The 10 dietary essential amino acids for swine are arginine, histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. Cystine and tyrosine can meet a portion of the requirement for methionine and phenylalanine, respectively. The percentages of crude protein listed in TABLES 48 and 49 provide the required levels of lysine (the first limiting amino acid) and sufficient amounts of the other essential amino acids in diets consisting of corn and soybean meal. The dietary lysine requirement during the early starter phase is quite high (1.70%) but decreases to 1.53% and 1.40% during the middle and final starter phases, respectively. The requirement continues to decrease throughout the growing-finishing stage from 1.12% during the early growing phase to 0.71% during late finishing.

The amino acids of greatest practical importance in diet formulation (ie, those most likely to be at deficient levels) are lysine, tryptophan, threonine, and methionine. Corn, the basic grain in most swine diets, is markedly deficient in lysine and tryptophan. The other principal grains for pigs (grain sorghum, barley, and wheat) are low in lysine and threonine. The first limiting amino acid in soybean meal is methionine, but sufficient amounts are provided when soybean meal is combined with cereal grains into a complete diet that meets the lysine requirement. An exception might be in young pigs that consume diets with high levels of soybean meal or diets containing dried blood products low in the sulfur-amino acids.

Milk protein is well balanced in essential amino acids but usually is too expensive to be used in swine diets, except for very young pigs. Dried whey, commonly used in starter diets, contains protein with an excellent profile of amino acids, but the total protein content of whey is low. Diets based on corn and animal-protein byproducts (eg, meat meal, meat and bone meal) are inferior to corn-soybean meal diets, but they can be improved significantly by adding tryptophan or supplements that are good sources of tryptophan. Animal proteins are also good sources of minerals and B-complex vitamins.

Diets formulated for early weaned pigs that contain high levels of dried animal plasma or dried blood cells may be deficient in methionine. However, high levels of methionine can depress growth, so methionine should not be added indiscriminately to diets. Supplemental valine may be of value in corn-soybean meal diets fed to lactating sows, but it is still too expensive to be considered as a dietary supplement.

Lysine is generally the first limiting amino acid in almost all practical diets, so if diets are formulated on a lysine basis, the other amino acid requirements should be met. However, caution must be exercised when a crystalline lysine supplement is included in the diet to meet a portion of the pig's lysine requirement. A general rule of thumb is that crude protein content can be reduced by 2 percentage points and the diet supplemented with 0.15% lysine (0.19% lysine•HCl). However, greater reductions in dietary protein coupled with additional lysine may result in deficiencies of tryptophan, threonine, and/or methionine unless they are also supplemented.

It is quite common today to formulate swine diets based on the concept of "ideal" protein; ie, to express essential amino acid

requirements as a percent of the lysine requirement. Additionally, it is becoming more popular to formulate swine diets on the basis of standardized (or true) or apparent digestible amino acids. This method is particularly advantageous when substantial amounts of byproduct feeds are included in the diet.

Minerals: These nutritional elements have many important functions in the body. The dietary requirements for the essential macro- and trace minerals are listed in TABLES 48 and 49.

Calcium and Phosphorus: Although used primarily in skeletal growth, calcium and phosphorus play important metabolic roles in the body and are essential for all stages of growth, gestation, and lactation. The NRC estimates requirements of 0.66% calcium and 0.56% total phosphorus for growing pigs of 25–50 kg body wt. The requirements are higher for younger pigs and lower for finishing pigs, but the ratios of calcium:phosphorus are approximately the same for all weight groups. These levels are adequate for maximal growth (rate and efficiency of gain), but they do not allow for maximal bone mineralization. Generally, maximal bone ash and strength can be achieved by including 0.1%–0.15% additional calcium and phosphorus in the diet.

For gestating and lactating sows, calcium and phosphorus requirements are influenced by stage of gestation (the first 90 days versus the final 25 days of gestation), parity, milk production, and other factors (see TABLE 49). The higher requirements during late gestation are attributed to rapid development of the fetuses. Swine producers may choose to feed slightly higher levels to sows to ensure adequacy of these minerals and to prevent posterior paralysis in heavy milking sows. The calcium and phosphorus requirements listed are based on daily feed intakes of 4.7–5.7 lb (2.1–2.6 kg) during gestation and 13.1–14.6 lb (5.9–6.6 kg) during lactation (these amounts include 5% wastage). If less feed is consumed per day, the percentages of calcium and phosphorus may need to be adjusted upward.

The ratio of total calcium:total phosphorus should be kept between 1.25:1 and 1:1 for maximal utilization of both minerals. A wide calcium:phosphorus ratio reduces phosphorus absorption, especially if the diet is marginal in phosphorus. The ratio is less critical if the diet contains excess phosphorus. When based on digestible phosphorus, the ideal ratio of calcium to

digestible phosphorus is between 2:1 and 2.5:1.

Most of the phosphorus in cereal grains and oilseed meals is in the form of phytic acid (organically bound phosphorus) and is poorly available to pigs, whereas the phosphorus in protein sources of animal origin, such as meat meal, meat and bone meal, and fish meal, is in inorganic form and is highly available to pigs. Even in cereal grains, availability of phosphorus varies. For example, the phosphorus in corn is only 10%–20% available, whereas the phosphorus in wheat is 50% available. Therefore, swine diets should be formulated on an “available phosphorus” basis to ensure that the phosphorus requirement is met. The NRC publication expresses the digestible phosphorus requirements as apparent total tract digestible (ATTD) and standardized total tract digestible (STTD) phosphorus. ATTD phosphorus represents the phosphorus digested, and STTD phosphorus is the digestible phosphorus corrected for endogenous phosphorus excretions.

Phosphorus supplements such as monocalcium or dicalcium phosphate, defluorinated phosphate, and steamed bone meal are excellent sources of highly available phosphorus. These supplements also are good sources of calcium. Ground limestone also is an excellent source of calcium.

Phosphorus is considered a potential environmental pollutant, so many swine producers feed diets with less excess phosphorus than in the past to reduce phosphorus excretion. Supplemental phytase, an enzyme that degrades some of the phytic acid in feedstuffs, is commonly added to diets to further reduce phosphorus excretion. The general recommendation is that dietary calcium and phosphorus can both be reduced by 0.05%–0.1% when ≥ 500 units of phytase per kg of diet are included.

Sodium and Chloride: These minerals are provided by common salt, which contains 40% sodium and 60% chloride. The recommended level of salt is 0.25% in growing and finishing diets, 0.5–0.75% in starter diets, and 0.5% in sow diets. These levels should provide ample sodium and chloride to meet the animal's requirements. Animal, fish, and milk byproducts can contribute some of the sodium and chloride requirement.

Potassium, Magnesium, and Sulfur: Practical diets contain ample amounts of these minerals from the grain and protein sources, and supplemental sources are not needed. Magnesium oxide supplementation

has been used to prevent cannibalism, but controlled studies do not support this practice.

Iron and Copper: These minerals are involved in many enzymes systems. Both are necessary for formation of Hgb and, therefore, for prevention of nutritional anemia. Because the amount of iron in milk is very low, suckling pigs should receive supplemental iron, preferably by IM injection of 100–200 mg in the form of iron dextran, iron dextrin, or gleptoferron during the first 3 days of life (*see also* IRON TOXICITY IN NEWBORN PIGS, p 3077). Giving oral or injectable iron and copper to sows will not increase piglet stores at birth nor will it increase the iron in colostrum and milk sufficiently to prevent anemia in neonatal pigs. High levels of iron in lactation feed results in iron-rich sow feces that pigs can obtain from the pen. Iron can also be supplied by mixing ferric ammonium citrate with water in a piglet waterer or by frequently placing a mixture of iron sulfate and a carrier, such as ground corn, on the floor of the farrowing stall.

The copper requirement for growing pigs is low (3–6 ppm) but higher for sows. The estimated copper requirement of 5 ppm for sows in the previous NRC publication was increased to 10 ppm for gestation and 20 ppm for lactation in the 2012 edition.

Copper at pharmaceutical levels in the diet (100–250 mg/kg) is an effective growth stimulant for weanling and growing pigs. The action of copper at high levels appears to be independent of, and additive to, the growth-stimulating effect of antibiotics. Copper sulfate at high levels in the diet results in very dark-colored feces. Also, high copper diets result in marked increases in the copper content of excreted manure.

Iodine: The thyroid gland uses iodine to produce thyroxine, which affects cell activity and metabolic rate. The iodine requirement of all classes of pigs is 0.14 mg/kg of diet. Stabilized iodized salt contains 0.007% iodine; when fed at sufficient levels to meet the salt requirement, it will also meet the iodine needs of pigs.

Manganese: Although essential for normal reproduction and growth, the quantitative requirement for manganese is not well defined. Manganese at 2–4 mg/kg in the diet is adequate for growth, but a higher level (25 mg/kg) is needed by sows during gestation and lactation.

Zinc: Zinc is an important trace mineral with many biologic functions. Grain-soy-bean meal diets must contain supplemental zinc to prevent parakeratosis (*see* p 975).

Higher levels of zinc may be needed when dietary calcium is excessive, especially in diets typically high in phytic acid such as corn-soybean meal diets. Pharmacologic levels of zinc (1,500–3,000 mg/kg) as zinc oxide have consistently been found to increase pig performance during the postweaning period. In some instances, high levels of zinc oxide have been reported to reduce the incidence and severity of postweaning diarrhea. Responses to zinc oxide and antibiotics seem to be additive in nature, much like the responses to high copper and antibiotics; however, there is no advantage to including high copper and high zinc in the same diet. Similar to copper, high levels of dietary zinc cause increased zinc content in the excreted manure. For sows, the estimated zinc requirement was increased from 50 ppm in the previous NRC publication to 100 ppm in the 2012 edition.

Selenium: The selenium content of soils and, ultimately, crops is quite variable. In the USA, areas west of the Mississippi River generally contain higher amounts of selenium, whereas areas east of the river tend to yield crops deficient in selenium. Under most practical conditions, 0.2–0.3 mg of added selenium/kg of diet should meet the requirements. This trace mineral is regulated by the FDA, and the maximal amount of selenium that can be added to swine diets is 0.3 mg/kg.

Chromium: This trace mineral, which is a cofactor with insulin, is required by pigs, but the quantitative requirement has not been established. In some studies, chromium at a supplemental level of 200 mcg/kg (ppb) improved carcass leanness in finishing pigs and improved reproductive performance in gestating sows, but these effects have been somewhat inconsistent.

Cobalt: Cobalt is present in the vitamin B₁₂ molecule and has no benefit when added to swine diets in the elemental form.

Vitamins: These micronutrients serve many important roles in the body. The estimated requirements for the essential vitamins are given in TABLES 48 and 49.

Vitamin A: This fat-soluble vitamin is essential for vision, reproduction, growth and maintenance of epithelial tissue, and mucous secretions. Vitamin A is found as carotenoid precursors in green plant material and yellow corn. β -Carotene is the most active form of the various carotenes. Unfortunately, only about one-fourth of the total carotene in yellow corn is in the form of β -carotene. The NRC suggests that for

pigs, 1 mg of chemically determined carotene in corn or a corn-soybean mixture is equal to 267 IU of vitamin A.

The use of stabilized vitamin A is common in manufactured feeds and in vitamin supplements or premixes. Concentrates containing natural vitamin A (fish oils most often) may be used to fortify diets. Green forage, dehydrated alfalfa meal, and high-quality legume hays are also good sources of β -carotene. Both natural vitamin A and β -carotene are easily destroyed by air, light, high temperatures, rancid fats, organic acids, and certain mineral elements. For these reasons, natural feedstuffs probably should not be entirely relied on as sources of vitamin A, especially because synthetic vitamin A is very inexpensive. An international unit of vitamin A is equivalent to 0.30 mcg of retinol or 0.344 mcg of retinyl acetate.

Vitamin D: This antirachitic, fat-soluble vitamin is necessary for proper bone growth and ossification. Vitamin D occurs as the precursor sterols, ergocalciferol (vitamin D₂) and cholecalciferol (vitamin D₃), which are converted to active vitamin D by UV radiation. Although pigs can use vitamin D₂ (irradiated plant sterol) or vitamin D₃ (irradiated animal sterol), they seem to preferentially use D₃. Some of the vitamin D requirement can be met by exposing pigs to direct sunlight for a short period each day. Sources of vitamin D include irradiated yeast, sun-cured hays, activated plant or animal sterols, fish oils, and vitamin premixes. For this vitamin, 1 IU is equivalent to 0.025 mg of cholecalciferol. The estimated vitamin D requirement of 200 IU/kg for gestating and lactating sows was increased to 800 IU/kg in the 2012 NRC publication.

Vitamin E: This fat-soluble vitamin serves as a natural antioxidant in feedstuffs. There are eight naturally occurring forms of vitamin E, but D- α -tocopherol has the greatest biologic activity. Vitamin E is required by pigs of all ages and is closely interrelated with selenium. The vitamin E requirement is 11–16 IU/kg of diet for growing pigs and 44 IU/kg for sows. Some nutritionists recommend higher dietary levels for sows in the eastern corn belt of the USA, where selenium levels in feeds are likely to be low. Vitamin E supplementation can only partially obviate a selenium deficiency.

Green forage, legume hays and meals, cereal grains, and especially the germ of cereal grains contain appreciable amounts of vitamin E. Activity of vitamin E is

reduced in feedstuffs when exposed to heat, high-moisture conditions, rancid fat, organic acids, and high levels of certain trace elements. One IU of vitamin E activity is equivalent to 0.67 mg of D- α -tocopherol or 1 mg of DL- α -tocopherol acetate.

Vitamin K: This fat-soluble vitamin is necessary to maintain normal blood clotting. The requirement for vitamin K is low, 0.5 mg/kg of diet. Bacterial synthesis of the vitamin and subsequent absorption, directly or by coprophagy, generally will meet the requirement for pigs. Although rare, hemorrhages have been reported in newborn as well as growing pigs, so supplemental vitamin K is recommended at 2 mg/kg of diet as a preventive measure. Generally, hemorrhaging problems can be traced back to the feeding of diets with moldy grain or other ingredients that contain molds.

Riboflavin: This water-soluble vitamin is a constituent of two important enzyme systems involved with carbohydrate, protein, and fat metabolism. Swine diets are normally deficient in this vitamin, and the crystalline form is included in premixes. Natural sources include green forage, milk byproducts, brewer's yeast, legume meals, and some fermentation and distillery by-products.

Niacin (Nicotinic acid): Niacin is a component of coenzymes involved with metabolism of carbohydrates, fats, and protein. Pigs can convert excess tryptophan to niacin, but the conversion is inefficient. The niacin in most cereal grains is completely unavailable to pigs. Swine diets are normally deficient in this vitamin, and the crystalline form is included in premixes. Natural sources of niacin include fish and animal byproducts, brewer's yeast, and distiller's solubles. Based on recent research, the NRC increased the niacin requirement to 30 ppm during all phases of growth.

Pantothenic Acid: This vitamin is a component of coenzyme A, an important enzyme in energy metabolism. Swine diets are deficient in this vitamin, and the crystalline salt, D-calcium pantothenate, is included in vitamin premixes. Natural sources of pantothenic acid include green forage, legume meals, milk products, brewer's yeast, fish solubles, and certain other byproducts.

Vitamin B₁₂: This vitamin, also called cyanocobalamin, contains cobalt and has numerous important metabolic functions. Feedstuffs of plant origin are devoid of this

vitamin, but animal products are good sources. Although some intestinal synthesis of this vitamin occurs, vitamin B₁₂ is generally included in vitamin premixes for swine.

Thiamine: This vitamin has important roles in the body, but it is of little practical significance for swine because grains and other feed ingredients supply ample amounts to meet the requirement in pigs.

Vitamin B₆: A group of compounds called the pyridoxines have vitamin B₆ activity and are important in amino acid metabolism. They are present in plentiful quantities in the natural feed ingredients usually fed to pigs. The requirement for vitamin B₆ in young pigs (5–25 kg) was increased by 3–4 fold in the 2012 NRC publication compared with the previous edition.

Choline: Choline is essential for the normal functioning of all tissues. Pigs can synthesize some choline from methionine in the diet. Sufficient choline is found in the natural dietary ingredients to meet the requirements of growing pigs. However, in some studies, choline supplemented at 440–800 mg/kg of diet increased litter size in gilts and sows. Natural sources of choline include fish solubles, fish meal, soybean meal, liver meal, brewer's yeast, and meat meal. Choline chloride, which is 75% choline, is the common form of supplemental choline used in feeds. If choline is added as a supplement to sow diets, it should not be combined with other vitamins in a premix, especially if trace minerals are present, because choline chloride is hygroscopic and destroys some of the activity of vitamin A and other less stable vitamins.

Biotin: This vitamin is present in a highly available form in corn and soybean meal, but the biotin in grain sorghum, oats, barley, and wheat is less available to pigs. There is evidence that when these latter cereal grains are fed to swine, especially breeding animals, biotin may be marginal or deficient. Reproductive performance in sows has been found to improve with biotin additions. Although not as clear, there is evidence that reproductive performance also is improved with addition of biotin to corn-soybean meal diets. In some instances, biotin supplementation decreased footpad lesions in adult pigs. For insurance, biotin supplementation is recommended, especially for sow diets. Raw eggs should not be fed to pigs because egg white contains avidin, a protein that complexes with biotin and renders it unavailable.

Folacin: This group of compounds has folic acid activity. Sufficient folacin is present in natural feedstuffs to meet the requirement for growth, but some studies have shown a benefit in litter size when folic acid was added to sow diets.

Ascorbic Acid (Vitamin C): Pigs are thought to synthesize this vitamin at a rapid enough rate to meet their needs under normal conditions. However, a few studies have shown benefits in performance of early-weaned pigs under stressful conditions when this vitamin was added to the diet.

Fatty Acids: Linoleic acid, arachidonic acid, and probably other long-chain, polyunsaturated fatty acids are required by pigs. However, the longer chain fatty acids can be synthesized *in vivo* from linoleic acid, so linoleic acid is considered the dietary essential fatty acid. The NRC estimates the linoleic acid requirement at 0.1% for growing and breeding swine. The requirement is generally met by the fat present in natural dietary ingredients. The oil in corn is a rich source of linoleic acid.

FEEDING LEVELS AND PRACTICES

Performance of weanling, growing, and finishing pigs; gestating sows; and lactating sows and their nursing pigs is related to both the quality of the diet and the amount consumed on a daily basis. Knowing the amount of feed animals consume is important in the overall feeding management process. Weanling, growing, and finishing pigs are ordinarily allowed to consume feed *ad lib*, and the amount consumed is affected by the energy density of the diet, environmental temperature, gender, and feed quality (eg, absence of molds), as well as a host of other management factors such as feeder design, crowding, etc.

Growing-Finishing Pigs: Daily feed intakes of various weight classes of growing-finishing pigs fed a diet containing 3,300 kcal of ME/kg (typical of a corn-soybean meal diet) as estimated by the NRC growth model are shown in TABLE 48. These intake levels represent an average for barrows and gilts. Feed intakes will be slightly higher for barrows and slightly less for gilts weighing 50–135 kg. Preventing overcrowding and cooling pigs with automatic water sprayers during hot weather help to alleviate reduced feed

intake. These intake levels can be used as a guide to project total feed requirements or prescribe in-feed medication.

Gestating Gilts and Sows: For gestating gilts and sows, the NRC estimates that a feeding level of approximately 4.7–4.9 lb/day (2.1–2.2 kg/day) during the first 90 days of gestation and 5.6–5.7 lb/day (2.5–2.6 kg/day) for the final 25 days to farrowing of a corn-soybean meal diet (3,300 kcal ME/kg) provides sufficient energy for maintenance; some lean and fat tissue accretion (particularly in gilts); and the energy needs of the developing fetuses, placenta, and other supporting tissues (*see* TABLE 49). Mature sows do not need more energy than that required for maintenance and some increase in body weight. If gestation diets contain oats, alfalfa meal, or other energy diluents, higher feeding levels will be needed to meet the sow's daily energy requirement. Attempts to limit voluntary feed intake during gestation by allowing *ad lib* access to extremely high-fiber diets has not been successful; invariably, excess weight gain occurs.

Producers should adjust the feeding level of pregnant gilts and sows to keep them in good condition. Excess body condition at the end of gestation is often associated with reduced feed intake during lactation and sometimes results in reduced litter size, greater incidence of dystocia, more pig overlay, and a greater incidence of postpartum dysgalactia syndrome (*see* p 1373). Poor body condition results in a greater incidence of shoulder sores in sows, lower birth weights, and thin sows at weaning with delayed return to postweaning estrus (or even anestrus). Litter size at the subsequent farrowing can also be negatively affected if sows are in poor condition at breeding.

The amino acid requirements of first-litter gilts are higher than those for sows. Both gilts and sows require higher levels of dietary amino acids during the latter stage of gestation than in the initial 90 days of gestation. (*See* TABLE 49.)

Lactating Gilts and Sows: The NRC estimates that lactating gilts and sows nursing 11–11.5 pigs that gain 240 g/day during a 21-day lactation require 13.1–14.6 lb (6.0–6.6 kg) of feed (3,300 kcal of ME/kg) daily to meet their energy requirements (*see* TABLE 49). The amount of energy and feed depends on number of pigs nursed, weight gain of the pigs (both of these factors influence milk production), and weight loss of the sow. High-energy diets should be fed

ad lib to sows during lactation, or sows should be hand-fed all they will consume three times daily. Proper temperature regulation in the farrowing room and the use of drip-coolers during hot weather help to alleviate low feed intake.

If feed intake is too low, sows will lose excessive weight during lactation (*see* p 2340). If this is a problem, including 3%–6% fat in the lactation diet or top-dressing the lactation feed with additional fat should be considered. If problems persist, more energy during the final 3–6 wk of pregnancy may be helpful.

Diets high in protein and amino acids should be fed to prolific sows nursing large litters to maximize milk production and to prevent excessive weight loss of the sow. Such sows may require diets containing 16%–18% or more crude protein (minimum of 0.9% lysine). If energy intake is sufficient, high-protein lactation diets will minimize or even eliminate weight loss in sows during lactation.

Major Feed Ingredients

A fundamental principle of the economics of pork production is to feed the most economical cereal grains and to correct the deficiencies by supplementation with good-quality protein sources, minerals, and vitamins. Dependable mineral and vitamin premixes or complete manufactured supplements are commercially available. Fortified corn-soybean meal diets are very popular in pig operations, but other cereals and protein sources can be used.

Corn (maize) is by far the most widely used grain for feeding pigs in the USA. It is very palatable and high in energy but relatively low in crude protein. In addition, corn is deficient in lysine, tryptophan, threonine, and several other essential amino acids, as well as vitamins and minerals.

Grain sorghum is a major energy source for pigs in western and southwestern USA. The protein content is variable depending on factors such as variety, whether the crop was grown on irrigated or dry land, amount of fertilizer used, and other environmental factors. In general, grain sorghum can be substituted for corn on an equal-weight basis, but because the ME value is slightly lower than that of corn, a poorer feed conversion should be expected.

Wheat has about the same energy content as corn and contains 2%–3% more protein and 0.05%–0.1% more lysine than corn. Wheat can be substituted for corn on either an equal-weight basis or on a lysine basis, but not on a crude protein basis or it

will result in a lysine deficiency. Wheat can constitute all of the grain in a swine diet. The two main types of wheat grown in the USA, hard red winter and soft red winter, have equivalent nutritional value.

Barley has ~85%–90% of the feeding value of corn, even though it usually contains 2%–3% more protein. Scabby barley should not be fed to pigs.

Oats have a relatively low energy content and, therefore, should not account for >20%–25% of the cereal grain in the diet. Generally, when oats are included in the diet, the rate and efficiency of gain should be expected to decline. Rolled oats groats are sometimes used in starter diets because of their excellent palatability.

Cereal grains should be ground or rolled to maximize their feeding value. Corn and grain sorghum should be reduced to a medium-fine particle size (550–600 microns). Wheat should be ground more coarsely (650–700 microns) to prevent pasting. Fine grinding improves feed conversion, but excessive reduction in particle size may lead to an increased incidence of gastric ulcers. Pelletizing of diets may result in a small improvement in gain and especially feed efficiency. In general, the benefit is greatest with pelleted diets that contain high levels of fiber, such as barley-based diets. Cereal grains should be as free as possible from mycotoxins. Aflatoxins, vomitoxin, zearalenone, fumonisins, and other mycotoxins can reduce animal performance, depending on level in the feed, and can especially cause reproductive problems in breeding animals.

Soybean meal accounts for >90% of the supplemental protein fed to pigs in the USA. It is very palatable and has an excellent amino acid profile that complements the amino acid pattern in cereal grains. Ground, full-fat soybeans can also be fed to swine but only after they are heated (by extrusion or roasting) to inactivate the trypsin inhibitors and other heat-labile antinutritional factors.

Canola meal also is an excellent protein source. Low-gossypol cottonseed meal (<100 ppm free gossypol), peanut meal, sunflower meal, and other oilseed-based meals can be used in swine feed but generally not as the sole source of supplemental protein because of the lower lysine content of their protein. Animal protein sources such as meat meal, meat and bone meal, or fish meal can supply a portion of the supplemental protein in swine diets.

Distillers dried grains with solubles (DDGS) is a byproduct that has received a

lot of attention in recent years because of the increased number of ethanol plants that use corn to produce ethanol for fuel. This byproduct is an excellent and generally economical feed ingredient for swine.

Although DDGS has essentially no starch and considerably more fiber than corn, it is considerably higher in fat (corn oil); hence, the ME content of DDGS containing 9%–12% fat is similar to that of corn. Recently, some ethanol plants extract a portion of the oil from the solubles before adding the solubles back to the dried grains. This results in a “low-fat” DDGS, generally 5%–9% fat, which has slightly less ME than conventional DDGS. Further removal of fat, called “de-oiled DDGS” (<5% fat) has substantially less ME than either of the other types of DDGS, so it has a lower feeding value. DDGS is also higher in protein than corn, but the quality of protein (ie, balance of amino acids), like corn protein, is poor.

A considerable amount of research has been done with DDGS in recent years. Diets containing 20%–25% DDGS are well utilized by pigs, but when high levels (>30%) of DDGS are fed in finishing diets, body fat of pigs becomes more unsaturated, as evidenced by higher iodine values. This results in softer, more flexible bellies that are more difficult to process into bacon slices. To overcome this problem, producers should consider either removing DDGS from the late finishing diet or reducing the level of DDGS to 10% during the final 3–4 wk of the finishing period.

Feeding Management of Sows and Litters

Gestation diets adequate in all nutrients should be fed to sows to produce healthy, vigorous pigs. Sows should be fed so that they are in good body condition at farrowing—not too fat or too thin. Thin sows tend to farrow smaller pigs that have a poorer chance of survival than larger, more vigorous pigs. After farrowing, the sow should be returned to full feed as soon as possible. Constipation in sows is generally not a problem if the sow is eating well. Wheat bran or dried beet pulp can be included in the farrowing diet at 5%–10% if constipation is a problem, or chemical laxatives such as potassium chloride or magnesium sulfate can be included in the diet at 0.75%–1%.

Newly farrowed pigs should be checked to ensure that each has nursed. If necessary, milk flow may be stimulated by giving oxytocin. If the sow is slow in coming into milk, weak pigs may benefit from receiving artificial milk, but success depends on good

management and sanitation. Nutritional anemia should be prevented by giving an iron injection before 3 days of age or by other means discussed previously. Pigs from large litters may be transferred to sows with smaller litters after they receive colostrum; however, the transfer should be done within the first 24 hr after birth. A palatable pig starter diet should be provided beginning at 2–3 wk if pigs are weaned later than 3 wk of age. (See also HEALTH-MANAGEMENT INTERACTION: PIGS, p 2160, and MANAGEMENT OF REPRODUCTION: PIGS, p 2201.)

Feeding Management of Weaning Pigs

Pigs weaned at an early age (3–4 wk) perform best if fed a complex starter diet for 1–2 wk after weaning. Typically, the starter diet contains dried whey and/or lactose, dried blood products, and a high level of lysine. Some producers use a medicated early weaning program or segregated early weaning program to produce healthier pigs. This entails weaning at 10–16 days of age and requires excellent nutritional management. Such diets should contain even higher levels of lysine as well as high levels of lactose (as the sugar or from dried whey) and 3%–7% dried animal plasma. A gradual transition should eventually be made to less expensive starter diets and then to corn-soybean meal diets.

The nutritional needs of growing/finishing pigs are best met by a full-feeding program. Limit-feeding reduces the rate and efficiency of gain but may improve carcass quality of finishing pigs. Proper design and adjustment of self-feeders is necessary to prevent feed wastage or restricted growth.

Growth Stimulants

For many years, antibiotics and other chemotherapeutic agents have commonly been added to swine diets to promote growth and feed efficiency, reduce mortality and morbidity, and improve health. The greatest response to these growth enhancing agents is in young pigs, with lesser responses as pigs progress in age and weight. The levels of antibiotics fed and drug withdrawal requirements should be in accordance with manufacturers' recommendations and legal restrictions. (See also GROWTH PROMOTANTS AND PRODUCTION ENHANCERS, p 2758.)

The antibiotics approved as feed additives for swine include bacitracin methylene disalicylate, bacitracin zinc, bambermycins, chlortetracycline, lincomycin, neomycin, oxytetracycline, penicillin, tiamulin, tylosin, and virginiamycin. Chemotherapeutic

agents include carbadox, roxarsone, sulfamethazine, and sulfathiazole. Several of these are approved only in combination with certain other additives. Apramycin also is approved for use as a water medication. Also, pharmaceutical levels of zinc (1,500–3,000 ppm) as zinc oxide, or copper (100–250 ppm) as copper sulfate or tribasic copper chloride are effective growth stimulants in young pigs.

However, FDA action has changed how antibiotics can be used. According to Final Guidance 213 and the Veterinary Feed Directive (VFD) rule, antimicrobials medically important in human medicine (this includes all of the antimicrobials approved for swine except carbadox, bacitracin, and bambarnycins) previously used at subtherapeutic levels for production purposes (improved growth and efficiency) are no longer allowed for that purpose. Instead, they are allowed only for disease prevention and only under veterinary supervision and oversight. This regulation applies to antibiotics used in feed or water. Companies that produce those antimicrobials are asked to voluntarily remove the production improvement claim on their product labels. These products will no longer be available to producers on an “over-the-counter” basis; they will only be available on a VFD basis.

Microbials that are directly fed (once referred to as probiotics), such as live cultures of *Lactobacillus acidophilus*, *Streptococcus faecium*, and *Saccharomyces cerevisiae*, have been evaluated as possible substitutes for antibiotics, but controlled studies have not shown consistent, beneficial responses from their inclusion. In some instances, inclusion of specific sugars (mannanoligosaccharides, fructooligosaccharides [also called prebiotics]) have shown promise as possible alternatives to antibiotics for young pigs, but growth responses are less consistent and of lower magnitude than from the inclusion of antibiotics. The direct-fed microbials and oligosaccharides are thought to encourage growth of desirable microorganisms in the GI tract, such as lactobacilli species and bifidobacteria that partially displace some of the less desirable microorganisms, including some pathogenic microbes.

Certain “repartitioning agents” have been tested with finishing swine and found to be very effective in improving growth rate, feed conversion, and carcass leanness. Examples are β -agonists, such as ractopamine and porcine somatotropin. As of 2015, ractopamine is the only such agent

approved for use in pigs in the USA. These agents affect nutrient requirements, in particular by increasing the dietary requirements for amino acids.

NUTRITIONAL DISEASES

Diagnosis of nutritional deficiencies by observation is difficult. Quite often, the clinical signs are the result of a complex of mismanagement and infectious diseases, including parasitism, as well as malnutrition. For most nutritional deficiencies, the signs are not specific, eg, poor appetite, reduced growth, and unthriftiness. Deficiency of a single nutrient may bring about inanition, and the subsequent starvation may cause multiple deficiencies. Then, too, a nutritional deficiency may exist without the appearance of definite signs. In the field, the deficiency may be only slight or borderline, which makes diagnosis difficult.

Diagnosis of a deficiency by observing the response to nutritional therapy is not always clear, particularly for long-term deficiencies, the lesions of which may be irreversible. A nutritional deficiency should be diagnosed positively only after observation of several of the expected clinical signs and a careful review of the dietary, disease, and management history of the animals.

Protein Deficiency: Protein deficiency, which may result from suboptimal feed intake or a deficiency of one or more of the essential amino acids, causes reduced gains, poor feed conversion, and fatter carcasses in growing and finishing pigs. In lactating sows, milk production is reduced, excess weight loss occurs, and sows may fail to exhibit postweaning estrus or have delayed return to estrus. For optimal use of protein, all essential amino acids must be liberated during digestion at rates commensurate with needs. Therefore, protein supplements should not be handfed at infrequent intervals but should be mixed with the grain or be available at all times with grain on a free-choice basis.

No evidence has been presented to support the theory of “protein poisoning” in pigs. Diets containing as much as 35%–50% protein were found to be laxative and less efficiently used, but no toxic effects were noted.

Fat Deficiency: Certain long-chain polyunsaturated fatty acids are essential for swine. Linoleic acid is essential in the diet

and is used to produce longer-chain fatty acids that are probably also essential. A linoleic acid deficiency induces hair loss, scaly dermatitis, skin necrosis on the neck and shoulders, and an unthrifty appearance in growing pigs. Conventional swine diets generally contain adequate fat from the natural ingredients to furnish ample amounts of essential fatty acids.

Mineral Deficiency: Deficiencies of **calcium** or **phosphorus** result in rickets (*see* p 1051) in growing pigs and osteomalacia (*see* p 1052) in mature pigs. Signs include deformity and bending of long bones and lameness in young pigs, and fractures and posterior paralysis (a result of fractures in the lumbar region) in older pigs. Sows that produce high levels of milk and nurse large litters are particularly susceptible to posterior paralysis toward the end of lactation or after weaning if dietary calcium or phosphorus is deficient. These signs can also result from a deficiency of vitamin D, but phosphorus deficiency is the most common cause.

Pigs fed diets low in **salt** (NaCl) grow poorly and inefficiently, largely because of a marked reduction in feed intake. Although not specific for salt deficiency, poor hair and skin condition may also develop. There have been reports of salt-deficient pigs attempting to consume urine of other pigs.

Sows fed diets deficient in **iodine** produce hairless pigs that are weak or stillborn. With a borderline deficiency, the newborn pigs may be weak only at birth, but their thyroids are enlarged and have histologic abnormalities. (*See also* NON-NEOPLASTIC ENLARGEMENT OF THE THYROID GLAND, p 558.) Some feedstuffs (including soybeans and soybean meal) contain goitrogens that may cause marginal goiter if iodine is not included in the diet. Iodized salt at recommended levels prevents this deficiency.

Deficiencies of **iron** and **copper** reduce the rate of Hgb formation and produce typical nutritional anemia. Signs of nutritional anemia in suckling pigs include low Hgb and RBC count, pale mucous membranes, enlarged heart, skin edema about the neck and shoulders, listlessness, and spastic breathing (thumps). Iron deficiency is more common than copper deficiency and is most common in nursing pigs that do not receive an iron injection or oral iron early in life.

A deficiency of **zinc** results in parakeratosis (*see* p 975) in growing pigs, particularly when fed diets high in phytic acid (or phytate, the primary form of phosphorus in cereal grains and oilseed meals) and more

than the recommended amount of calcium. The exact mode of action of zinc in the prevention of parakeratosis is not known.

Deficiencies of **selenium** and/or **vitamin E** can cause sudden death of young, rapidly growing pigs (*see* p 1174). In addition, selenium/vitamin E deficiency in nursing pigs makes them more susceptible to iron toxicosis from iron injections (*see* p 3077.)

Vitamin Deficiency: Most commercial diets are fortified with vitamins, and vitamin premixes are readily available for farm-mixed feeds, so deficiencies are less common than they were years ago. Deficiency of **vitamin A** results in disturbances of the eyes and the epithelial tissues of the respiratory, reproductive, nervous, urinary, and digestive systems. Reproduction is impaired in sows, and they may farrow blind, eyeless, weak, or malformed pigs. Herniation of the spinal cord in fetal pigs is reported as a unique sign of vitamin A deficiency in pregnant sows. Growing pigs deficient in vitamin A show incoordination and develop night blindness and respiratory disorders. Vitamin A deficiency is rare because of the ability of the liver to store this vitamin.

Signs of **vitamin D** deficiency include rickets, stiffness, weak and bent bones, and posterior paralysis. These signs are indistinguishable from those of a calcium or phosphorus deficiency (*see* above).

Vitamin E deficiency can result in poor reproduction and impaired immune system. Many of the signs of vitamin E deficiency are similar to those of selenium deficiency (*see* above).

Pigs deficient in **vitamin K** have prolonged blood clotting time and may die from hemorrhages. Certain components in moldy feed can interfere with vitamin K synthesis. Also, excessive levels of dietary calcium interfere with vitamin K activity, causing these signs.

In pigs deficient in **riboflavin**, reproduction is impaired; postpubertal gilts fail to cycle but show no other clinical signs. Deficient sows are anorectic and farrow dead pigs 4–16 days prematurely. The stillborn pigs have very little hair, often are partially resorbed, and may have enlarged forelegs. Growing pigs fed diets low in riboflavin gain weight slowly and have a poor appetite, a rough coat, an exudate on the skin, and possibly cataracts.

Pigs deficient in **niacin** have inflammatory lesions of the digestive tract and exhibit diarrhea, weight loss, rough skin and coat, and dermatitis on the ears. Intestinal conditions can be due to niacin deficiency

or bacterial infection. Deficient pigs respond readily to niacin therapy and, although not a cure for infectious enteritis, adequate dietary niacin probably allows the pig to maintain its resistance to bacterial invasion.

Growing pigs and pregnant sows develop a typical "goose-stepping" gait, ataxia, and a noninfectious bloody diarrhea when maintained on diets deficient in **pantothenic acid**. When the deficiency becomes severe, anorexia develops.

Pigs with a **choline** deficiency exhibit incoordination and an abnormal shoulder conformation. At necropsy, they may have fatty livers and usually show kidney

damage. Sows deficient in choline have reduced litter size and may give birth to spraddle-legged pigs.

Biotin deficiency includes excessive hair loss, skin ulcerations and dermatitis, exudates around the eyes, inflammation of the mucous membranes of the mouth, transverse cracking of the hooves, and cracking or bleeding of the footpads.

Neonatal pigs fed synthetic diets low in **vitamin B₁₂** show hyperirritability, voice failure, and pain and incoordination in the hindquarters. Histologic examination of the bone marrow reveals an impaired hematopoietic system. Fatty livers are also noted at necropsy.

NUTRITION: SHEEP

The economical and efficient production of sheep for meat, wool, show and/or pets is contingent on proper feeding, husbandry practices, and health care. All of these are influenced by dietary intake. Maintenance of breeding animals, a high percentage of the lamb crop weaned, growth of lambs, optimal weaning weights, and a heavy fleece weight and fleece quality are important to efficiency. The nutritional requirements for maintenance, reproduction, growth, finishing, and wool production are complex because sheep are maintained under a wide variety of environmental conditions; however, attempts should be made to ensure each production unit or individual sheep has adequate nutrient intake to be healthy and productive.

NUTRITIONAL REQUIREMENTS

An adequate diet for optimal growth and production must include water, energy (carbohydrates and fats), proteins, minerals, and vitamins. Under field conditions of particular stress, additional nutrients may be needed. (For detailed nutrient requirements for sheep, refer to the most current *Nutrient Requirements of Small Ruminants*, published by the National Research Council [www.nap.edu].)

Water: A clean, fresh, easily accessible source of water should be available at all times. As a minimum requirement in temperate environments, the usual

recommendations are ~1 gal. (3.8 L) of water/day for ewes on dry feed in winter, 1½ gal./day for ewes nursing lambs, and ½ gal./day for finishing lambs. In many range areas, water is the limiting nutrient; even when present, it may be unpotable because of filth or high mineral content. For best production, all sheep should have their water availability monitored daily during all weather conditions. However, the cost of supplying water often makes it economical to water range sheep every other day. When soft snow is available, range sheep do not need additional water except when dry feeds such as alfalfa hay and pellets are fed. If the snow is crusted with ice, the crust should be broken to allow access. Still, when possible, sheep should have unlimited access to fresh, clean water.

Energy: Because so much of the diet can depend on grass and forage that is either sparse or of poor quality, the provision of adequate energy is important. Poor-quality forage, even in abundance, may not provide sufficient available energy for maintenance and production. The energy requirement of ewes is greatest during the first 8–10 wk of lactation. Because milk production declines after this period and the lambs have begun foraging, the requirement of the ewe is then reduced to prelanbing levels. The easiest way to assess energy adequacy in sheep is to perform and record body condition using an objective 1–5 scoring system, with 1 being extremely thin and 5 being extremely obese.

The body condition score is determined by palpating the amount of fat covering on the spinous processes and transverse processes in the lumbar region. Most healthy productive ewes will have a score of 2–3.5. Sheep with a score of 1–2 should be examined and fed to attain a higher score, whereas those with a score >3.5 should be fed less. Dietary changes should be done slowly, and abrupt reduction in total energy intake should always be avoided, particularly in middle to late gestation.

Protein: Good-quality forage and pasture generally provide adequate protein for mature sheep. However, sheep do not digest poor-quality protein as efficiently as do cattle, and there are instances when a protein supplement should be fed with mature grass and hay, or when on winter range. Therefore, a minimum of 7% dietary crude protein is needed for maintenance in most sheep. Protein requirements depend on the stage of production (growth, gestation, lactation, etc) and the presence of certain diseases (internal nematode parasites, dental disease, etc). If available forages are unable to supply adequate dietary crude protein, protein supplements, such as oilseed meals (cottonseed meal, soybean meal) or commercially blended supplements should be fed to meet nutrient requirements. Protein should be fed to meet, but not exceed, requirements. Excess protein feeding can be beneficial in cases of excessive internal parasite burdens but result in increased production costs and may result in higher incidences of diseases (eg, heat stress, pizzle rot).

Sheep can convert nonprotein nitrogen (such as urea, ammonium phosphate, and biuret) into protein in the rumen but possibly less efficiently than beef cattle. This source of nitrogen can provide at least a part of the necessary supplemental nitrogen in high-energy diets with a nitrogen:sulfur ratio of 10:1. In lamb-finishing diets, the inclusion of alfalfa, approved growth stimulants, and a source of fermentable carbohydrates (eg, ground corn, ground milo) enhance nitrogen utilization.

Minerals: Sheep require the major minerals sodium, chlorine, calcium, phosphorus, magnesium, sulfur, potassium, and trace minerals, including cobalt, copper, iodine, iron, manganese, molybdenum, zinc, and selenium. Trace mineralized salt provides an economical way to prevent deficiencies of sodium, chlorine, iodine, manganese, cobalt, copper, iron, and zinc.

Selenium should be included in rations, mineral mixtures, or other supplements in deficient areas. Sheep diets usually contain sufficient potassium, iron, magnesium, sulfur, and manganese. Of the trace minerals, iodine, cobalt, and copper status in ewes are best assessed via analysis of liver biopsy tissue. Zinc adequacy can be assessed from the careful collection of nonhemolyzed blood placed in trace element-free collection tubes. Selenium status is easily assessed by collection of whole, preferably heparinized, blood.

Salt: In the USA, except on certain alkaline areas of the western range and along the seacoast, sheep should be provided with ad lib salt (sodium chloride). Sheep need salt to remain thrifty, make economical gains, lactate, and reproduce. Mature sheep will consume ~0.02 lb (9 g) of salt daily, and lambs half this amount. Range operators commonly provide 0.5–0.75 lb (225–350 g) of salt/ewe/mo. Salt as 0.2%–0.5% of the dietary dry matter is usually adequate.

Calcium and Phosphorus: In plants, generally the leafy parts are relatively high in calcium and low in phosphorus, whereas the reverse is true of the seeds. Legumes, in general, have a higher calcium content than grasses. As grasses mature, phosphorus is transferred to the seed (grain). Furthermore, the phosphorus content of the plant is influenced markedly by the availability of phosphorus in the soil. Therefore, low-quality pasture devoid of legumes and range plants tends to be naturally low in phosphorus, particularly as the forage matures and the seeds fall.

Sheep subsisting on mature, brown, summer forage and winter range sometimes develop a phosphorus deficiency. Sheep kept on such forages or fed low-quality hay with no grain should be provided a phosphorus supplement (ie, defluorinated rock phosphate) added to a salt-trace mineral mixture. Because most forages have a relatively high calcium content, particularly if there is a mixture of legumes, diets usually meet maintenance requirements for this element. However, when corn silage or other feeds from the cereal grains are fed exclusively, ground limestone should be fed daily at the rate of 0.02–0.03 lb (9–14 g).

Sheep seem to be able to tolerate wide calcium:phosphorus ratios as long as their diets contain more calcium than phosphorus. However, an excess of phosphorus may be conducive to development of urinary calculi or osteodystrophy. A calcium: phosphorus ratio of 1.5:1 is

appropriate for feedlot lambs. For pregnant ewes, the diet should contain $\geq 0.18\%$ and, for lactating ewes, $\geq 0.27\%$. A content of $0.2\%–0.4\%$ calcium is considered adequate, as long as the ratio is maintained between 1:1 and 2:1.

Iodine: Occasionally, the iodine requirements of sheep are not met in the natural diet and thus iodine supplements must be fed. Goitrogenic substances are found in many types of plants (eg, *Brassica* spp) and interfere with the use of iodine by the thyroid. Regions naturally deficient are found throughout the western USA, in the Great Lakes area, and in other parts of the world. A deficiency of iodine (manifested as goiter in the adult and as lack of wool and/or goiter in lambs) can be prevented by feeding stabilized iodized salt to pregnant ewes. The young of iodine-deficient ewes may be aborted, stillborn, or born with goiters. Diets containing iodine at $0.2\%–0.8\%$ ppm are usually sufficient, depending on the animals' level of production (maintenance/growth, lactation, etc).

Cobalt: Sheep require ~ 0.1 ppm of cobalt in their diet. Cobalt-deficient soils are found in North America but are relatively rare compared with other parts of the world. Normally, legumes have a higher content than grasses. Because cobalt levels of the feedstuffs are seldom known, a good practice is to feed trace mineralized salt that contains cobalt.

Copper: Pregnant ewes require ~ 5 mg of copper (Cu) daily, which is the amount provided when the forage contains ≥ 5 ppm. However, the amount of copper in the diet necessary to prevent copper deficiency is influenced by the intake of other dietary constituents, notably molybdenum (Mo), inorganic sulfate, and iron. High intake of molybdenum in the presence of adequate sulfate increases copper requirements. Because sheep are more susceptible than cattle to copper toxicity, care must be taken to avoid excessive copper intake (see p 3073). Toxicity may be produced in lambs being fed diets with $10–20$ ppm of copper, particularly if the Cu:Mo ratio is $>10:1$. The Cu:Mo ratio should be maintained between $5:1$ and $10:1$.

Selenium: Selenium is effective in at least partially controlling nutritional muscular dystrophy. Areas east of the Mississippi River and in the northwestern USA appear to be low in selenium. The dietary requirement is ~ 0.3 ppm. Providing selenium-containing mineral mixture may prevent selenium deficiency if animals are allowed

free access. Levels of $7–10$ ppm or higher may be toxic.

Zinc: Growing lambs require ~ 30 ppm of zinc in the diet on a dry-matter basis. The requirement for normal testicular development is somewhat higher. Classic zinc deficiency (parakeratosis) is more common in other small ruminants (goats), but is occasionally encountered in sheep, particularly if fed excessive quantities of dietary calcium (legumes).

Vitamins: Sheep diets usually contain an ample supply of vitamins A (provitamin A), D, and E. Under certain circumstances, however, supplements may be needed. The B vitamins and vitamin K are synthesized by the rumen microorganisms and, under practical conditions, supplements are unnecessary. However, polioencephalomalacia can be seen and is due to aberrations in ruminal thiamine metabolism, secondary to altered ruminal pH and/or microflora content. Vitamin C is synthesized in the tissues of sheep. On diets rich in carotene, such as high-quality pasture or green hays, sheep can store large quantities of vitamin A in the liver, often sufficient to meet their requirements for as long as 6 mo.

Vitamin D₂ is derived from sun-cured forage, and vitamin D₃ from exposure of the skin to ultraviolet light. When exposure of the skin to sunshine is reduced by prolonged cloudy weather or confinement rearing, and when the vitamin D₂ content of the diet is low, the amount supplied may be inadequate. The requirement for vitamin D is increased when the amounts of either calcium or phosphorus in the diet are low or when the ratio between them is wide. But such dietary modification should be done cautiously, because vitamin D toxicity is a severe syndrome. Fast-growing lambs kept in sheds away from direct sunlight or maintained on green feeds (high carotene) during the winter months (low irradiation) may have impaired bone formation and show other signs of vitamin D deficiency. Normally, sheep on pasture seldom need vitamin D supplements.

The major sources of vitamin E in the natural diet of sheep are green feeds and the germ of seeds. Because vitamin E is poorly stored in the body, a daily intake is needed. When ewes are being fed poor-quality hay or forage, supplemental vitamin E may result in improved production, lamb weaning weights, and colostrum quality. Vitamin E deficiency in young lambs may contribute to nutritional muscular dystrophy if selenium intake is low.

FEEDING PRACTICES

Feeding Farm Sheep

Sheep make excellent use of high-quality roughage stored either as hay or low-moisture, grass-legume silage or occasionally chopped green feed. Good-quality hay or stored forage is a highly productive feed; poor-quality forage, no matter how much is available, is suitable only for maintenance. Hay quality is determined primarily by the following: 1) its composition, eg, a mixture of grasses and legumes such as brome/alfalfa or bluegrass/clover; 2) the stage of maturity when cut, eg, the grass before heading and alfalfa before one-tenth bloom; 3) method and speed of harvesting because they affect loss of leaf, bleaching by sun, and leaching by rain; and 4) spoilage and loss during storage and feeding. In general, the same factors influence the quality of silage. Complete analysis of cut-stored forages enhances the utilization of these feedstuffs and allows for the most efficient use of supplemental grains and minerals.

Feeding Ewes

The period from weaning to breeding of ewes is critical if a high twinning rate is desired. Ewes should not be allowed to become excessively fat but should make daily gains from weaning to breeding. The rate of gain depends on the desired weight but should be ~60%–70% of projected mature weight at breeding and 80%–90%

of projected mature weight at lambing. If pasture production is inadequate, ewes may be confined and fed high-quality hay and a small amount of grain if necessary. Breeding while grazing legume pastures (eg, sage, white clovers) may tend to depress the size of the lamb crop, lowering the intake of certain feedstuffs. After mating, ewes can be maintained on pasture, thus allowing feed to be conserved for other times of the year. Good pasture for this period allows the ewes to enter the winter feeding period in good condition. When pasture is unavailable, an appropriate ration should be formulated (see TABLE 50).

During the last 6–8 wk of pregnancy, growth of the fetus is rapid. This is a critical period nutritionally, particularly for ewes carrying more than one fetus. Beginning 6–8 wk before lambing, the plane of nutrition should be increased gradually and continued without interruption until after lambing. The amount offered depends on the condition or fat covering of the ewes and quality of the forage. If ewes are in fair to good condition, 0.5–0.75 lb (225–350 g) daily is usually sufficient. The roughage content of the ration should provide all the protein required for all nonlactating ewes. If necessary, the ewes may be classified according to age, condition, and number of fetuses and divided into groups for different treatment.

Lactating Ewes: Succulent pasture furnishes adequate energy, protein, vitamins, and minerals for ewes and lambs;

TABLE 50 RATIONS FOR PREGNANT EWES UP TO 6 WK BEFORE LAMBING

Feed	Ration No.			
	1	2	3	4

TABLE 51 GRAIN MIXTURE FOR PREGNANT EWES

Feed	Mixture No.			
	1	2	3	4
	%	%	%	%
Whole barley, corn, or wheat	60	75	75	50
Whole oats	30	—	25	50
Beet pulp, dried	—	25	—	—
Wheat bran	10	—	—	—

no added grain is necessary. When pasture is not being used (confinement rearing), ewes should be fed one of the rations outlined for pregnant ewes in TABLE 50, and 1–1.5 lb (450–675 g) of one of the grain mixtures in TABLE 51. Ewes should have access to a mixture of trace mineralized salt and dicalcium phosphate. Ewes with twin or triplet lambs should be separated from those with single lambs and fed more concentrates (grain) and/or better-quality forages. Ewes nursing twin lambs produce 20%–40% more milk than those with singles. Under confinement rearing or accelerated lambing, lambs are commonly weaned at 2 mo of age. The ewe's milk production declines rapidly after this period, and creep feed is more efficiently converted into weight gains when fed to lambs than to the ewe.

Feeding Lambs

From ~2 wk of age, lambs should have free access to creep feed. Where pasture is limited, they should be creep-fed for 1–2 mo until adequate forages are available. If pasture will not be available until the lambs are 3–4 mo old, they can be finished in a dry lot. The grain used should be ground coarse or rolled, but as the feeding period progresses, whole grains may be used. Small amounts of fresh, clean grain should be slowly introduced to the lambs' diet. The amount of grain is increased gradually until the lambs are on full feed.

Feeding lambs from birth to market in a dry lot, together with early weaning at 2–3 mo of age, has become more popular throughout the USA. A complete diet of hay, grain, and vitamin-mineral supplement is ground, mixed, and either fed as is or pressed into pellets $\frac{1}{16}$ - or $\frac{3}{16}$ -in. (5–10 mm) long. Such lambs usually reach market weight in $3\frac{1}{2}$ –4 mo. See also TABLE 52 for examples of creep rations used in dry lot feeding.

Rearing Lambs on Milk Replacer:

Orphaned lambs, extras, triplets, or those from poor-milking ewes can be raised on milk replacers to improve productivity. Such lambs should receive 10%–20% of their body wt in colostrum divided into multiple feedings within 18–24 hr of birth. If ewe colostrum is unavailable, a frozen, pooled supply from several cows can be used. Milk replacers designed specifically for lambs are available and contain ~30% fat, 25% protein, and a high level of antibiotic. Under certain conditions, it may be advisable to inject orphaned lambs with vitamins A, D, and E and selenium. In handrearing systems, ewe milk replacers are preferable; however, good quality replacers designed for calves may be fed to lambs. When mixing milk replacers, care should be taken to ensure that the powder and water are properly mixed into a suspension. Feeding small quantities throughout numerous feedings helps reduce the incidence of bloat and/or diarrhea. Milk replacers should be fed at 10%–20% of the lamb's body wt, divided into 4–6 feedings/day during the first week of life. The number of feedings can be reduced over time to twice a day by 3–4 wk of age.

Multiple-nipple pails or containers can be used. Cold milk replacer can be used by older lambs who nurse more often. By 9–10 days of age, lambs should be given water in addition to the milk if a creep ration is offered. They can be weaned abruptly at 4–5 wk of age if consumption of creep feed and water intake is at a reasonable level.

Finishing Feeder Lambs: Lambs should be preconditioned before they leave the producer's property. This includes starting on feed, vaccinating, worming, and under some conditions, shearing. If this is not done, the lambs should be rested for several days and fed dry, average-quality hay after arrival at the feedlot. See also TABLE 53 for some recommended formulas for finishing lambs.

TABLE 52 CREEP RATIONS FOR SUCKLING AND EARLY-WEANED LAMBS

Feed	Mixture No.			
	1	2	3	4
	%	%	%	%

Antibiotic	—	—	0.002	0.002

There is no best method or diet for finishing lambs. They may be finished on good to excellent quality forage (alfalfa, wheat) with no supplemental grain. They

may be started on pasture or crop residue and moved to grain feeding systems as the forage is used up. When fed in a dry lot, they are usually allowed free access to feed-

TABLE 53 RECOMMENDED FORMULAS FOR FINISHING LAMBS^a

Feed	Starter 10-day Period		High Roughage		High Concentrate	Corn Silage
	Loose	Pelleted	Loose	Pelleted		
Grain (corn, barley, or milo) ^b	500	200	780	400	1,500	540
Alfalfa hay	1,280	1,700	1,000	1,400	200	
Molasses	100	100	100			
Oilseed meal	100		100			100
Urea					45	
Beet pulp			200	200		
Silage						1,350
Limestone	10				35	10
Trace mineralized salt	10		20	20	35	
Antibiotic (g)	50	20	20	10	20	10
Vitamin A (IU/ton)						1,000,000

^a Lb/ton or kg/metric ton; feeder lambs should have ~14% crude protein in rations (dry basis).

^b Wheat can be substituted for other grains, but a period of time should be allowed for adaptation.

stuffs. These diets may be completely pelleted, ground and mixed, a mixture of ground forage (alfalfa) pellets and grain, and/or high-concentrate type. Self-feeding usually results in maximal feed intake and gain, and labor costs may be reduced. Hand-feeding can be mechanized with an auger system or self-unloading wagon. It involves feeding at regular intervals so that the lambs consume all the feed before more feed is offered. Feed consumption and gain can be controlled. When used, corn silage should be hand-fed to minimize spoilage.

Producers who feed lambs year-round, or feed heavy lambs, usually prefer to place the lambs on full feed as soon as possible (10–14 days). Lambs can be started safely on self-fed, ground, or pelleted diets containing 60%–70% hay. Within 2 wk, the hay can be reduced to 30%–40% when the ration is not pelleted. Other roughages such as cottonseed hulls or silage can be used in a similar manner.

Corn, sorghum, or alfalfa silage can replace about half the hay with hand-feeding, but finish and yield will be decreased to some extent. *See also* TABLE 52 for rations that can be used in self-feeding. Corn, barley, milo, wheat, or a mixture of these are used; 0.5% salt and 0.5% bone meal or equivalent should be added to the grain. Pelleting of rations for finishing lambs is beneficial when low-grade roughages or high-roughage rations are used. Caution should be used when feeding large amounts of wheat; lambs not adapted to it are more apt to develop acute indigestion than if fed grains such as corn, sorghum, or barley.

Mineral supplements, including salt, should be offered separately whether or not they are included in the grain mixture. Approved growth stimulants usually increase growth rate 10%–15% and feed efficiency 8%–10% but may decrease carcass quality.

Feeding Mature Breeding Rams

Mature breeding rams should be grazed on pasture when available, or fed rations 1, 2, or 3 according to TABLE 50. If rams are in a thrifty condition at breeding time and the ewes are on a good flushing pasture, it should not be necessary to grain-feed the rams while with the ewes. Rams should be maintained at a good body condition (3–3.5 on a 1–5 scale) before the breeding season.

Feeding Range Sheep

The condition of the sheep, the amount and kind of forage on the range, and the climatic conditions determine the kind and amount of supplement to feed. Supplements usually

consist of high-protein pellets or cottonseed meal and salt, medium-protein pellets, low-protein pellets or corn, alfalfa hay, and minerals. When the diets of sheep on the western winter range are supplemented properly, the lamb crop can be increased 10%–15% and wool production increased by ~1 lb (400–500 g) per ewe.

One recommended practice is to feed ~0.25 lb (115 g) of high-protein (36%) supplement or 0.33–0.5 lb (150–225 g) of medium-protein (24%) pellets ~3 wk before and during the breeding season, during extremely cold weather, and for ~1 mo before green feed starts in the spring. In addition, small lambs, small yearling ewes, old ewes with poor teeth, and thin ewes should be separated from the main flock and fed one of the above supplements from approximately December 1 (northern hemisphere) until shearing time. In many instances, the old ewes, lambs, and yearlings from more than one band can be maintained in a flock for special dietary supplementation.

When sheep are unable to obtain a full ration of forage because of deep snow or other weather conditions, 1–3 lb (450–1,350 g) of alfalfa hay and 0.2–0.3 lb (90–150 g) of a low-protein pellet mixture or corn should be fed (*see* TABLE 54). If alfalfa hay is not available, 0.5–1 lb (225–450 g) per head of a low-protein pellet mixture should be fed daily for emergency feeding periods.

Deficiencies of Range Forages: Deficiencies most apt to be seen among range forages are protein, energy, salt, and phosphorus. These are most prevalent as the forages approach maturity or are dormant, and they may appear singly or in combination. Range sheep often travel long distances and are exposed to cold weather, resulting in higher energy requirements. Protein supplements (soybean or cottonseed meal, alfalfa pellets, etc) increase digestibility and use of poor-quality forages. When possible, the inclusion of a phosphorus supplement (eg, dicalcium phosphate, monocalcium phosphate, defluorinated rock phosphate) to a salt or trace mineral salt mixture may greatly improve productivity.

Most ranges used for winter grazing are considered adequate in carotene, because many species of browse furnish as much carotene as sun-cured alfalfa hay. However, when sheep are required to graze dry grass ranges for >6 mo without intermittent periods of green feed, vitamin A supplements are recommended. The addition of 45–50 IU of vitamin A/kg/day improves

TABLE 54 PATTERN FOR RANGE SUPPLEMENTS FOR SHEEP

productivity in cases of extended consumption (>2 mo) of dry or weathered forages.

Mineral Mixtures: On the range, portable mineral boxes are convenient for sheep. One of these mineral mixtures should be fed free choice. A salt and dicalcium phosphate or phosphorus supplement (defluorinated rock phosphate) can be used if there are no iodine or trace-mineral deficiencies. Iodized salt is substituted for regular salt when an iodine deficiency exists, and trace mineralized salt is substituted if deficiencies of trace minerals are present.

Under winter range conditions, the amount of phosphorus supplement that should be added to range pellets varies with the type of range forage available, the rate of feeding, and the ingredients used in the pellets. It is suggested that 36%, 24%, and 12% protein pellets contain 1.5%, 1%, and 0.5% phosphorus, respectively. When feeding supplemental protein, 36% protein pellets should be fed at the rate of 0.25 lb (115 g) per head daily, the 24% protein pellets at 0.33–0.5 lb (150–225 g), and the 12% protein pellets at 0.2–0.5 lb (90–225 g), together with alfalfa or clover hay. Care should be taken when adding supplemental phosphorus and magnesium to the diet of rams or wethers, because this is associated with urolithiasis.

NUTRITIONAL DISEASES

Nutritional diseases in sheep are for the most part the same as those seen in goats (*see* NUTRITION: GOATS, p 2308).

Enterotoxemia: This feed-related malady causes almost sudden death in sheep due to a toxin produced by *Clostridium perfringens* type D and sometimes type C. The organism appears to be widespread in nature. Under conditions of high carbohydrate consumption or high intake of immature succulent forage, the causative bacteria multiply rapidly and produce an ϵ toxin that increases intestinal permeability. Protection of lambs is possible by vaccinating twice at least 10 days apart with *C perfringens* type D toxoid or by administering antitoxin at birth. (*See also* ENTEROTOXEMIAS, p 609.)

White Muscle Disease: White muscle disease is caused by low levels of selenium and possibly vitamin E. Signs include stiffness (especially in the hindquarters), tucked-up rear flanks, arched backs, pneumonia, and acute death. On necropsy, white striations are found in cardiac, diaphragmatic, and skeletal muscles. Levels of AST and lactic dehydrogenase are increased, indicating muscle damage. Blood levels of the selenium-containing glutathione peroxidase are reduced. Although several feedstuffs are fairly rich in selenium and vitamin E, it may be a good management practice in deficient areas to inject lambs shortly after birth with a preparation of vitamin E and selenium designed for parenteral use. The use of a selenium and/or vitamin E supplemented trace mineral mixture (up to 90 ppm) as the only source of salt fed may be useful as a preventive measure. (*See also* NUTRITIONAL MYOPATHIES IN RUMINANTS AND PIGS, p 1172.)

NUTRITION: SMALL ANIMALS

Domestic dogs and cats are both members of the order Carnivora. Observations of feral canids indicate that their feeding habits are broad and include various parts of plants as well as both small and large prey. By comparison, cats do not show omnivorous feeding behaviors and have a requirement for specific animal-derived sources of nutrients, such as preformed vitamin A, arachidonic acid, and taurine. As a result, dogs are classified nutritionally as omnivores, while cats are classified as true carnivores.

Using appropriate feeding practices is one of the most important components of maintaining companion animal health. Nutritional management is also important as an integral part of both preventive health care and treatment protocols for medical and surgical patients, and ignoring nutritional needs can often be more detrimental to a dog or cat than the illness or injury for which it is being treated. Feeding an appropriately formulated and tested complete and balanced commercial diet is the simplest way to meet the nutritional requirements of dogs or cats. Numerous products are available, and many are formulated for specific life stages. However, dogs and cats can thrive eating a variety of commercial or appropriately formulated home-prepared foods.

Despite the wide availability of commercially complete and balanced diets for dogs and cats, malnutrition still occurs. Malnutrition is defined as an imbalance of nutrients and includes both nutrient deficiencies and nutrient excesses. In recent years, obesity has become the most common nutritional disorder encountered in small animal medicine. Obesity is a serious medical condition that can lead to a variety of related health problems as well as shortened life span.

Body weight in combination with body condition score (BCS) is used in many species to provide an estimate of nutritional adequacy and can help determine ideal body weight. BCS is a semiquantitative assessment of body composition that ranges from cachectic to severely obese. Physical examination, visual observation, and palpation are used to assign a BCS.

Two BCS systems exist for dogs and cats, a 5-point system and a 9-point system (see TABLE 55). In a 9-point system, each unit increase in BCS above ideal represents body weight ~10%–15% greater than ideal body weight. For example, a dog or cat with a BCS of 7 is approximately 20%–30% heavier than its ideal weight.

Parameters used to assess BCS include evaluation of fat cover over the ribs, down the topline (waist), around the tailbase, and ventrally along the abdomen (abdominal tuck in front of hind legs). It is important to use both a visual assessment and palpation to assign a BCS (see TABLE 56).

NUTRITIONAL REQUIREMENTS AND RELATED DISEASES

Dogs are a biologically diverse species, with normal body weight of 4–80 kg (2–175 lb). Normal birth weight of pups depends on breed type (120–550 g). The first 2 wk of a puppy's life is spent eating, seeking warmth, and sleeping. External food sources beyond bitch's milk are rarely needed, unless the bitch cannot produce enough milk or the puppy is orphaned. In these cases, the puppy must be handreared. Growth rates of puppies are rapid for the first 5 mo; in this period, pups gain an average of 2–4 g/day/kg of their anticipated adult weight. The growth rate begins to plateau after 6 mo, and growth may be completed by 8–12 mo.

TABLE 55 BODY CONDITION SCORE SCALES^a FOR DOGS AND CATS

Body Condition	5-Point Scale	9-Point Scale
Very thin	1	1
Ideal weight	3	4–5 (dogs); 5 (cats)
Obese	5	9

^a The scale used should be noted in the record (eg, BCS = 4/5 or BCS = 4/9).

TABLE 56 PARAMETERS USED TO ASSESS BODY CONDITION SCORE

Body Condition	Ribs	Overhead View	Side View	Tail Base
Very thin	Ribs easily felt with no fat cover; prominent visibility of individual ribs in dogs with short hair coats	Accentuated hourglass shape	Severe abdominal tuck	Bones are raised with no tissue between the skin and bone
Ideal	Ribs easily felt with slight fat cover; individual ribs not visible	Lumbar waist well-proportioned	Abdominal tuck present	Smooth contour but bones can be felt under a thin layer of fat
Obese	Ribs difficult to feel under thick fat cover	Lumbar waist not visible	No abdominal tuck; fat hangs from abdomen	Thickened and difficult to feel under prominent layer of fat; dimple may be visible at tail base

of age in small and medium breeds and by 10–16 mo in large and giant breeds.

By comparison, the average mature body weight of domestic cats is 3.2 kg (7 lb) for toms and 2.8 kg (6 lb) for queens. Normal birth weight of kittens is 90–100 g. The growth rate is exceptionally rapid for the first 3–4 mo, and kittens gain 50–100 g/wk. The growth rate begins to plateau at 150–160 days of age, and growth is usually completed within 200–220 days.

Dogs and cats require specific dietary nutrient concentrations based on their life stage. The Association of American Feed Control Officials (AAFCO) publishes dog and cat nutrient profiles for adult maintenance and reproduction (*see* TABLES 57 and 58). The National Research Council (NRC) also publishes nutrient profiles for dogs and cats for various life stages, most recently in 2006 (*see* TABLES 59 and 60). Both AAFCO and NRC list minimum nutrient requirements and maximum nutrient requirements for nutrients with potential toxicity.

In developed countries, nutritional diseases are rarely seen in dogs and cats, especially when they are fed good quality, commercial, complete and balanced diets. Nutritional problems occur most commonly when dogs and cats are fed imbalanced homemade diets, when cats are fed diets formulated for dogs, or when dogs or cats are fed certain human foods. Dog or cat foods or homemade diets derived from a single food item are inadequate. For example, feeding predominantly meat or even an exclusive

hamburger and rice diet to dogs or cats can induce calcium deficiency and secondary hyperparathyroidism. Raw, freshwater fish contain thiamine antagonists and can induce thiamine deficiency when fed to cats. Feeding liver can induce vitamin A toxicity in both dogs and cats.

Cats have some dietary requirements that are different from those of dogs and can develop nutritional deficiencies when fed diets formulated to meet the nutritional needs of dogs. For example, unlike dogs, cats require dietary sources of vitamin A, arachidonic acid, and taurine. Cats also require higher quantities of fat and protein than dogs, as well as of the amino acid arginine and the vitamins niacin and pyridoxine (vitamin B₆). Cats lack the enzyme glucokinase, which unfortunately has led some to believe that cats cannot digest dietary carbohydrates. Cats produce the enzyme hexokinase, which allows them to digest and use properly processed dietary carbohydrates.

Well-intentioned owners occasionally cause problems by feeding dogs and cats certain human foods. For example, raisins and grapes contain an unknown substance that is toxic to dogs and can cause kidney damage. Chocolate contains theobromine and much smaller amounts of caffeine, both of which are methylxanthines. Dogs and cats metabolize theobromine much more slowly than people. Initial signs of toxicity include GI signs, such as vomiting and diarrhea. This can progress to polyuria, muscle tremors, cardiac arrhythmias,

seizures, and death. Macadamia nuts are also potentially toxic to dogs and cats and can cause weakness, depression, vomiting, ataxia, muscle tremors, hyperthermia, and tachycardia. As few as six macadamia nuts can be toxic to dogs. Onions and garlic contain thiosulfate, which can cause oxidative damage to RBCs and result in anemia. Onions are more toxic than garlic. Guatemalan avocados contain a substance

called persin, which can cause dyspnea, pulmonary edema, and pleural and pericardial effusion in goats and possibly dogs. Food high in fat, such as chicken skin, can result in some dogs developing pancreatitis. Broccoli toxicity has been reported to occur in dairy cattle, but it is a poorly documented problem in dogs and cats. Sugar free foods containing xylitol can cause liver damage in dogs. Raw food diets

^c Kittens can alternatively be fed free choice

(see p 2375) are also not recommended for dogs and cats. Raw meat products may contain pathogens. (See also FOOD HAZARDS, p 2964.)

Nutrient deficiencies have also been seen in dogs and cats fed “natural,” “organic,” or “vegetarian” diets produced by owners with good intentions. Many published recipes have been only crudely balanced by computer, if at all, using nutrient averages. In addition, most homemade diets do not undergo the scrutiny and rigorous testing applied to commercial complete and balanced diets. If pet owners wish to feed their pets homemade diets, the diets should be prepared and cooked using recipes formulated by a veterinary nutritionist.

Some nutritional diseases are seen secondary to other pathologic conditions or anorexia, or both. Owner neglect is also a frequent contributing factor in malnutrition.

Energy: The most useful measure of energy for nutritional purposes is metabolizable energy (ME), which is defined as that portion of the total energy of a diet that is retained within the body. It is typically measured in calories or joules. The caloric content of pet foods is usually expressed in kilocalories (kcal), which is 1,000 calories. Dogs and cats require sufficient energy to

allow for optimal use of proteins and to maintain optimal body weight and condition through growth, maintenance, activity, pregnancy, and lactation.

Energy requirements for dogs and cats are not a linear function of body weight. Recent evidence indicates that dogs maintained in households require fewer calories per day than dogs kept in kennels, but considerable variability exists. Breed differences also affect caloric needs independent of body size, eg, Newfoundlands appear to require fewer calories/day than Great Danes. Other factors that determine daily energy needs include activity level, life stage, percent lean body mass, age, and environment. Even when specific formulas are used, any given animal may require as much as 30% more or less of the calculated amount. Consequently, general recommendations may need to be modified within this 30% range, and body condition scoring should be regularly performed.

The precise ME values for many dog food ingredients have not been experimentally determined and are often estimated using those for other monogastric species (such as pigs) or calculated using Atwater physiologic fuel values modified for use with typical dog food ingredients. Likewise,

the precise ME values for many cats are not known, although it is believed that the factors used for dogs may apply. The modified Atwater ME values for dogs are 3.5 kcal/g for carbohydrate and protein and 8.5 kcal/g of fat. The impact of various environmental temperatures is described in the recent NRC publication on nutrient requirements of dogs and cats and has been documented under certain conditions. For example, energy requirements increased from 120 to 205 kcal/kg^{0.75} in Huskies as ambient temperatures decreased from 14°C in summer to -20°C in winter. Effects of environmental temperature are not well characterized in cats, because most of the research was done under thermoneutral (68°–72°F [20°–22°C]) conditions. However, unacclimatized adult cats increased their daily caloric intakes nearly 2-fold when environmental temperatures of 23°C and 0°C were studied.

Caloric Requirements: Energy requirements are quite variable among dogs and cats. Animals with the same body weight can have 3-fold variation in daily kcal requirements, which are affected by age, neutering status, physiologic status (growth, gestation, lactation, etc), physical activity, environmental temperature, and any underlying abnormalities. Any recommendations for kcal requirements are only starting points and may need to be modified based on the response of the individual dog or cat.

Many formulas are available to calculate caloric requirements for dogs and cats. A simple method for healthy dogs and cats starts with calculating the resting energy requirement (RER). The RER is the energy requirement for a healthy but fed animal, at rest in a thermoneutral environment. It includes energy expended for recovery from physical activity and feeding. There is an exponential and a linear formula for calculating RER. The exponential formula ($RER = 70 \text{ [body wt in kg}^{0.75}]$) can be used for animals of any body weight, whereas the linear formula ($RER = 30 \times [\text{body wt in kg}] + 70$) is restricted for use in animals that weigh >2 kg and <45 kg.

The maintenance energy requirement (MER) is the energy requirement of a moderately active animal in a thermoneutral environment. It includes energy needed to obtain, digest, and absorb food in amounts to maintain body weight, as well as energy for spontaneous activity. The formulas to calculate MER take into account age and neuter status.

Formulas for daily maintenance energy requirements (kcal/day) are listed in TABLE 63.

Nutrient Classifications

The six classes of nutrients are water, protein, fat, carbohydrates, vitamins, and minerals. Only protein, fat, and carbohydrate provide energy; vitamins, minerals, and water do not.

Water: Water is the most important nutrient; a lack of water can lead to death in a matter of days. Clean, fresh water should be available at all times. Multiple water sources encourage consumption. This is particularly important in cats, which often do not drink a lot of water.

Several approaches have been used to estimate daily water needs. There are general guidelines for daily fluid requirements in dogs and cats, but individual variations exist. The quantity of water required depends on a number of different factors, including the animal's diet, environment, activity level, and health status. The moisture content of canned pet foods varies from 60% to >87%. Dry pet foods contain 3%–11% water, and semimoist foods contain 25%–35% water. As a result, dogs and cats consuming predominantly canned food generally drink less water than those consuming predominantly dry diets.

In a thermoneutral environment, most mammalian species need ~44–66 mL/kg body wt. Another approach considers that water needs appear to be highly associated with the amount of food consumed. In this case, daily maintenance fluid requirements in mL should equal the animal's MER in kcal of ME. A third technique sets daily water intake as 2–3 times the dietary dry matter intake. When provided ample amounts of water, healthy animals can effectively self-regulate their intake. Water deficiency can be seen as a result of poor husbandry or disease. Dehydration is a serious problem in many different disorders, including those of the GI, respiratory, and urinary systems.

Protein: Protein is required to increase and renew the nitrogenous components of the body. A primary function of dietary protein is as a source of essential amino acids and nitrogen for the synthesis of nonessential amino acids. Amino acids supply both nitrogen for the synthesis of all other nitrogenous compounds and energy when catabolized. Ten amino acids are essential in the diet of dogs: arginine, histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. Cats have a dietary requirement for an additional amino acid, taurine. Other nonessential amino acids may become

conditionally essential when an animal has an underlying disorder that either interferes with synthesis of the amino acid or results in its excessive consumption or loss.

Protein requirements of dogs and cats vary with age, activity level, temperament, life stage, health status, and protein quality of the diet. Most commercial dog foods contain a combination of plant- and animal-based proteins, with protein digestibilities of 75%–90%. Digestibility is less for plant protein ingredients, protein of poor biologic value, and for poor-quality diets. If excessive heat is used in processing, proteins can become chemically unavailable for digestion and absorption; however, these are not the types of temperatures typically used to produce commercial pet foods.

Healthy adult dogs need a minimum of 2.62 g of protein of high biologic value per kg metabolic body wt (ie, $BW_{\text{kg}}^{0.75}$)/day (NRC guidelines). Healthy puppies 4–14 wk old and >14 wk old need a minimum of 9.7 g and 12.5 g of protein of high biologic value per kg metabolic body wt/day, respectively. The cat has a higher protein requirement than most species, and healthy adult cats need a minimum of 3.97 g of protein of high biologic value per kg metabolic body wt/day. Healthy kittens need a minimum of 9.4 g of protein of high biologic value per kg metabolic body wt/day. The biologic value of a protein is related to the number and types of essential amino acids it contains and to its digestibility and metabolizability. The higher the biologic value of a protein, the less protein is needed in the diet to supply the essential amino acid requirements. Egg has been given the highest biologic value, and organ and skeletal meats have a higher biologic value than plant-based proteins.

General guidelines for dietary protein requirements in dogs and cats exist, but requirements vary depending on the digestibility of the protein in the diet. If an animal is consuming a diet containing predominantly plant protein sources, protein requirements may be higher than if the animal is consuming a diet containing predominantly animal protein sources. The dietary requirement for protein in healthy adult dogs is satisfied when the dog's metabolic need for amino acids and nitrogen is satisfied. Optimal diets for growing puppies should contain a minimum of 22% protein as dry matter (AAFCO guidelines) or 45 g protein/1,000 kcal ME for puppies 4–14 wk old and 35 g protein/1,000 kcal ME for puppies >14 wk old (NRC guidelines). Adult dogs require a minimum of 18%

protein as dry matter (AAFCO guidelines) or ~20 g protein/1,000 kcal of ME required (NRC guidelines).

Optimal diets for growing kittens should contain at least 24%–28% ME as protein or 30% protein as dry matter (AAFCO guidelines) or 45 g protein/1,000 kcal ME (NRC guidelines). Optimal diets for adult cats should contain ~20% ME as protein or 26% protein as dry matter (AAFCO guidelines) or 40 g protein/1,000 kcal ME (NRC guidelines). Growing kittens are more sensitive to the quality of dietary protein and amino acid balance than are adult cats. Protein suitable for cats must supply >500 mg of taurine/kg diet dry matter. Unless synthetic essential amino acids are added, some animal protein is necessary in the diet to prevent taurine depletion and development of feline central retinal degeneration or dilated cardiomyopathy.

Without sufficient energy from dietary fat or carbohydrate, dietary protein ordinarily used for growth or maintenance of body functions is less efficiently converted to energy. Too little high biologic protein in the diet, relative to the energy density, can cause an apparent protein deficiency.

Signs produced by protein deficiency or an improper protein:calorie ratio may include any or all of the following: reduced growth rates in puppies and kittens, anemia, weight loss, skeletal muscle atrophy, dull unkempt hair coat, anorexia, reproductive problems, persistent unresponsive parasitism or low-grade microbial infection, impaired protection via vaccination, rapid weight loss after injury or during disease, and failure to respond properly to treatment of injury or disease. High protein intakes per se do not cause skeletal abnormalities in dogs (including osteochondrosis in large breeds) or renal insufficiency later in life in dogs or cats.

Fats: Dietary fat consists mainly of triglyceride with varying amounts of free fatty acids and glycerol. Lipids can either be simple (triglycerides, wax) or complex (containing many other elements).

Triglycerides are divided into short, medium, and long chain based on the number of carbon atoms in the fatty acid chain. Essential fatty acids are long-chain fatty acids that cannot be synthesized in the body; most fatty acids consumed in the diet are long-chain fatty acids. Most nutrients consumed are digested and absorbed in the small intestines, where they then enter the blood supply via the portal vein and are delivered to the liver. When long-chain fatty acids are consumed, they are digested and

absorbed into the small-intestinal epithelial cells; however, they are not transported directly into the blood supply but rather enter the lymphatics first. There are conflicting studies regarding the fate of dietary medium-chain fatty acids. Most studies suggest that medium-chain fatty acids do not require initial transport in the lymphatics and instead can be absorbed from the intestines directly into the blood supply via the portal vein.

Fatty acids are either saturated, indicating there are no double bonds, or unsaturated, indicating there are one or more double bonds. Fatty acids that contain more than one double bond are called polyunsaturated fatty acids (PUFA). PUFA are designated as either omega-3, omega-6, or omega-9 fatty acids, depending on the location of the first double bond. The more double bonds a fatty acid contains, the more prone it is to rancidity if not properly preserved. Saturated fatty acids are used primarily for energy in the body, whereas unsaturated fatty acids are found in cell membranes and blood lipoproteins.

Dietary fatty acid profiles are reflected in the fatty acid composition of tissues and cell membranes. In general, as the fat content of a diet increases, so does the caloric density and palatability, which promotes excess calorie consumption and obesity. Fat is a concentrated source of energy, yielding ~2.25 times the ME (as an equal dry-weight portion) of soluble carbohydrate or protein. The addition of too much dietary fat relative to other nutrients may result in excessive energy intake and subsequent suboptimal intakes of protein, minerals, and vitamins.

Dietary fats also facilitate the absorption, storage, and transport of the fat-soluble vitamins (A, D, E, and K). They are also a source of essential fatty acids (EFA), which maintain functional integrity of cell membranes and are precursors of prostaglandins and leukotrienes.

Dietary fats, especially the unsaturated variety, require a protective (natural or synthetic preservatives) antioxidant system. If antioxidant protection from a natural preservative system (eg, vitamin C or mixed tocopherols) or from synthetic preservatives (eg, BHA, BHT, ethoxyquin) in the diet is insufficient, dietary and body polyunsaturated fats become oxidized and lead to steatitis. Rancid fats in the diet can also result in fat-soluble vitamin deficiency.

Dietary fat requirements vary with age and species. Optimal diets for growing puppies should contain a minimum 8% fat as dry matter (AAFCO guidelines) or 5.9 g of fat per kg metabolic body wt/day (NRC

guidelines) or 21.3 g fat/1,000 kcal ME (NRC guidelines). Optimal diets for adult dogs should contain a minimum 5% fat as dry matter (AAFCO guidelines) or 1.3 g of fat per kg metabolic body wt/day (NRC guidelines) or 10 g fat/1,000 kcal ME (NRC guidelines). Optimal diets for growing kittens and adult cats should contain a minimum 9% fat as dry matter (AAFCO guidelines), 4.7 g of fat per kg metabolic body wt/day for kittens, 4.7 g of fat per kg metabolic body wt/day for adult cats (NRC guidelines), or 22.5 g fat/1,000 kcal ME for growing kittens and adult cats (NRC guidelines).

Dogs and cats have a dietary requirement for specific EFA, including linoleic acid, an unsaturated EFA found in appreciable amounts in corn and soy oil. Cats also have a dietary requirement for another unsaturated EFA, arachidonic acid. Unlike dogs, cats cannot readily convert linoleic to arachidonic acid, which must be obtained from animal sources. Recommendations for dietary intake of both linoleic acid and arachidonic acid are ~5 g and 0.2 g/kg diet, respectively, for kittens and adult cats. Both linoleic acid and arachidonic acid are omega-6 fatty acids.

Recent studies suggest that α -linolenic acid (an omega-3 fatty acid) is also essential in dogs and possibly in cats. This omega-3 fatty acid is found primarily in flaxseed oils. The amount of dietary α -linolenic acid needed likely depends on the linoleic acid content. Although the required amounts of this omega-3 fatty acid are presently unknown, current minimal recommendations include 0.8 g/kg diet of α -linoleic acid when linoleic acid is 13 g/kg diet (dry-matter basis) for puppies and 0.44 g/kg diet of α -linoleic acid when linoleic acid is 11 g/kg diet (dry-matter basis) for adults. In addition, the longer chain omega-3 fatty acid, docosahexaenoic acid (DHA), may be conditionally essential for normal neurologic growth and development of puppies and kittens. Puppies fed diets containing DHA perform better in learning experiments and are easier to train than puppies fed diets without DHA. Eicosapentaenoic acid (EPA) is another longer chain omega-3 fatty acid that has been shown to be beneficial in the diet for treatment of certain skin, renal, and GI conditions, as well as cancer, arthritis, and hyperlipidemia. These longer chain omega-3 fatty acids are found primarily in marine sources of lipids. Very little α -linolenic acid gets converted to DHA/EPA in dogs and cats. Therefore, when choosing omega-3 fatty acids to treat certain

medical conditions, it is best to choose marine sources. NRC recommends a level of 0.025 g/1,000 kcal ME of a combination of DHA and EPA for both kittens and adult cats. NRC recommends levels of DHA and EPA in the diet of 0.13 g/1,000 kcal ME for puppies and 0.11 g/1,000 kcal ME for adult dogs.

Most commercial adult dog foods typically contain 5%–15% fat (dry-matter basis). Puppy diets usually contain 8%–20% fat (dry-matter basis). One reason for this wide range of fat content is the purpose of the diet; work, stress, growth, and lactation require higher levels than maintenance. As much as 60% of the calories in a cat's diet may come from fat, although diets that contain 8%–40% fat (dry-matter basis) have also been fed successfully. Because fat can add considerably more calories to a finished diet, the amount of protein relative to energy must be balanced appropriately to the life stage and typical intakes expected for an animal's size and needs.

EFA deficiencies are extremely rare in dogs and cats fed properly preserved complete and balanced diets formulated according to AAFCO profiles. Deficiencies of EFA induce one or several signs, such as a dry, scaly, lusterless coat; inactivity; or reproductive disorders such as anestrus, testicular underdevelopment, or lack of libido. Fatty acid supplements are often recommended for dogs with dry, flaky skin and dull coats, but underlying metabolic conditions should always be evaluated first.

Carbohydrates and Crude Fiber:

Carbohydrates in pet foods include low- and high-molecular-weight sugars, starches, and various cell wall and storage nonstarch polysaccharides or dietary fibers. The four carbohydrate groups functionally are absorbable (eg, monosaccharides such as glucose, galactose, and fructose), digestible (eg, disaccharides, some oligosaccharides), fermentable (eg, lactose, some oligosaccharides), and poorly fermentable (eg, fibers such as cellulose, which is an insoluble fiber).

Although there is no minimum dietary requirement for simple carbohydrates or starches for dogs and cats, certain tissues, such as the brain and RBCs, require glucose for energy. If inadequate amounts of dietary carbohydrates are available, the body will synthesize glucose from glucogenic amino acids and glycerol. Cats normally use glucogenic amino acids and glycerol to synthesize glucose, which is one reason why cats are classified as true carnivores. However, dogs usually synthesize glucose

from dietary carbohydrates. The use of dietary protein to synthesize energy in dogs diverts amino acids away from functions such as synthesis of nonessential amino acids and building muscle. Carbohydrates can become conditionally essential when energy needs are high, such as during growth, gestation, and lactation. Different carbohydrate sources have varying physiologic effects. In cats, carbohydrates apparently are not essential in the diet when ample protein and fats supply glucogenic amino acids and glycerol. However, properly cooked nonfibrous carbohydrates are utilized well by both cats and dogs. In both dogs and cats, if starches are not cooked, they are poorly digested and may result in flatulence or diarrhea. Except for the occasional case of lactose or sucrose intolerance, most cooked carbohydrates are well tolerated in both dogs and cats.

Fiber: Fiber is defined as the edible parts of plants or analogous carbohydrates that are resistant to digestion and absorption in the small intestine and have complete or partial fermentation in the large intestine. Although there is no dietary requirement for fiber in dogs and cats, there are health benefits of having certain fiber sources in the diet. Fiber is resistant to hydrolysis by mammalian digestive secretions but is not an inert traveler through the GI tract. Increased levels of fiber in diets increase fecal output, normalize transit time, alter colonic microflora and fermentation patterns, alter glucose absorption and insulin kinetics, and, at high levels, can depress diet digestibility.

The diverse nature of fiber has led to numerous classification methods. One way fiber is classified is based on its solubility. Soluble fibers have greater water-holding capacity than insoluble fibers. Fiber sources such as beet pulp, cellulose, and rice bran have low solubilities, while gum arabic, methylcellulose, and inulin have high solubility. Psyllium contains both low-soluble and high-soluble fiber. Although the classification of fiber based on its solubility is still used, fiber is better classified based on its rate of fermentability. Fermentation is defined as the capacity of fiber breakdown by intestinal bacteria, and this definition more accurately assesses the potential benefits of fiber in the GI tract. Fermentation of fiber produces the short-chain fatty acids acetate, propionate, and butyrate. Short-chain fatty acids have numerous benefits, including supplying energy to the large-intestinal epithelial cells, stimulating intestinal sodium and water absorption, and

lowering the pH in the large intestines—an environment that favors survival of beneficial bacteria in the GI tract.

Conversely, fermentation also produces less desirable substances such as gases, ammonia, and phenols. Highly fermentable fibers are rapidly metabolized by intestinal bacteria and produce large amounts of gas that can result in cramping and diarrhea. Production of less desirable fermentation products can be minimized by using a moderately fermentable fiber source; examples include beet pulp, inulin, and psyllium. Beet pulp provides good fecal quality in dogs without affecting other nutrient digestibility when included at ≤7.5% (dry-matter basis).

Dietary fermentable fiber also functions as a prebiotic in dogs and cats. Prebiotics are defined as nondigestible food ingredients that selectively stimulate the growth or activity of beneficial bacteria in the intestines, such as *Bifidobacterium* and *Lactobacillus*. They also inhibit the survival and colonization of pathogenic bacteria. The beneficial bacteria produce short-chain fatty acids and some nutrients (eg, some B vitamins and vitamin K). Beneficial bacteria also function as immunomodulators and reduce liver toxins (eg, blood amine and ammonia).

Dietary fructooligosaccharides (FOS) and mannanoligosaccharides (MOS) also promote the survival and growth of beneficial bacteria in the GI tract. FOS are nondigestible oligosaccharides consisting of chains of fructose molecules. Dietary sources of FOS include beet pulp, psyllium, and chicory. Beneficial bacteria are able to use FOS as a metabolic fuel, whereas pathogenic bacteria cannot. FOS also enhance the effectiveness of the GI immune system. MOS are similar to FOS, except the predominant sugar molecule in MOS is mannose instead of fructose. Dietary sources of MOS include natural fibers found in yeast cells. MOS use a different mechanism than FOS to inhibit the growth of harmful bacteria. Pathogenic bacteria attach to the intestinal wall using finger-like projections called fimbriae. Fimbriae bind to specific mannose residues on intestinal cells. Fimbriated mannose-specific pathogens can also bind to MOS instead of adhering to the intestinal epithelium, and harmful bacteria are then excreted in the feces.

Several chemical methods are used to determine the fiber level of a food; all extract the components of fiber to different degrees, which results in different estimates of fiber level for the same feedstuff. Crude

fiber, which is what is listed on pet food labels, quantifies insoluble dietary fiber, which is primarily cellulose, some lignin, and a small amount of hemicellulose. However, it does not measure a large portion of insoluble dietary fiber, nor any of the soluble dietary fiber. Therefore, crude fiber is not an accurate measure of total dietary fiber. The physiologic effects of fiber are not uniform across all fiber types, and relying solely on fiber content listed on pet food labels does not accurately reflect either fiber content and fiber types in commercial pet foods, or the physiologic effects from a diet.

Vitamins: Most commercial dog and cat foods are fortified with vitamins to levels that exceed minimal requirements. There is no AAFCO dietary requirement for vitamin C for dogs and cats, because they are able to synthesize it in the liver. Although dogs and cats can synthesize vitamin C in levels sufficient to prevent signs of deficiency, supplementation may provide additional health benefits because vitamin C functions as a free radical scavenger and an antioxidant in the body.

There is also no AAFCO dietary requirement for vitamin K for dogs and cats, because intestinal bacteria are able to synthesize it. However, any condition that alters the intestinal microflora, such as antibiotic therapy, may result in vitamin K deficiency. As a result, NRC recommends vitamin K at 0.33 mg/1,000 kcal ME in puppies, at 0.45 mg/1,000 kcal ME in adult dogs, and at 0.25 mg/1,000 kcal ME in kittens and adult cats.

Deficiencies of fat-soluble vitamins (A, D, and E in dogs; A, D, E, and K in cats) and some of the 11 water-soluble B-complex vitamins have been produced experimentally. Water-soluble vitamins are usually readily excreted if excess amounts are consumed and are thought to be far less likely to cause toxicity or adverse effects when ingested in megadoses. Vitamin B₁₂ is the only water-soluble vitamin stored in the liver, and dogs may have a 2- to 5-yr depot. Fat-soluble vitamins (except for vitamin K in cats) are stored to an appreciable extent in the body, and when vitamins A and D are ingested in large amounts (10–100 times daily requirement) throughout a period of months, toxic reactions may be seen. Only clinically relevant vitamin-related imbalances are described below.

Vitamin A: Excessive consumption of liver can lead to hypervitaminosis A and may produce skeletal lesions, including

deforming cervical spondylosis, ankylosis of vertebrae and large joints, osseocartilagenous hyperplasia, osteoporosis, inhibited collagen synthesis, decreased chondrogenesis in growth plates of growing dogs, and narrowed intervertebral foramina.

Unlike most other mammals, cats cannot convert β -carotene to vitamin A, because they lack the intestinal dioxygenase enzyme necessary for β -carotene cleavage. Therefore, cats require a preformed source in their diet, such as that supplied by liver, fish liver oils, or synthetic vitamin A.

Signs of a vitamin A deficiency in cats are similar to those in other species, except that classic xerophthalmia, follicular hyperkeratosis, and retinal degeneration are rarely seen and usually are associated with concomitant protein deficiency. Nonetheless, cats fed diets deficient in vitamin A exhibited conjunctivitis, xerosis with keratitis and corneal vascularization, retinal degeneration, photophobia, and slowed pupillary response to light. Certain of these alterations also result from the retinal degeneration that is seen in taurine deprivation.

Hypovitaminosis A in cats may exhaust vitamin A reserves of the kidneys and liver; affect reproduction to cause stillbirths, congenital anomalies (hydrocephaly, blindness, hairlessness, deafness, ataxia, cerebellar dysplasia, intestinal hernia), and resorption of fetuses; and cause the same changes in epithelial cells noted in other animals. Squamous metaplasia of the respiratory tract, conjunctiva, endometrium, and salivary glands has been noted. Changes such as subpleural cysts lined by keratinizing squamous epithelium and extensive infectious sequelae are frequent in the lungs and are occasionally noted in the conjunctiva and salivary glands. Focal dysplasia of pancreatic acinar tissue and marked hypoplasia of seminiferous tubules, depletion of adrenal lipid, and focal atrophy of the skin have been reported. Borderline deficiency is more common, especially in chronic ill health.

Retinol at 9,000 IU/kg of diet should meet dietary needs for vitamin A during gestation and lactation and exceed the needs of growing kittens. See TABLES 58, 61, and 62 for dietary levels of vitamin A and other nutrients recommended by AAFCO and NRC.

Vitamin D: Vitamin D deficiency results in rickets in young animals and osteomalacia in adult animals. Classic signs of rickets are rare in puppies and kittens and most often are seen when homemade diets are fed without supplementation. Rickets has

been reported in kittens fed diets deficient in vitamin D, even though dietary amounts of calcium and phosphorus were normal. In rickets, serum calcium and phosphorus are decreased or low normal with a corresponding high parathyroid hormone level; bone mineralization is decreased, and the metaphyseal areas are enlarged. Osteomalacia rarely causes clinical signs in dogs or cats. Hypervitaminosis D causes hypercalcemia and hyperphosphatemia with irreversible soft-tissue calcification of the kidney tubules, heart valves, and large-vessel walls. Death in dogs is either related to chronic renal failure or acutely due to a massive aortic rupture. Death in cats is related to chronic renal failure.

Vitamin E: In cats, steatitis results from a diet high in PUFA, particularly from marine fish oils when these are not protected with added antioxidants. Kittens or adult cats develop anorexia and muscular degeneration; depot fat becomes discolored by brown or orange ceroid pigments. Lesions are seen in cardiac and skeletal muscles and are similar to those described in other species.

Thiamine: Thiamine deficiency generally does not develop in cats fed properly prepared, commercial, complete, and balanced diets. Thiaminase, which tends to be high in uncooked freshwater fish, can produce a deficiency by rapid destruction of dietary thiamine. Although canned commercial cat foods may contain fish, the heat associated with canning is sufficient to destroy thiaminase. Destruction of thiamine has also resulted from treatment of food with sulfur dioxide or overheating during drying or canning, but deficiencies are now rare.

Thiamine-deficient cats develop anorexia, an unkempt coat, a hunched position, and with time, convulsions that become more severe, leading later to prostration and death. At necropsy, small petechiae may be found in the cerebrum and midbrain. Diagnosis can be confirmed in the early stages by giving 100–250 mg thiamine, PO or IM, bid for several days. Recovery occurs in minutes to hours but, if the diet is not supplemented after this treatment, relapse can be expected. Thiamine deficiency may cause a number of other neurologic disorders, including impairment of labyrinthine righting reactions, seen as head ventroflexion and loss of the ability to maintain equilibrium when moving or jumping; impairment of the pupillary light reflex; and dysfunction of the cerebellum, suggested by ataxia, ataxia, and dysmetria.

Minerals: Minerals can be classified into three major categories: macrominerals (sodium, potassium, calcium, phosphorus, magnesium) required in gram amounts/day, trace minerals of known importance (iron, zinc, copper, iodine, fluorine, selenium, chromium) required in mg or mcg amounts/day, and other trace minerals important in laboratory animals but that have an unclear role in companion animal nutrition (cobalt, molybdenum, cadmium, arsenic, silicon, vanadium, nickel, lead, tin). A balanced amount of the necessary dietary minerals in relation to the energy density of the diet is important. As intake of a mineral exceeds the requirement, an excessive amount may be absorbed, or a large amount of the unabsorbed mineral may prevent intestinal absorption of other minerals in adequate amounts. Indiscriminate mineral supplementation should be avoided because of the likelihood of causing a mineral imbalance.

Mineral deficiency is rare in well-balanced diets. Manipulation of dietary intake of calcium, phosphorus, sodium, magnesium (dogs and cats), and copper (dogs) for therapeutic effect is common. Limited evidence exists for the recommendations of dietary mineral requirements for cats in TABLES 61 and 62; many are based on the mineral content of successfully fed diets.

Macrominerals: Calcium and phosphorus deficiencies are uncommon in well-balanced growth diets. Exceptions may include high-meat diets high in phosphorus and low in calcium and diets high in phytates, which inhibit absorption of trace minerals. In dogs and cats, the requirements for dietary calcium and phosphorus are increased over maintenance during growth, pregnancy, and lactation. In dogs, the optimal calcium:phosphorus ratio should be ~1.2–1.4:1; however, minimum and maximum ratios by AAFCO are 1:1 to 2.1:1. Less phosphorus is absorbed at the higher ratios, so an appropriate balance of these two minerals is necessary. Also, insufficient supplies of calcium or excess phosphorus decrease calcium absorption and result in irritability, hyperesthesia, and loss of muscle tone, with temporary or permanent paralysis associated with nutritional secondary hyperparathyroidism. Skeletal demineralization, particularly of the pelvis and vertebral bodies, develops with calcium deficiency. By the time there is a pathologic fracture and the condition can be confirmed radiographically, bone demineralization is severe. Often, there is a history of feeding a diet composed almost entirely of meat, liver, fish, or poultry.

Excess intakes of calcium are more problematic for growing (weaning to 1 yr) large- and giant-breed dogs. Excessive supplementation (>3% calcium [dry-matter basis]) causes more severe signs of osteochondrodysplasia and decreased skeletal remodeling in young, rapidly growing large-breed dogs than in dogs fed diets with lower dietary calcium (1%–3% [dry-matter basis]). The clinical signs of lameness, pain, and decreased mobility have not been reported in small-breed dogs or more slowly growing breeds fed the higher calcium amounts.

Magnesium is an essential cofactor of many intercellular metabolic enzyme pathways and is rarely deficient in complete and balanced diets. However, when calcium or phosphorus supplementation is excessive, insoluble and indigestible mineral complexes form within the intestine and may decrease magnesium absorption. Clinical signs of magnesium deficiency in puppies are depression, lethargy, and muscle weakness. Excessive magnesium is excreted in the urine. In cats, there is evidence that magnesium concentrations >0.3% (dry-matter basis) may be detrimental if the diet is too alkaline.

Trace Minerals: Iodine deficiency is rare when complete and balanced diets are fed but may be seen when high-meat diets are used (dogs and cats) or when diets contain saltwater fish (cats). Kittens with iodine deficiency show signs of hyperthyroidism in the early stages, with increased excitability, followed later by hypothyroidism and lethargy. Abnormal calcium metabolism, alopecia, and fetal resorption have been reported. The condition can be confirmed by thyroid size (>12 mg/100 g body wt) and histopathology at necropsy. The cause of hyperthyroidism that develops in older cats with increased blood thyroxine and triiodothyronine is unknown.

Iron and copper found in most meats are used efficiently, and nutritional deficiencies are rare except in animals fed a diet composed almost entirely of milk or vegetables. Deficiency of iron or copper is marked by a microcytic, hypochromic anemia and, often, by a reddish tinge to the hair in a white-haired animal.

Deficiency of zinc results in emesis, keratitis, achromotrichia, retarded growth, and emaciation. Decreased zinc availability has been noted in canine diets containing excessive levels of phytate, which emphasizes the value of feeding trial tests over laboratory nutrient analyses of pet foods.

Manganese toxicity has been reported to produce albinism in some Siamese cats; a deficiency of manganese in other species results in bone dyscrasia.

DOG AND CAT FOODS

Pet Food Labels

Current regulations require that all labels of pet foods manufactured and sold in the USA must contain the following items: 1) product name, 2) net weight of the product, 3) name and address of the manufacturer, 4) guaranteed analysis, 5) list of ingredients, 6) the words "dog or cat food" (intended animal species), 7) statement of nutritional adequacy, and 8) feeding guidelines. The AAFCO has also adopted an amendment that will require all pet food labels to contain information on the calorie content of the diet, expressed both in kcal ME/kg and per familiar household unit (eg, cups, cans).

The product name is the primary means by which a specific pet food is identified. The way ingredients are listed in the product name may also indicate the percentage of that ingredient present in the product, eg, using the term "beef" in the product name requires that beef ingredients must be at least 70% of the total product or ≥95% of the total weight of all ingredients, excluding water. Using the term "beef dinner," "beef entree," or "beef platter," etc, implies that beef must be at least 10% of the total product, and at least 25% but not more than 95% of the total weight of all ingredients, excluding water. Using the term "with beef" means at least 3% of the total product must be beef, and using the term "beef flavor" implies that there is only enough beef in the product to be detected by taste (<3%).

The product weight must be listed on the front of the pet food label within the bottom third of the principal display panel.

Guaranteed Analysis: This part of the label lists the minimal amounts of crude protein and crude fat and the maximal amounts of water and crude fiber on an as-fed (not dry-matter) basis. This analysis does not specify the actual amount of protein, fat, water, and fiber in the product. Instead, it indicates the legal minimums of protein and fat and the legal maximums of water and crude fiber content contained in the product. A laboratory proximate analysis lists the actual nutrient concentrations in the food, and two foods that have identical guaranteed analyses may have

very different proximate analyses. A guaranteed analysis for protein may list a minimal level of 25%, while the product may (and usually does) contain >25%. A certain variance above or below a minimum or maximum should be expected. Consequently, whenever possible, the manufacturer's average nutrient profile should be used to evaluate a food.

Direct product comparisons made between like (similar water content) products (ie, dry vs dry, or canned vs canned) are generally valid. However, comparisons across different food types should be made on a dry-matter or caloric basis. As a general rule, dry-food analyses can be converted to a dry-matter basis by simply adding 10% to the as-is value, because most dry foods contain ~10% water (eg, a dry-food protein content of 25% on an as-fed basis is equal to 27.5% dry-matter basis). Canned food analyses can be converted to a dry-matter basis by simply multiplying by 4, because most canned foods contain ~75% water (ie, a canned-food protein content of 6% on an as-fed basis is equal to 24% dry-matter basis). Alternatively, the approximate percent dry matter of a nutrient in a product can be calculated from the information in the guaranteed analysis. First, dry matter in the diet is calculated by subtracting the moisture level from 100%. Next, the percent of the nutrient of interest on a dry-matter basis is calculated using the following equation:

$$(\% \text{ nutrient [as fed]}/\% \text{ dry matter in diet}) \times 100 = \sim\% \text{ of nutrient (dry matter)}$$

Ingredient List: In the USA, all pet foods sold must be registered with state feed control officials and must contain approved ingredients generally regarded as safe, unless they are for specialized purposes such as the amelioration or prevention of disease. Such foods are considered to be drugs and must be approved by the FDA.

Ingredients are listed in descending order of weight, on an as-fed basis, in the food. Although a food ingredient (eg, chicken) may be listed first, if that ingredient is 75% moisture, it will contribute a much smaller percentage of total nutrients to the food dry matter. In addition, an ingredient such as corn may be listed by individual types, eg, flaked corn, ground corn, screened corn, kibbled corn, etc. In this case, the total corn amount may be a significant amount of the total food dry matter, but when presented as individual types, each type appears lower on the ingredient list. This is referred to as ingredient splitting.

No reference to quality or grade of an ingredient is allowed to be listed; therefore, it is difficult to evaluate a product solely on the basis of the ingredient list. The value of this list is limited to determining the sources of the proteins and carbohydrates for dogs or cats. This kind of information is useful when evaluating animals experiencing an adverse reaction to a food, possibly due to an allergy or intolerance to one or more ingredient sources such as beef, wheat, etc.

Product formulations can be either fixed or open. In a fixed formula, combinations of ingredients and nutrient profiles do not change regardless of fluctuating market prices of the ingredients. In an open formula, ingredients, and possibly actual nutrient profiles, change depending on availability and market prices. Most commercial complete and balanced diets have a fixed formulation.

Statement of Nutritional Adequacy:

This statement indicates how the food was tested (feeding versus laboratory analysis or formulation) and for which life stage the food is intended. AAFCO recognizes only four life stages: growth, maintenance, gestation, and lactation. The term "all life stages" is frequently used on a label and indicates that the product has been either formulated or tested for growth. By default, it is anticipated that such a food would also pass a maintenance protocol, because testing a food for growth generally includes gestation and lactation. There are no AAFCO-approved nutrient profiles for geriatric, senior, or weight loss stages.

The statement "complete and balanced" indicates the product contains all nutrients presently known to be required by dogs or cats and that these nutrients are properly balanced to the energy density of the diet. The "complete and balanced" claim must be substantiated by successfully completing AAFCO feeding trials, or the food must contain at least the minimal amount of each nutrient recommended by AAFCO. There are cautions "against the use of these requirements (levels) without demonstration of nutrient availability" because some of the requirements are based on studies in which the nutrients were supplied as purified ingredients and, therefore, are not representative of ingredients used in commercial pet foods. Laboratory analysis does not address the issue of bioavailability. Supplements, snacks, treat products (ie, those intended for intermittent or supplemental feeding), and therapeutic or dietary products (ie, those intended for use under

the direction of a veterinarian) are exempted from AAFCO testing.

Feeding Guidelines: These must be expressed in common terms, such as "feed (weight/unit of product) per body wt of dog or cat." They are general recommendations at best, and body weight and body condition must be monitored to prevent over- or underfeeding.

Pet Food Product Types

Commercial dog and cat foods are available in three principal forms: canned, dry, and semimoist. The classifications used depend on the processing method and water content more than on the ingredient content or nutrient profile. Complete and balanced commercial dog and cat diets are formulated to provide adequate quantities of each required nutrient without an intolerable excess of any nutrient. Supplementation of particular nutrients to commercially produced complete and balanced dog and cat foods should be done carefully and only with appropriate justification. Dog foods are not satisfactory for cats because most dog foods are lower in protein, often do not contain assured concentrations of taurine, and are not designed to produce a urinary pH of <6.5 (which helps prevent the crystallization of struvite or magnesium-ammonium-phosphate in the feline urinary tract. (*See also* FELINE LOWER URINARY TRACT DISEASE, p 2383.)

Dry Food: This is the most popular category of pet food in the USA and some other countries. Dry foods generally contain ~90% dry matter and 10% water. Approximately 95% of dry dog and cat foods are extruded, ie, they are made by combining and cooking ingredients (grains, meat and meat byproducts, fats, minerals, and vitamins), then forcing the mixture through a die. During cooking and extrusion, a temperature of ~150°C (~302°F) converts the starches into a form more easily digested, destroys toxins and inhibitory substances, and flash sterilizes the product. The food is then enrobed with fat and/or digest (material derived from controlled degradation of animal tissues, eg, chicken digest) during drying to increase palatability.

Advantages of dry food include a lower cost than canned or soft-moist food, and refrigeration of unused portions is not needed. Certain types of dry food may also provide beneficial massage of the teeth and gums to help decrease periodontal disease

(although unless specifically formulated to deter it, remain mainly ineffective in dogs for this purpose).

Canned Food: Canned dog and cat foods contain 68%–78% water and 22%–32% dry matter. Many of the same ingredients are used in canned pet foods as in dry-extruded types but usually not at the same levels of inclusion. Given their high moisture content, canned foods typically contain higher amounts of fresh or frozen meat, poultry, or fish products and animal byproducts. Many canned pet foods contain textured proteins derived from grains, such as wheat or soy. These materials function as meat analogues, having a physical structure similar to that of meat and high nutritional quality. The use of meat in combination with some of the textured proteins not only controls costs but can improve the overall nutritional profile of the final product.

Canned pet food processing begins with blending meat or meat analogues and fat ingredients with water and dry ingredients, such as vitamins and minerals, for proper nutrient content. The mixture is blended and sometimes ground to produce a fine slurry, depending on product profile. After cans are filled, they are sealed and retorted (a heat and pressure-cooking process that also sterilizes the contents), assuring destruction of foodborne pathogens. Advantages of canned food include a long shelf life in a durable container and high palatability. However, canned food is more expensive than dry food.

Soft-moist Food: Soft-moist dog and cat foods contain 25%–40% water and 60%–75% dry matter. They do not require refrigeration and are preserved using humectants—substances that bind water so that it is unavailable for bacteria and mold growth and assure shelf life. They include simple sugars (usually sucrose), sorbitol, propylene glycol, and salts. Many soft-moist foods are acidified using phosphoric, malic, or hydrochloric acid to further retard spoilage. Advantages of soft-moist foods include convenience, high energy digestibility, and palatability. However, soft-moist food is more expensive than dry food.

Home-cooked Diets: Dogs can be successfully maintained on properly formulated home-cooked diets; this is much more difficult in cats. Advantages of home-cooked diets include the use of fresh, high-quality ingredients chosen by the owner. Disadvantages include preparation time, variable quality control and diet

consistency, higher cost, and the difficulty in formulating and preparing a nutritionally complete and balanced diet. It is most difficult to formulate a nutritionally complete and balanced diet with sufficient nutrient density in a small volume of food that is palatable for cats. Many home-cooked diets result in foods that are high in protein and caloric density and have inappropriate calcium:phosphorus ratios and inadequate levels of calcium, copper, iodine, fat-soluble vitamins, and several of the B vitamins. Many published recipes for feline diets have very high ash or mineral levels because of the extent of synthetic nutrient supplementation required. If owners choose to feed a home-cooked diet, they should use a recipe formulated by a veterinary nutritionist (vs found on the Internet). It is also important to realize that no home-cooked diets have undergone the testing and research used to formulate complete and balanced commercial pet foods.

Raw Meat-based Diets: Raw meat-based diets have received a lot of attention in recent years. The controversy, lack of good data, and paucity of high-quality research make it difficult for veterinarians to make informed recommendations to pet owners regarding this feeding practice. However, the American Animal Hospital Association, the American Veterinary Medical Association, and the Canadian Veterinary Medical Association have all developed statements discouraging the feeding of raw or undercooked animal-source protein to dogs and cats. In addition, in 2010, the Delta Society's Pet Partners Program initiated a policy precluding animals eating raw meat-based diets from participating in the Therapy Animal Program.

There are two main types of raw meat-based diets: home-prepared and commercial. In addition, a variety of raw dried or freeze-dried pet treats fall under this category. Home-prepared diets include a variety of feeding regimens, including BARF (Bone and Raw Food or Biologically Appropriate Raw Food), the Ultimate Diet, and the Volhard Diet. Commercial raw meat-based diets most commonly are fresh, frozen, pasteurized, or freeze-dried. Some of these commercial diets are formulated to meet AAFCO nutrient profiles, but many are not.

One of the biggest areas of controversy surrounding these types of diets are the safety of these diets to not only the pets consuming them, but to the pet owners and others who are exposed to the animals

consuming them. Even if owners purchase meat meant for human consumption to produce home-prepared diets, there is no assurance these ingredients are free of pathogens and safe to consume uncooked. Raw chicken is a common source of *Salmonella*, and it is estimated that 21%–44% of chicken purchased from retail locations meant for human consumption throughout North America is contaminated with *Salmonella*. Even if a pet owner takes precautions while handling and preparing these diets, it has been shown that after consumption of a single meal contaminated with *Salmonella*, 44% of dogs shed *Salmonella* in their feces for as long as 7 days, and none of these dogs was symptomatic for *Salmonella* infection. *Salmonella* contamination rates for beef and pork intended for human consumption are estimated to range from 3.5%–4%; however, beef and pork are a source of other potential pathogens, including the pathogenic strain of *E coli* O157:H7. *Campylobacter* spp is estimated to be present in 29%–74% of chicken, and *Listeria* spp is estimated to be present in 15%–34% of chicken and 25%–52% of beef and pork. In two separate studies, consumption of raw meat was shown to significantly increase the seroprevalence rate of *Toxoplasma gondii* in cats.

Some commercial raw meat-based diets are frozen or freeze-dried; however, neither freezing nor freeze-drying destroys all the potential pathogens in these products. Some commercial raw meat-based diet manufacturers now use high-pressure pasteurization in an attempt to reduce the risk of pathogens. Although this process can reduce the numbers of many pathogens, it usually does not completely eliminate them, and bacteria and viruses vary in their susceptibility to this process. Commercial pet foods have also been recalled in recent years because of contamination from *Salmonella*; however, considering the number of commercially available pet food products, the percentage of products affected is relatively small compared with the number of raw meat-based diets affected.

Another concern, particularly of home-prepared raw meat-based diets, is nutrient imbalances. In a European study that evaluated 95 homemade raw meat-based diets being fed to dogs, 60% had major nutritional imbalances. There have been a number of case reports pertaining to the development of vitamin D-dependent rickets type I and nutritional secondary hyperparathyroidism associated with dogs being fed raw meat-based diets. Other concerns regarding the practice of feeding raw meat

and bones to dogs and cats is the risk associated with esophageal and intestinal foreign bodies and perforation. Feeding raw bones has also been associated with slab fractures and other dental problems in dogs.

Proponents of raw diets often cite that raw meat-based diets are the evolutionary diet of dogs and cats and that domestic dogs and cats have never evolved into being able to digest and absorb commercial pet foods. However, a recent report shows that dogs have 36 regions of the genome that differ from that of wolves, and 10 of these regions play a critical role in starch digestion and fat metabolism. Therefore, the genetic makeup of domestic dogs and cats is not the same as that of wolves. Proponents of raw diets also cite that cooking destroys essential enzymes needed for digestion. While a small amount of protein is destroyed during cooking, and enzymes are proteins, there is no evidence that animals or people require these exogenous sources of enzymes. In addition, many of these enzymes are destroyed in the highly acidic environment in the stomach and never reach the small intestines, where most nutrients are absorbed.

Finally, veterinarians must also consider the potential legal implications of recommending raw meat-based diets. While zoonotic risks can be associated with feeding both commercial and home-prepared diets, if a pet owner, for example, develops a *Salmonella* infection from feeding a contaminated commercial diet, the pet food manufacturer is generally at risk of legal action. However, veterinarians who recommend home-prepared raw meat-based diets are potentially liable if an owner becomes sick from preparing these diets or as a result of pets shedding pathogens in their feces.

FEEDING PRACTICES

Domestication and use of dogs and cats as companions may have modified eating patterns of these animals to varying extents. Easier access to food and consistency of food quality has led to increased food consumption and the possibility of decreased energy expenditure overall. Hence, there is greater risk of obesity. At the same time, longevity of companion animals has also increased and, along with it, the emergence of other chronic progressive diseases such as osteoarthritis, cancer, and immune and cognitive disorders. Healthy dogs and cats eat a variety of foods. During a 24-hr period, most dogs will eat 1–3 meals, whereas most cats will eat frequent small meals, as many as 18 a day.

Although odor, consistency, taste, and learned dietary habits determine which foods a dog will eat, most dogs are indiscriminate eaters. Finicky, begging dogs have learned such behaviors. Likewise, odor, consistency, taste, and learned dietary habits determine which foods a cat prefers, but how much a cat will eat is affected by factors such as noises, lights, food containers, the presence or absence of people or other animals (including other cats), physiologic state, and disease. Cats can and will refuse to eat to the point of starving themselves under stressful conditions. These cats are at risk of developing hepatic lipidosis, which can be fatal if not treated early and aggressively.

Some dogs and cats have adequate appetite controls and maintain an optimal body condition, even with dietary changes. By contrast, other dogs and cats overeat, consume excessive calories, and become obese. The thickness of the fat layer over the rib cage and pelvic bones is a good indicator of obesity, as is regular body condition scoring over time (see TABLES 55 and 56).

Dietary modifications are required by changes in life stage, environment, body weight and condition, and disease. Energy density varies from 2,500 to >5,000 kcal/kg dry matter for dog foods and from 3,000 to >5,000 kcal/kg dry matter for cat foods. Therefore, general feeding recommendations cannot be given for all dogs and cats on any particular food. Instead, feeding recommendations should be individualized. The best feeding method is one that maintains optimal body weight and condition, bearing in mind that disease conditions may require dietary changes.

When a dietary change is necessary, it should not be done abruptly. New food should be introduced gradually throughout 5–7 days. Also, it is better to offer slightly less than the calculated new food amount. Overindulgence and abrupt changes are frequently the inciting cause of GI disorders that may ultimately lead to diet refusal. In dogs, the new food should be introduced slowly by replacing 25% more of the old food every day or two until the new diet makes up the entire amount fed. Cats can easily become habituated to a particular food and may resist any dietary change. In cats, new food should also be introduced slowly. Some cats have definitive preferences for dry food, whereas others prefer the same food moistened or canned.

If the dog or cat is to be switched from a canned to a dry diet, it may be useful to moisten the product by adding sufficient

warm water, and the food can be warmed to release odors and flavors that encourage consumption. Dry-matter digestibilities are 60%–90% for dog food and 75%–90% for cat food because of ingredient quality, crude-fiber content, processing, and level of intake. Small, formed, brown feces suggest high nutrient digestion and absorption, while large volumes of pale feces indicate less dietary utilization.

Maintenance: After a dog has reached ~90% of its expected adult weight, a diet less nutrient dense than the growth diet is recommended. The dietary goal is to maintain optimal body weight and condition for that particular dog. Some adult dogs can be fed free choice, but most cannot without becoming obese. The best feeding regimen to use in most adult dogs to prevent obesity is portion-controlled feeding, eg, feeding two premeasured meals at regular times each day. Most dogs will eat all their food immediately, but some dogs will graze throughout the day.

Many owners feed treats and snacks, which are often an important aspect of the human-animal bond. Complete and balanced treat products that use low-fat, high-fiber ingredients are available. However, most treats are not complete and balanced; therefore, to prevent nutrient deficiencies, the total daily amount of treats should be <10% of the total caloric intake. Nutritional supplements are not required and, in fact, may be harmful. In an animal prone to obesity, the caloric content of all treats fed should be considered in an effort to match energy intake to expenditure. Regular assessment of the animal's body condition helps ensure minimal weight gain beyond optimal adult values throughout life.

Most inactive, neutered adult cats can be fed a reduced fat diet (9% dry-matter basis) ad lib, but increasing the insoluble fiber content may be necessary in some animals to satisfy hunger: Cats exposed to variations in temperature (eg, cats that remain outdoors year-round or at night) may eat more during the winter. The need for a different nutritional profile in older cats versus middle-aged cats may be necessary. Middle-aged cats are at increased risk of developing obesity, whereas older cats often have a difficult time keeping weight on. The ability of older cats to digest protein and fat is often less than that of younger and middle-aged cats. Therefore, it is important to feed a diet with highly digestible protein and fat sources. The quantity of these nutrients in the diet may also have to be modified (usually increased) to compensate

for impaired protein and fat digestion. However, depending on activity level, feeding a food with a different fat and fiber content (increased or decreased as needed) may be required to maintain optimal body weight and condition.

Growth and Reproduction in Dogs:

Growth, pregnancy, and lactation greatly increase nutrient demands over those of maintenance. Growth diets have increased nutrient density, digestibility, and bioavailability to provide nutrients necessary in a smaller volume of food. Supplementation of calcium, phosphorus, and vitamin D beyond amounts present in complete and balanced diets designed for growth and reproduction is rarely necessary and may be contraindicated.

Growth: Overfeeding during growth increases growth rate. This is not desirable, because it is incompatible with proper skeletal development and also contributes to obesity later in life. Feeding methods for growing puppies should be individualized for the puppy and owner. General recommendations are that puppies between weaning and 6 mo of age should be fed three times a day; puppies 6–12 mo old should be fed twice daily. Large- and giant-breed puppies should be fed complete and balanced growth diets that have been tested in feeding trials and that contain calcium, fat, and protein at levels closer to the minimums stated by AAFCO. Small-breed puppies may have to be fed more than three times a day using a tested diet that contains calcium, fat, and protein at levels greater than the minimums stated by AAFCO.

Only limited data have been published with respect to breed growth curves. Nonetheless, a slow growth rate is preferable to a fast growth rate. Weight gains should be closely monitored (weekly), and feeding recommendations adjusted such that the puppy gains a small amount of weight each week. When growing large-breed puppies were fed 50%–70% of their littermate's ad lib intake, adult height, length, and bone or muscle mass were not stunted; only total body fat was affected. It is difficult to stunt the growth of a puppy being fed a complete and balanced growth diet that has passed an approved AAFCO feeding trial using meal feeding of an appropriate amount for 2–3 times/day.

Gestation: Feeding recommendations for pregnant bitches through the first two-thirds of gestation are the same as those for maintenance. A common mistake is to overfeed during early gestation and to underfeed during lactation. In the last third

of gestation, the total amount of food offered should be increased at least 20%–30% over the amount for maintenance. Growth diets are often used during gestation because of their higher energy density and smooth transition after parturition to support lactation.

Lactation: Depending on litter size, lactating bitches often require energy levels 2–4 times those of maintenance to avoid excessive loss of body condition. Ad lib feeding using a complete and balanced growth diet containing 10%–20% fat (dry-matter basis) that has passed an approved AAFCO feeding trial is recommended to maintain lactation and to permit optimal body weight and condition to be required by weaning. If a bitch loses significant body condition during lactation, the fat content of the diet should be increased to 20%–30% fat (dry-matter basis), and she should be fed ad lib.

Growth and Reproduction in Cats:

One of the most important differences between queens and bitches is that pregnant queens exhibit a linear increase in weight (fetal growth) throughout pregnancy. As a result, pregnant queens need to consume more calories almost immediately after becoming pregnant. In contrast, fetal growth is minimal during the first two trimesters of pregnancy in the bitch, and caloric intake does not generally have to be increased until sometime between the end of the second trimester and the beginning of the third trimester.

Because queens tend to lose weight during lactation regardless of diet fed, it has been assumed that net tissue reserves should increase somewhat in preparation for lactation. A growth diet for kittens that contains 10%–35% fat, 30%–40% protein, and low (<5%) fiber (dry-matter basis) should be fed. Growing kittens and pregnant and lactating queens can be fed ad lib or several times a day to meet their daily needs. During the latter third of gestation, the amount of food and level of nutrient intake normally increases an average of 25%, although energy intakes for cats during pregnancy have been estimated to be as much as 40% greater than for maintenance. Some queens may eat less early in gestation and immediately before parturition; such changes are of concern only if prolonged. Queens require 2–3 times the normal food intake during lactation, depending on litter size. Supplementing an already balanced diet is not necessary and should be discouraged.

Geriatric Dogs and Cats: Older dogs and cats may not be as efficient in metabolizing dietary protein than younger animals. They may actually require more dietary protein than their younger counterparts to maintain protein reserves and maximize protein turnover rates. In addition, decreased fat digestion occurs with age in cats, so geriatric cats may actually require a higher-fat diet than their younger counterparts. In contrast, some dogs and cats begin old age considerably overweight, whereas others may show some loss of condition. Feeding an appropriate food with a different nutrient profile with respect to energy, fat, or fiber content (increased or decreased) may be needed to maintain optimal body weight and condition. Geriatric dogs and cats should be monitored in a preventive health program that includes periodic assessments of body weight and condition. The incidence of chronic degenerative organ disease increases with age, and early diagnosis fosters earlier treatment and more effective nutritional management.

Work or Stress: The caloric needs of working or stressed dogs may exceed the levels of a maintenance diet, depending on the animal and extent of work performed. Most diets designed for work or stress have increased levels of animal fats, with the other nutrients appropriately balanced to the increased energy density. At extreme levels of stress (eg, an Alaskan sled dog requiring 10,000 kcal/day), many recommend not only increasing the percent ME from fat but also from protein, while minimizing the contribution of carbohydrate.

Any daily feeding recommendation should be considered an estimate or starting point and should be modified based on continual evaluation of the dog's weight and condition, skin and coat, performance, and general attitude. Feeding a smaller amount of the daily ration (eg, $\frac{1}{3}$ of the daily amount) before beginning a work shift is recommended with the remainder being fed thereafter. Plenty of fresh water should be available, and opportunities to stop work for a water break should be scheduled in any daily work routine for these dogs.

NUTRITION IN DISEASE MANAGEMENT

Nutrition is an important part of disease management, even though few disorders can be cured solely with diet. The interaction between illness, health, and nutritional status is multifactorial and complex. The

nutritional requirements of many sick dogs and cats are qualitatively the same as those of healthy ones; however, they differ in the amounts required—certain nutrients may be needed in greater amounts or may need to be restricted.

Adverse Reaction to Foods: Food reactions are classified using specific terminology. An adverse reaction to a food is a clinically abnormal response to any type of food ingested. Food intolerance is a type of adverse reaction that does not involve the immune system, eg, food poisoning. A food allergy is a type of adverse reaction that does involve the immune system, eg, colitis or atopic dermatitis. (See **FOOD ALLERGY**, p 855, and **LOCALIZED ANAPHYLACTIC REACTIONS**, p 824.)

Dogs and cats with food allergy usually have GI signs (eg, vomiting or diarrhea, or both) or a pruritic skin condition, especially in the regions of the ears, rear, and feet. The prevalence of true food allergies is very small. Some dogs and cats with nonseasonal pruritus are having an adverse reaction to food. Unfortunately, food allergy cannot be differentiated from food intolerance, and skin testing for food allergies is unreliable. Blood tests are also an unreliable way to diagnose food allergies in dogs and cats. Hence, given all the possible etiologies and limited diagnostics available, any animal suspected of having an adverse reaction to food should undergo a food trial. The length of time needed for a food trial depends on the condition being managed. Food trials for adverse reactions to food associated with clinical signs involving the GI tract should continue for ≥ 2 wk, whereas food trials for clinical signs involving dermatologic conditions should continue for ≥ 10 –12 wk.

During a food trial, the only item fed should be a diet containing a single novel protein source or a hydrolyzed protein diet. A careful dietary history must be obtained from the pet owner before selecting the type of diet. If the owner elects to feed a commercially prepared food, several products are available for dogs that use single novel protein sources (eg, kangaroo, venison, rabbit, duck, or fish). Commercially available diets available for cats use protein sources consisting of rabbit, duck, venison, and lamb. Fish is not a novel option for most cats, and there is a possible, but yet unclear, relationship between adverse food reactions in cats fed foods containing scombroid fish and histamine content. Most importantly, the formulation of whatever product or diet is fed must be fixed to

ensure that the ingredient composition is consistent from batch to batch. These products are more expensive not only because of their unique and limited sources of protein but also because of the quality control procedures required to ensure fixed formulations and to eliminate cross-contamination with previous production batches of different foods.

A newer alternative diet commercially available for use in dogs and cats with suspected adverse reactions to food is a hydrolyzed protein diet. Protein is the most common nutrient associated with adverse reactions to food, because it is needed to bridge two IgE molecules together to cause the release of histamine. The protein in hydrolyzed diets is broken down into smaller peptide fragments that are too short to bridge two IgE molecules. Although these diets are helpful in many dogs and cats with adverse reactions to food, they are expensive, and some animals with allergies to the protein sources in these diets will still react to the typical hydrolyzed protein diet. Therefore, a novel protein diet is often tried first; if clinical signs do not resolve, then a hydrolyzed protein diet can be used.

Simplified homemade diets are also possible using the same protein sources suggested above (or other ingredient sources the owner wants to test). Homemade diets actually allow for a wider selection of source ingredients. Beef, wheat, and dairy products should be discouraged for use as a protein source in dogs, and beef, fish, and dairy products should be discouraged for use in cats, because animals have likely been exposed to these sources if previously fed foods with an open formulation. The basic recipe should closely resemble "complete and balanced," but single sources of protein can be sequentially tested and replaced. The owner is responsible for quality control and consistency and must be willing to make such a diet for ≥ 2 wk for GI conditions and ≥ 10 –12 wk for dermatologic conditions. On average, there is no price advantage in making a homemade diet over using commercially prepared foods. Formulating a homemade diet containing hydrolyzed protein is both very difficult and expensive.

The trial diet should be exclusively fed for the recommended length of time, and all treats, snacks, and table foods eliminated unless they are made of the exact same ingredients as the trial diet or contain a hydrolyzed protein source. All chewable medications and supplements must be eliminated from the trial diet, because most contain the same protein and additive

ingredients as pet foods and treats. Other therapies such as hyposensitization and flea control are necessary in animals with concurrent disease. Testing various suspect ingredients by reintroducing them to the diet one at a time followed by recurrence of clinical signs is affirmation of an adverse reaction to that ingredient. Dietary ingredients reintroduced may reproduce clinical signs as early as 12 hr after ingestion but can take as long as 10 days. Lifelong treatment is dietary avoidance, which may be difficult if the offending ingredients are not positively identified.

Anemia: Iron or copper deficiency (or both) is the major cause of hypochromic, microcytic anemia. A folic acid and B₁₂ (cobalamin) deficiency also produces anemia. Most commercial diets have more than required amounts of iron, copper, and vitamins; therefore, secondary causes such as inadequate food intake, malabsorption, hemorrhage, or heavy parasite infection should be investigated. Feeding an unbalanced homemade diet may also result in anemia.

Rarely can severe iron deficiency be corrected with diet alone, and feeding large quantities of liver in an attempt to correct iron deficiency is usually ineffective and can result in vitamin A toxicosis. Most animals require a supplemental source of iron administered either PO or IM to correct severe iron deficiency and, depending on the underlying cause, may need to continue receiving a supplemental source of iron indefinitely. If the underlying cause of iron deficiency is related to hemorrhage, parasitism, consuming an unbalanced diet, or consuming too little of a complete and balanced diet, once the underlying cause is eliminated and the iron deficiency is corrected, long-term supplemental iron may not be necessary.

Folic acid and vitamin B₁₂ are necessary to support normal cell division, and treatment for vitamin B₁₂ deficiency usually requires parenteral administration of vitamin B₁₂. Vitamin B₁₂ deficiency develops most commonly from intestinal malabsorption; however, it can also result from short-gut syndrome. Vitamin B₁₂ absorption in the GI tract is limited to the ileum, and surgical removal of large portions of the ileum may result in the need for lifelong parenteral B₁₂ supplementation.

Anorexia: Partial anorexia is seen when the animal is eating some food but not enough to provide at least 30 kcal/kg body wt in dogs and 40 kcal/kg body wt in cats.

Complete anorexia occurs when the animal does not consume any food for ~3 days.

Anorexia (partial or complete) accompanies many underlying disorders, including drug reactions or reactions to environmental changes. Pain may also be a significant contributor to anorexia, and in most cases when the pain is adequately controlled, the anorexia resolves. Learned food aversions may also contribute to anorexia. This occurs most commonly when animals are started on a therapeutic diet while they are ill, eg, offering a therapeutic diet to manage renal failure while the animal is still in a uremic crisis. Food aversions can also occur as a result of force-feeding. Obviously, therapeutic diets do not help if they are not consumed. Eating some of a diet that is less than optimal is better than none of the "right" one. Assuming that an animal will eat a therapeutic diet when it gets hungry enough is inappropriate, and allowing an animal to starve in an attempt to stimulate its appetite is never recommended. If a particular diet is refused, an alternative(s) should be tried until one that the animal will eat is identified. Anorectic dogs and cats can sometimes be persuaded to eat by adding highly flavored substances to the diet (eg, animal fat, meat drippings, fish [fish juices or oils for cats]) or by hand-feeding. If these are not successful, nutritional support intervention may be necessary.

Nutritional support can be provided by either enteral or parenteral routes. Unless there is a contraindication to using the gut, enteral support is usually preferred over parenteral support. Enteral support is more physiologic, cheaper, and safer than parenteral support. In addition, more dietary options are available for enteral support than for parenteral support.

Many options for feeding tubes are available, including esophagostomy tubes, nasogastric or nasoesophageal tubes, gastrostomy tubes, and jejunostomy tubes. Both esophagostomy tubes and nasogastric or nasoesophageal tubes can be placed without the need for any specialized equipment. Nasogastric tubes are used more commonly for short durations (1–7 days) or when sedation or anesthesia are contraindicated. Esophagostomy tubes and gastric tubes are more commonly used when nutritional support is required for longer durations (weeks or months). Dogs and cats can be maintained at home with tube feedings (except in the case of jejunostomy tubes) after the procedure has been accepted by the animal and fully explained to the owner and if the frequency of feeding is something the owner can

reasonably manage and the animal can tolerate.

It is advisable to take a stepwise approach to reintroduction of calories, and multiple small meals are often tolerated better than large meals. Vomiting, diarrhea, or refeeding syndrome can be a consequence of being too aggressive with reintroduction of calories. The size of the tube determines what dietary options can be used. Sizes 5 or 8 French tubes usually limit feeding to liquid enteral diets. Larger esophagostomy or gastrostomy tubes can also accommodate critical care diets and blenderized therapeutic diets. If use of a feeding tube is contraindicated or a tube cannot be placed, dogs and cats can be maintained by IV solutions that provide adequate calories, protein, electrolytes, B vitamins, and selected trace minerals until access to the small intestine is possible. Unfortunately, the parenteral route is more expensive and is associated with a higher incidence of complications, including catheter problems, infection, and electrolyte abnormalities.

Cachexia: Cachexia is most commonly associated with cases of neoplasia or chronic renal or cardiac disease. Cachexia appears to be a response to increased catabolism with either normal or decreased appetite. The deterioration of the animal's condition clearly indicates that nutritional requirements are not being met, and the dietary goal is to increase the caloric density and palatability of the food while meeting the animal's requirements for protein and other nutrients. The usual management of cachexia is to feed smaller amounts of a more calorically dense (ie, higher fat content), complete and balanced diet more frequently (3–6 meals/day). The form of food (dry or canned) that the dog or cat prefers should be fed. Tube feeding and partial or complete parenteral nutritional support (*see above*) should also be considered if the dog or cat continues to lose weight and condition.

Diarrhea: Diarrhea can result from numerous GI diseases and can also occur secondary to disease outside the GI tract. Primary causes of GI disease are numerous and include adverse reaction to food, infections (bacterial, parasitic, fungal, and viral), inflammatory bowel disease, neoplasia, and toxin- or drug-induced. Certain breeds of dogs are predisposed to GI disease. German Shepherds are at increased risk of developing antibiotic-responsive diarrhea (formerly known as small-intestinal bacterial overgrowth),

TABLE 64

CHARACTERISTICS OF SMALL-BOWEL AND LARGE-BOWEL DIARRHEA

Characteristics	Small Bowel	Large Bowel
Blood in feces	Melena	Hematochezia
Fecal quality	Loose, watery “cow-pie”	Loose to semiformed
Fecal volume	Large quantities	Small quantities
Frequency of defecation	Normal to increased	Increased
Mucus in feces	Absent	Usually present
Tenesmus	Absent	Usually present
Urgency	Absent	Usually present
Weight loss	May be present	Rare

Doberman Pinschers and Rottweilers are at increased risk of parvoviral enteritis, and Yorkshire Terriers are at increased risk of lymphangiectasia.

Clinical signs associated with diarrhea are different in small-bowel versus large-bowel diarrhea (see TABLE 64). Dietary recommendations may vary depending on where the diarrhea is localized and the underlying cause.

Animals with small-bowel diarrhea usually benefit from a highly digestible diet, whereas those with large-bowel diarrhea often benefit from prebiotics (see p 2369). Small, frequent meals (3–6/day) should be offered. Probiotics are an additional tool available for management of small- or large-bowel diarrhea. Probiotics are defined as nutritional supplements containing live, viable, beneficial bacteria in sufficient numbers to provide a health benefit. Not all probiotics are created equal—a probiotic effective in one species may be ineffective in another. Probiotic bacteria provide many of the same benefits to the host as prebiotics. Synbiotics are a mixture of prebiotics and probiotics in which the prebiotic increases the survival of and nourishes the probiotic bacteria. Although clinical studies of probiotics in dogs and cats are limited, probiotics have been helpful in numerous causes of diarrhea.

Constipation: Constipation results from impaired peristalsis or increased water absorption from the large intestine. The objective of dietary management is to provide a balanced diet with increased amounts of insoluble fiber (10%–25% dry-matter basis to effect) or moderately fermentable fiber in dogs or a highly

digestible balanced diet containing prebiotics in cats. Constipated cats tend to do poorly on diets supplemented with insoluble fiber. Animals should be fed 2–4 times/day. In dogs, adding canned pumpkin or psyllium to the diet is also sometimes effective in mild cases of constipation.

Congestive Heart Failure (CHF): One objective in managing CHF is to reduce water retention; restricting sodium intake and lowering sodium levels encourage diuresis. Typical commercial dog and cat foods have a sodium content of 0.45%–0.9% (450–900 mg sodium/100 g diet dry matter). Dietary sodium restriction is classified as mild (400 mg sodium/100 g diet dry matter) to severe (240 mg sodium/100 g diet dry matter). In view of these values, commercial dog and cat diets cannot even be classified as mild sodium restriction. Therefore, commercially prepared low-sodium diets or recipes that use low-sodium foods must be substituted. Sodium restriction often requires a special diet, although some manufacturers provide veterinary therapeutic diets for heart disorders. When using a home-prepared diet, all processed meats, cheeses, bread, heart, kidney, liver, salted fats, whole eggs, and snack foods should be avoided. Foods reasonably low in sodium include beef, rabbit, chicken, horsemeat, lamb, freshwater fish, oatmeal, corn, and rice.

Failed cardiac contractility may contribute to CHF, and taurine supplementation should be used to exclude a possible depletion of this amino acid in cardiac muscle. Both dogs and cats can develop dilated cardiomyopathy secondary to taurine deficiency. Some breeds of dogs with dilated cardiomyopathy may respond

favorably to carnitine supplementation, which has also been beneficial in some breeds of dogs with CHF (including Boxers and Cocker Spaniels), in dogs with cystine or urate urolithiasis, and in dogs consuming a protein-restricted diet. Because obesity can be a contributing factor in CHF, a weight management program is needed in obese animals in addition to sodium restriction. In some instances, edema may give the appearance of obesity and mask emaciation. The edema should first be resolved, so that body weight and condition can be evaluated. If the animal is underweight, the food intake should be increased or the caloric content of the diet increased. If renal failure is also present, protein and phosphorus intake must be restricted.

Diabetes Mellitus (DM): Most DM in dogs is type 1 (insulin dependent) due to immune-mediated destruction of pancreatic islet cells (*see* p 579). Although insulin sensitivity remains high in most diabetic dogs, no residual insulin production is left in the pancreas, and exogenous insulin therapy is required. Some dogs develop DM as a result of chronic pancreatitis causing widespread destruction of both endocrine and exocrine pancreatic tissue. Obesity does not appear to be a risk factor for developing DM in dogs, although obese dogs can have insulin resistance. Type 2 DM has not been reported in dogs, although some dogs may develop diestrus-associated diabetes that results in insulin resistance secondary to progesterone production. Remission of diabetes is possible when dogs are spayed or diestrus ends.

Some diabetic dogs have concurrent diseases, such as hyperadrenocorticism, and they may be very difficult to regulate if the hyperadrenocorticism remains untreated. Underlying urinary tract infection can also result in poor regulation and insulin resistance until the infection is cured. For diabetic dogs receiving insulin therapy, the nutritional requirements of any concurrent disease may take precedence over the dietary therapy for diabetes. Dietary recommendations for diabetic dogs without concurrent disease include feeding a diet that contains a moderate amount of a blend of soluble and insoluble fiber (3.5 g/100 kcal), such as a mixture of beet pulp and cellulose. Independent of the type of diet chosen, dietary intake should be consistent from day to day. Diabetic dogs usually require insulin twice a day, and it is recommended that dogs be fed first to ensure they eat before administering insulin.

Cats most commonly develop type 2 DM, although some cats may develop type 1, often secondary to chronic pancreatitis. The most common risk factors for DM in cats are obesity and increasing age. Most of these cats develop amyloid-mediated destruction of pancreatic islets. Although residual insulin capacity remains in most type 2 diabetic cats, insulin resistance is a characteristic of this form of DM.

Feline DM is similar to type 2 DM in people, and the main goals of therapy for diabetic cats are to control excess body weight and maintain optimal body condition, to reduce postprandial hyperglycemia and glucose toxicity, and to stimulate endogenous insulin secretion. Transient DM occurs in ~20% of diabetic cats, and these cats go into spontaneous remission usually within 1–4 mo after starting therapy for DM. The most likely reason for this is that untreated diabetic cats may develop glucose toxicity, and hyperglycemia decreases pancreatic β -cell function. When the cat is treated for DM and hyperglycemia is controlled, the glucose toxicity interfering with pancreatic islet cell function is removed.

Traditionally, diabetic cats have been fed fiber-supplemented diets similar to those recommended for diabetic dogs, and some cats have done well. However, more recently it has been shown that feeding diabetic cats a diet high in protein (>45% of calories) and low in carbohydrates (<20% of calories) improves glucose regulation and increases incidence of spontaneous remission. Nonetheless, some diabetic cats may have concurrent diseases for which the dietary management takes precedent.

Feline Lower Urinary Tract Disease (FLUTD): FLUTD (*see* p 1531) has many possible underlying causes, including urolithiasis, urethral plugs, urinary tract infection, neoplasia, neurologic abnormalities, feline idiopathic cystitis (FIC), and anatomic defects. The underlying cause of FLUTD must be determined, because treatment for one cause may be contraindicated for other causes. The most common cause of FLUTD is FIC, followed by urolithiasis. Urethral plugs are most commonly composed of either mucus or mucus and struvite crystals. Urinary tract infections in cats without renal failure or diabetes mellitus is uncommon.

Urine dilution appears to be helpful in the treatment of FIC, because it decreases the concentration of substances in the urine that may be irritating to the bladder mucosa. Numerous ways to dilute urine have been

investigated in cats, but one of the safest and most effective is to feed a canned-food diet. Other dietary modifications have been used to dilute urine, including sodium supplementation. Although sodium-supplemented diets are helpful in cats with FIC, they are contraindicated in cats with underlying renal disease. Highly acidic diets are not recommended, because highly acidic urine may increase sensory nerve fiber transmission in the bladder and increase pain perception. Regardless of treatment, clinical signs of FIC usually spontaneously resolve in 2–7 days. Unfortunately, FIC recurs within 12 mo in approximately half of the cats that experience spontaneous remission, and multiple recurrences are possible.

The two most common uroliths in the lower urinary tract of cats are magnesium ammonium phosphate (struvite) and calcium oxalate, although other mineral types are possible. Dietary management varies depending on the specific mineral composition of the urolith; however, regardless of composition, diluting the urine is important. Medical dissolution is an option for struvite uroliths but not for calcium oxalate uroliths. Producing a dilute urine reduces the concentration of minerals and crystals that form uroliths. Feeding a canned-food diet and encouraging water intake, eg, with water fountains, are safe and simple ways to dilute urine. Three major pet food companies have formulated diets for cats to manage both struvite and calcium oxalate. Two of these diets have high levels of sodium and, therefore, are contraindicated in cats with underlying renal disease. Diets reduce risk factors for developing uroliths but unfortunately do not prevent recurrence, which is common for calcium oxalate.

Fever: Fever increases energy requirements because of increased metabolic activity—a 1°F (0.5°C) rise causes an increase in caloric need of ~7 kcal/kg body wt/day. A highly palatable diet should be fed in quantities that can be consumed easily, and the caloric content should be increased by feeding a higher fat diet, if such a diet is not contraindicated. Because animals with fever generally have a decreased appetite, offering smaller meals more frequently with personal attention and encouragement may help stimulate intake. Feeding a feline growth diet or a calorically dense recovery-type diet also increases protein and energy intake in smaller feedings.

Gastric Dilatation (Bloat): Currently, there is little evidence to suggest that

certain specific nutrients in the diet, such as soy protein, lead to the development of gastric dilatation in susceptible dogs (*see* p 384). The most common risk factors for developing gastric dilatation and volvulus (GDV) include breed risks (ie, large breeds with a deep chest), eating only one meal/day, elevated feeding bowls, and vigorous exercise 1 hr before or 2 hr after eating. Prophylactic gastropexy has been shown to prevent GDV if performed at the time of elective surgical neutering, and owners of high-risk breeds should be so advised. Other recommendations to prevent GDV include feeding multiple small meals/day and avoiding vigorous exercise before and after eating.

Head Trauma, Burns, and Respiratory Diseases:

It is unknown whether the metabolic effects and energy expenditure in dogs and cats with severe head trauma, burns with ≥50% loss of skin, or prolonged dyspnea are the same as those in people with similar conditions. However, it is a reasonable supposition. The brain is one of the most metabolically active tissues; thus, providing aggressive nutritional support early is essential. Head trauma significantly alters neurologic control of metabolic rate, which is usually increased. Burns and other causes of significant areas of skin loss increase heat and water loss to the environment, thereby increasing energy needs. Increased respiratory rate and dyspnea are deceptively intense work that also result in increased energy needs. If a dog or cat is in an oxygen cage for >1 day, nutritional support (feeding IV or via feeding tube) should be instituted.

Brain trauma, burns, and sepsis are all conditions with high metabolic demands, and the amount of energy needed varies among animals. In all cases, energy is provided minimally at 30 kcal/kg body wt (dogs) or 40 kcal/kg body wt (cats) and increased in increments of 5 kcal/kg as the condition progresses and if weight loss is apparent. The energy source should be predominantly fat (60%–90% calories from fat, 10%–40% from glucose), because the body metabolism is predominantly lipolytic under these conditions, with the liver utilizing fat better than glucose during response to burns or trauma. Protein intake must also be matched with the energy intake to avoid net protein and muscle catabolism. Food that is 30%–45% protein and 25%–30% fat (dry-matter basis) and that is complete and balanced for all other nutrients should be fed using tube feeding. Human baby foods are not suitable for this

purpose. These nutritional goals can also be met by parenteral (IV) nutrition, remembering that enteral and parenteral support are not mutually exclusive.

Hepatic Disease: Dietary recommendations for dogs vary depending on the underlying cause and severity of liver dysfunction, and care must be taken to avoid overwhelming the metabolic capacity of the liver. In contrast, it is equally important not to unnecessarily restrict protein intake, because protein requirements are as high or higher in dogs with liver disease than in dogs without liver disease. Therefore, in dogs without encephalopathy, providing adequate intake of energy and a high-quality protein is essential to ensure a positive protein and energy balance and enable hepatic regeneration. Dietary antioxidants, such as vitamins C and E, as well as taurine, may also help minimize oxidative damage. Dietary copper restriction is recommended in dogs with documented increased copper levels in the liver.

In dogs with hepatic encephalopathy, reduced levels of high-quality protein may be necessary to reduce the accumulation of ammonia and other hepatic toxins. Soluble fiber or moderately fermentable fiber is helpful; colonic fermentation of these fibers produces short-chain fatty acids, which reduce both the intraluminal pH of the colon and the absorption of ammonia. Short-chain fatty acids also increase the blood supply to the colon and the amount of ammonia transported into the colon.

Frequent feeding of small meals (4–6/day) lowers the amount of nutrients or metabolites that require hepatic processing at a single time, thereby imposing less metabolic demand on the liver. Animals with liver disorders are frequently anorectic. Thus, food consumption and body weight and condition should be monitored.

Feline hepatic lipidosis is the most common liver disease in cats. It usually occurs in obese cats that are anorectic. This life-threatening condition requires aggressive nutritional support to reverse the changes in the liver. Most cats require a feeding tube. Energy-dense, high-protein diets, such as critical care diets, are usually selected for cats without encephalopathy. A step-wise reintroduction to calories is necessary to prevent complications, such as vomiting or electrolyte abnormalities. Hypokalemia is the most frequent electrolyte abnormality, and it can be exacerbated by too aggressive reintroduction to calories. Carnitine supplementation is also beneficial. Fluid needs must be met,

and parenteral fluid support may be needed in many cats, at least initially. In encephalopathic cats with hepatic lipidosis, dietary protein may need to be restricted but should not be severely so. These cats usually have protein malnutrition secondary to anorexia, and providing too little dietary protein can interfere with hepatic repair and regeneration.

See also HEPATIC DISEASE IN SMALL ANIMALS, p 429.

Hyperlipidemia in Dogs: Hyperlipidemia in dogs can be primary or secondary to hypothyroidism, pancreatitis, hepatic disease, diabetes mellitus, nephrotic syndrome, hyperadrenocorticism, or high-fat diets. Hyperlipidemia is present when blood lipids are increased with or without gross lipemia and probably results from abnormalities in the synthesis or use of plasma lipoproteins. In primary hyperlipidemia, the abnormalities can be familial and might be genetic, as has been suggested in Miniature Schnauzers. Some dogs with hyperlipidemia are asymptomatic. Clinically affected dogs may have recurrent seizures, depression, recurrent pancreatitis, vomiting, acute blindness, corneal opacity, and xanthogranulomas.

The goal of dietary management is to decrease the digestion and absorption of fat by feeding a diet restricted in fat (<10% dry-matter basis). The use of fish oil capsule supplements at a dosage of 1 g/4.5 kg body wt either once a day or in divided doses, depending on the number of capsules needed, helps reduce serum triglyceride concentrations. Although fish oil supplements generally do not return serum triglycerides to normal values, partial reduction is believed to mitigate the risk of pancreatitis or other problems related to marked increases of this lipid.

Malabsorption and Maldigestion in Dogs: Diseases of the small intestine and pancreas often lead to a vague clinical syndrome characterized by weight loss, vomiting, diarrhea (with or without steatorrhea), and changes in appetite. In such cases, a highly digestible diet low in fiber (0–5%), moderate in fat (10%–15%) and protein (20%–25%), and containing carbohydrate from noncerebral byproduct sources is recommended. Supplemental water-soluble vitamins should also be used. Malabsorption and maldigestion are often secondary to other underlying GI disease, such as inflammatory bowel disease. Appropriate management of the underlying disease may reverse malabsorption and

maldigestion. Exocrine pancreatic insufficiency (EPI) is one of the most common causes of malabsorption/maldigestion in dogs. Certain breeds of dogs, eg, German Shepherds, are at increased risk of developing EPI. EPI can also result from severe or chronic pancreatitis. In EPI, supplementation with a powdered enzyme supplement, mixed with the food a few minutes before feeding, should be considered. Parenteral administration of vitamin B₁₂ (cobalamin) is also required in some animals with EPI, especially cats. (See *also* MALABSORPTION SYNDROMES IN SMALL ANIMALS, p 400.)

Obesity: Obesity is the most common nutritional health problem in dogs and cats, and obesity-associated health risks continue to increase. Obesity is the excessive accumulation of adipose tissue—for dogs and cats, >20% above ideal body weight. Dogs and cats 10%–20% above ideal body weight are considered overweight. It is estimated that 24%–44% of dogs and 25%–30% of cats seen by veterinarians are overweight or obese, and ~50% of dogs 5–10 yr old are overweight or obese.

Obesity occurs when energy intake exceeds energy expenditure. Risk factors for developing obesity include 1) lack of exercise, 2) breed predisposition (breeds with an increased risk include Labrador Retrievers, Miniature Schnauzers, Dachshunds, Shetland Sheepdogs, Cocker Spaniels, Beagles, Basset Hounds, and Cairn Terriers), 3) increasing age (metabolic rate decreases with age as lean muscle mass decreases and fat mass increases, 4) neutering, 5) certain endocrine disorders, and 6) certain drugs, such as corticosteroids and phenobarbital.

Health problems associated with obesity include decreased life expectancy, impaired quality of life, chronic inflammation, pulmonary and cardiovascular problems, exercise and heat intolerance, joint and musculoskeletal problems (eg, arthritis), compromised immune function, pancreatitis (dogs), diabetes mellitus and hepatic lipidosis (cats), and increased morbidity and mortality during and after anesthesia.

Adipose tissue was long considered metabolically inert, and its primary role in disease was attributed to stress on the joints caused by increased weight bearing and increased workload on the heart. However, it is now known that adipose tissue is not inert, but rather a major endocrine organ that produces hormones and protein factors and signals called adipokines. The expression, production, and release of

many adipokines are increased in obesity, which results in persistent, low-grade inflammation and increased oxidative stress that plays a role in many chronic diseases, such as osteoarthritis and diabetes mellitus.

Treatment for obesity should include both short- and long-term goals. Short-term goals are to lose weight and reach an ideal body condition score. Long-term goals are to maintain ideal body condition score. Both of these goals require modification of behaviors that resulted in the dog or cat becoming overweight. Recommendations for lifestyle changes should be done in the context of maintaining the owner-animal bond. If this is ignored, owner compliance is unlikely.

The most successful weight loss programs include a combination of caloric restriction and exercise. The first step is to obtain a thorough diet history, followed by calculating the caloric intake appropriate to induce weight loss. Determining 60% of MER for dogs and 70% of MER for cats is one way to calculate starting caloric intake for a weight management program. Regardless of the formula used, the calculated caloric intake is only a starting point and may require modification based on response.

The next step is to decide on a diet for the weight loss program. Maintenance diets are generally not recommended for weight loss programs, because they are formulated to meet the nutritional needs of moderately active adults. Restricting caloric intake using maintenance diets may result in inadequate intake of some nutrients. Therapeutic weight loss diets are formulated to be restricted in calories while providing other nutrients in appropriate amounts. Adequate protein levels are important in any weight loss diet chosen. Most diets formulated for weight loss also have increased levels of dietary fiber. It is better to divide total daily caloric intake into multiple meals rather than one large meal. If giving treats is an important owner-pet interaction, providing the owner with low-calorie treat options is important. Most treats are not complete and balanced, so they should be restricted to <10% of the total caloric intake to avoid causing nutrient imbalances.

The next step is to decide on a rate of weight loss: a reasonable goal is loss of ~1% of body wt/wk. If the animal is losing weight at a slower rate than that chosen but is doing well otherwise and the owner is satisfied, then it may be best to allow weight loss to continue at the slower rate. The animal's weight should be monitored every 2 wk and the program modified if needed

based on response. Any weight loss is good weight loss, and celebrating successes with the owner helps maintain motivation.

Obese cats undergoing weight loss are at increased risk of developing hepatic lipodosis. Cats must continue to consume adequate calories and nutrients. If a cat does not like the weight loss diet chosen, then an alternative should be found. Starvation is never a safe or humane way to cause weight loss.

Pancreatitis in Dogs: The goal in treating pancreatitis is to minimize stimulation of the exocrine function of the pancreas until inflammation has decreased. Often, the dog has multiple episodes of vomiting. A standard treatment is nothing per os (NPO) until vomiting ceases, which can last 3–15 days. Antibiotic, fluid, and electrolyte therapy during NPO treatment is essential, and IV nutritional support (total parenteral nutrition) should be instituted if NPO therapy continues for ≥3 days. Adult and young dogs can be nutritionally maintained by IV parenteral solutions that provide adequate calories, protein, electrolytes, B vitamins, and selected trace minerals until oral feeding is possible. If the dog appears painful or uncomfortable, medications to manage pain as well as plasma transfusions should be administered.

Unfortunately, total parenteral nutrition does not provide any nutrients to the enterocytes, and atrophy of the gut occurs as in starvation. The amino acid glutamine provides ~40% of the energy needs to the small-intestinal epithelial cells; it can be provided orally in very small quantities every 8 hr to provide some nutrition for the enterocytes.

When oral feeding can be resumed, a commercially prepared, easily digestible diet that has moderate fiber (10%–15% dry-matter basis) and is low in fat (5%–10%) can be fed in small, frequent meals (3–6 times/day). Because recurrent episodes of pancreatitis are common, feeding a complete and balanced low-fat diet is recommended for long-term management. Obesity and hyperlipidemia are common concurrent problems and should be investigated and resolved.

Parvovirus Enteritis in Dogs: Parvovirus enteritis is most common in puppies 6–24 wk old. It is extremely infrequent in adult dogs. It is characterized by vomiting, diarrhea (often bloody), and weight loss. Severe cases can result in sepsis and disseminated intravascular coagulation. IV fluids, antiemetics, and antibiotic therapy

are important. Fluid rates must be sufficient to account for maintenance needs as well as ongoing losses. Crystalloid therapy or plasma transfusions may be necessary in hypoalbuminemic dogs. Food and water are usually withheld until vomiting ceases. Severe cases may require total parenteral nutrition. Once vomiting has ceased, small amounts of water are offered first. If there is no vomiting, then small amounts of an easily digestible diet should be fed until the dog recovers. (See also CANINE PARVOVIRUS, p 373.)

Chronic Kidney Disease (CKD): Numerous metabolic abnormalities that may alter an animal's nutritional status develop in progressive renal failure. These include impaired clearance of nitrogenous products of protein metabolism; impaired regulation of sodium, potassium, and phosphorus; acidosis; impaired vitamin D metabolism; and often anorexia. The objective of dietary management in renal failure is to lessen the metabolic demands on the kidneys and to diminish metabolic end-products that cannot be readily excreted. The first consideration is to ensure normal water homeostasis. Regardless of whether the animal is polyuric, oliguric, or anuric, water should always be readily available. In addition, dietary management remains the mainstay of therapy for animals with CKD. Therapeutic renal diets are formulated to address many of the metabolic abnormalities associated with CKD. Any therapeutic renal diet should be phosphorus restricted, supplemented with omega-3 fatty acids (EPA/DHA) that come from fish oil, alkalinizing, supplemented with B vitamins, and in cats supplemented with potassium. In addition, feeding moderately fermentable fiber can facilitate enteric dialysis and provide a nonrenal route of urea excretion. Newer research has also shown the benefits of antioxidants in the management of CKD in dogs. The rate of decline of glomerular filtration rate by use of both dietary omega-3 fatty acids and antioxidants were additive. In addition, research in dogs is also showing that higher protein levels than what are typically used in most therapeutic renal diets is beneficial as long as the diets are phosphorus restricted. Energy should be supplied primarily via feeding relatively more digestible fat and carbohydrates.

The criteria used (eg, serum creatinine concentration, BUN) to define when dietary modifications should be made are under debate. However, it is easier to change the diet when the animal is feeling reasonably well than when it is anorectic. There is good evidence that animals with International

Renal Interest Society (IRIS) Stage 3 and 4 CKD benefit from dietary management, and there is likely to be benefit in changing the diet early in the course of renal disease, such as that associated with IRIS Stage 2 CKD. Additional symptomatic and supportive care, such as H_2 -blockers, antiemetics, medications to treat hypertension, intestinal phosphate binders, calcitriol, erythropoietin, and potassium gluconate (in cats) may be necessary as the disease advances.

Urolithiasis in Dogs: The most common mineral composition for uroliths in dogs are primarily struvite (magnesium-ammonium-phosphate) and calcium oxalate, followed by urate and cysteine. Regardless of the type of stone, diluting the urine (eg, by encouraging water consumption) is warranted.

Struvite stones are more common in females than males. Most struvite stones in dogs are induced by infection with urease-producing bacteria. Although diet can be used to try to dissolve these stones, the most important therapy is to treat the urinary tract infection. Struvite stones can be medically dissolved, after which calculolytic therapeutic diets are usually unnecessary. Preventing a recurrence of the urinary tract infection and prompt treatment of a recurrence are important.

Calcium oxalate stones are not amenable to medical dissolution and must be removed through voiding, urohydropropulsion, surgery, or laser lithotripsy in symptomatic dogs. Two approaches are used for dietary management: 1) feeding an alkalinizing, protein-restricted diet low in oxalate, or 2) feeding a diet supplemented with sodium to encourage water consumption and production of dilute urine. Despite dietary management, the recurrence rate is high (33% in the first year and 50% by the third year).

Urate uroliths can occur in cases of liver disease, most commonly portosystemic shunts. However, two breeds of dogs,

Dalmatians and English Bulldogs, are predisposed to developing urate uroliths without overt liver dysfunction. Medical dissolution is an option and consists of using a protein-restricted diet low in purines and alkalinizing the urine in combination with treatment with allopurinol, a xanthine oxidase inhibitor. The use of low-dose allopurinol as a strategy to prevent recurrences is discouraged. Instead, water should be added to the diet in the maximal amount the dog can tolerate without needing to urinate overnight. Recurrence rates are high, especially in dogs 1–6 yr old; however, this stone type becomes much easier to manage once the dogs reach middle age.

Cystine urolithiasis is due to a renal tubular defect. It is most common in Dachshunds, English Bulldogs, French Bulldogs, and Newfoundlands. Medical dissolution is an option using dietary management and thiola. However, protein-restricted diets should be used with caution, because some of these dogs also have aminoaciduria and carnitinuria. (See **also** UROLITHIASIS IN SMALL ANIMALS, p 1525.)

Steatitis in Cats: Steatitis (pansteatitis, yellow fat disease) is seen most often in kittens fed exclusively large amounts of unsaturated fatty acids, oily fish such as tuna or mackerel (packed in oil not water), diets that do not have an appropriate balance of antioxidants relative to polyunsaturated fats, or diets that have gone rancid. Clinical signs are anorexia, fever, pain over the thorax and abdomen, neutrophilia, and subcutaneous nodules of necrotic fat. Cats with steatitis should be fed diets restricted in polyunsaturated fatty acids (monounsaturated and saturated fats are permitted) and given vitamin E supplementation at 10–20 mg, bid for 5–7 days. The diet of choice is a commercial food to which vitamin E (α -tocopherol) or other antioxidants have been added.

PUBLIC HEALTH PRIMER

Although only a minority of veterinarians report primary public health employment, virtually all veterinarians contribute to the overall public health effort. According to the World Health Organization, "health is a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity." Public health can be defined as the totality of all evidence-based public and private efforts that preserve and promote health and prevent disease, disability, and death. The concept of **One Health** is the collaborative effort of multiple health science professions, together with their related disciplines and institutions—working locally, nationally, and globally—to attain optimal health for people, domestic animals, wildlife, plants, and our environment.

One Health can be thought of as having three major subcomponents: basic sciences, clinical medicine, and public health. Major components of public health include population health, community health, mental health, environmental/ecological health, and occupational/recreational health. The differentiating variables among these components are the dynamics of the population(s), changing social/health behaviors, and, perhaps most importantly, the selection of the population to study/surveil. A relevant, frequently debated question is the definition of the "environment." Typically, it is equated with the "physical" environment and implies all influences other than social, economic, cultural, and genetic. An additional underlying theme in One Health is the economic environment in which it (and all professions that contribute to it) is pursued. Therefore, an understanding of basic economics is key to understanding the most practical application of (and opportunity for) One Health in a particular community, country, or region.

Public Health Practitioners: A generally accepted definition of a public health practitioner does not exist. However, for practical purposes, any health professional who sees and acts beyond the single patient is functioning in a public health capacity. Most typically, this includes physicians, veterinarians, dentists, nurses, epidemiologists, laboratorians, industrial hygienists, public health inspectors, and regulatory agency administrators. Allied health professionals, including optometrists, physi-

cian assistants, psychologists, pharmacists, entomologists, etc, also contribute according to the scope of their respective practices. No medical profession exists in a vacuum.

Many public health practitioners possess specific training, and various board-certifying bodies, accrediting entities, and professional societies bolster this training by requiring experience and fostering collaboration. These include the American College of Preventive Medicine, the American College of Veterinary Preventive Medicine, the American Public Health Association, the American Society of Public Health, and the Association of State and Territorial Health Officials.

Several overarching public health organizations have jointly developed a set of core competencies that reflect skills appropriate to the effective delivery of public health services. Core competencies are divided into the following eight domains: 1) analytic/assessment skills, 2) policy development/program planning skills, 3) communication skills, 4) cultural competency skills, 5) community dimensions of practice skills, 6) public health sciences skills, 7) financial planning and management skills, and 8) leadership and systems thinking skills.

PUBLIC HEALTH AGENCIES

In the USA, responsibilities and authorities for health services are spread across federal, state, and local levels of government. In addition, certain nongovernmental organizations perform critical functions regarding the provision and influence of public health policies.

Federal Level: The Constitution contains no legal basis for the provision of health care to the general population. Therefore, as per the Tenth Amendment, this responsibility automatically falls to the states. When the federal government directly influences national health care issues, it generally does so under the auspices of the Constitution's Interstate Commerce Clause, which gives Congress the power "to regulate commerce with foreign nations, and among the several states, and with the Indian tribes." The federal government also significantly influences health care issues in an indirect fashion through the provision of federal funds. Commonly, funds allocated to state and local governments for health issues are

contingent on that entity participating in national programs such as disease reporting and adhering to national health goals and standards.

The Department of Health and Human Services (DHHS) is the primary public health agency at the federal level and serves to assess the general health of the nation, establish national goals and policies, and direct federal efforts in support of the states. Major public health–oriented components of DHHS include the Agency for Healthcare Research and Quality (AHRQ), the Agency for Toxic Substances and Disease Registry (ATSDR), the Centers for Disease Control and Prevention (CDC), the Food and Drug Administration (FDA), the Health Resources and Services Administration (HRSA), the Indian Health Service (IHS), the National Institutes of Health (NIH), and the Substance Abuse and Mental Health Services Administration (SAMHSA).

Other federal departments with significant equities in national health care and public health responsibilities include 1) Department of Agriculture (USDA), which is responsible for meat inspection and disease prevention and control; 2) Department of Defense (DoD), which is responsible for health care policies and provision of health care for active duty members, family members, and retirees; 3) Department of Homeland Security (DHS), which is responsible for disaster planning and response; 4) Department of the Interior (DoI), which operates the National Park Service (public health and disease outbreak investigations on National Park lands), the Bureau of Indian Affairs (treaty obligations to tribes, including provision of health care and environmental health infrastructure projects), and the Bureau of Reclamation (provides potable drinking water and agricultural irrigation water to much of the western USA); 5) Department of Veteran Affairs (VA), which is responsible for health care policies and provision of health care for qualified veterans, and administers significant civilian medical education systems; and 6) Environmental Protection Agency (EPA), which sets and enforces national environmental health standards.

State Level: The state is the primary public health legal authority. Although specific activities and delegations may vary from state to state, state public health responsibilities generally include the following: 1) collection and maintenance of vital health data, 2) maternal and child health, 3) diagnostic and public health laboratories, 4) state-wide nutrition programs, 5) regulation of health facilities (including nursing homes),

6) environmental health programs (eg, safe drinking water, waste treatment), 7) state Medicaid program, and 8) regulation and licensing of medical professionals (eg, veterinarians, physicians, dentists, etc).

Local Level: Local public health agencies are structured and empowered to provide services where they are most effective—at the community level. These services may be primary or delegated from the state level and commonly include the following:

1) immunizations not covered under private insurance systems, 2) disease surveillance and investigation, 3) communicable disease control, 4) inspection and licensing of food establishments, 5) public health screening programs, 6) tobacco control programs, 7) disaster preparedness and response, and 8) care for the underserved, indigent, and disabled.

Nongovernmental Organizations

(NGOs): An NGO is any nonprofit, voluntary citizens group organized on a local, national, or international level. Task-oriented and staffed by individuals sharing common interests, NGOs perform a variety of service and humanitarian functions. Functions of health-oriented NGOs may include raising citizen concerns to governments, advocating and monitoring health policies, and encouraging political participation through public information dissemination. NGOs that exist and act domestically (and overseas in some cases) in the public health sector include the American Red Cross, the American Cancer Association, the American Lung Association, the CDC Foundation, Heifer International, the March of Dimes, and the Bill and Melinda Gates Foundation.

ROLE OF THE VETERINARIAN IN PUBLIC HEALTH/ONE HEALTH

Most veterinarians contribute, directly or indirectly, to public health goals and outcomes. Veterinary public health contributions can be categorized into six core domains, described below.

Diagnosis, Surveillance, Epidemiology, Control, Prevention, and Elimination of Zoonotic Diseases:

Most private veterinary practitioners contribute to public health during routine practice. Both large and small animal practitioners become skilled diagnosticians for acute and chronic diseases of animals that may affect the owners and their families and the surrounding communities. Specific examples of public health activities include performing routine

health examinations, maintaining immunization regimens, implementing parasite control programs, advising on the risks of animal contact for immunocompromised individuals, facilitating the use of guide and service dogs for people with disabilities, and promoting the benefits of the human-animal bond for the disabled and elderly, as well as war veterans and others suffering from post-traumatic stress disorder. Communities are best served when veterinarians approach collective health issues with a "herd health" perspective, applying relevant epidemiologic principles. In addition to these direct services, veterinary practitioners report disease events and trends to state public health and regulatory agencies, collaborate with human medical counterparts on zoonotic diseases, and advise local health boards and commissions. These relationships would not exist if not for the inextricable link between animal and human health.

In addition to managing direct zoonotic diseases in animals, veterinarians also diagnose, investigate, and control indirect zoonoses and non-zoonotic communicable diseases that affect human health. Examples include West Nile disease and coccidioidomycosis among pet animals, and bovine leukosis, foot and mouth disease, fowlpox, and many other diseases that affect the food supply, the national economy, and the livelihood of the nation's farmers.

Many factors contribute to the increasing vulnerability of livestock to infectious disease. These include increasing intensity and concentration of production agriculture, genetic convergence of many food-producing species, accessibility of livestock to external contact (despite rigorous biosecurity measures), scale and frequency of animal transport (domestic and international), increasing size of feedlots, lack of immunity to foreign animal diseases, the relatively porous nature of national borders, and the significant shortage of trained foreign animal disease diagnosticians and epidemiologists. Although many significant diseases transmitted by food-producing animals (eg, brucellosis, tuberculosis, coxiellosis/Q fever, etc) have been eradicated or controlled in North America and Europe by pasteurization and inspections at slaughter, still many others are seemingly ubiquitous (eg, listeriosis, salmonellosis, staphylococcosis, etc) and cause a significant fraction of the national burden of foodborne morbidity and mortality. Each year in the USA, there are reported approximately 20,000 foodborne illnesses, 4,200 hospitalizations, and 80 deaths, most of which are caused by pathogens of animal origin.

Management of Health Aspects of Laboratory Animal Facilities and Diagnostic Laboratories:

The challenges of recognizing resurgent infectious diseases and developing novel therapeutics have placed unprecedented emphasis on managing and maintaining laboratory animal colonies for research and diagnostic efforts. Providing these services both successfully and humanely falls to the veterinarians in these institutions. Because few nations have the individual capacity to provide these services internally, increasing emphasis is being placed on international collaboration and reference centers, many of which focus on zoonotic diseases and comparative medicine. Because most outbreaks of zoonotic disease occur in tropical regions devoid of local surveillance and diagnostic and response capacity, the role of these international collaboration and reference centers likely will expand, requiring larger numbers of trained, experienced veterinary personnel.

Biomedical Research: Building on the information from public health surveillance, research institutions must follow with a greater understanding of the interactions between hosts, parasites, vectors, pathogens, and the environment. Establishing a causal link between human and animal disease relies on such research efforts, often through some combination of molecular studies, mathematical theory, and experimental epidemiology, using either field or laboratory research. As highlighted by the World Health Organization, research of endemic and resurgent zoonoses is often handicapped by a lack of basic knowledge of host-parasite interactions. For many zoonotic species, even the route of transmission to people remains uncertain. In some cases, the molecular biology of the agents in human and animal hosts may be very different. For example, there are major research efforts aimed toward the identification of virulence factors for *E. coli* O157:H7 and the reasons for their differential expressions in people and cattle.

Health Education and Extension: Although training new veterinary practitioners and disseminating new capabilities to those already in practice falls largely on the nation's academic (especially land-grant) institutions, virtually all veterinarians help educate the public on the threat of infectious and noninfectious diseases. At the collegiate level, this will increasingly involve multidisciplinary relationships between schools of medicine, veterinary medicine, sociology, and basic sciences.

Enabling appropriate knowledge and awareness among the public requires a skillful blend of risk perception and risk awareness, especially because community stakeholders play significant roles in risk resolution. Most epidemiologists are employed by governmental or industrial stakeholders that have not historically been viewed as valid proxies for the public. This represents an important opportunity, perhaps responsibility, for veterinary practitioners to remain knowledgeable about disease threats and credible sources of that knowledge for their communities.

Production and Control of Biologic Products and Medical Devices: Ensuring that animal drugs, vaccines, and devices are safe and efficacious is a shared responsibility between the FDA, the USDA, and the EPA. In general, the FDA, specifically the Center for Veterinary Medicine, regulates animal drugs, animal feeds, and veterinary devices, whereas the USDA regulates animal vaccines and biologics. Specific to pesticides, FDA regulates certain flea and tick products for animals, whereas the EPA regulates others. Within each of these governmental agencies, veterinarians serve to encourage the development of novel products and, at the same time, protect the consumers of those products from false or misleading claims.

Another important function regarding biologic agents is the regulation of their storage, use, and transfer. Because of inherent virulence and transmissibility, access to many disease pathogens, termed **select agents**, has increasingly been limited to legitimate facilities for legitimate uses. The Federal Select Agent Program is jointly administered by the CDC and the USDA's Animal and Plant Health Inspection Service (APHIS). This effort oversees the possession, use, and transfer of certain biologic agents and toxins that have the potential to pose a severe threat to the public, to animal or plant health, or to animal or plant products.

Government/Legislative Activity: Significant numbers of veterinarians are employed at various levels of state and federal government. More than 3,000 veterinarians are employed at the federal level, nearly two-thirds of which are with the USDA. Other federal agencies employing large numbers of veterinarians include the DoD (Army and Air Force) and DHHS (CDC, FDA, and NIH). Public health programs comprise the vast majority of these opportunities, with direct animal care

being a minor fraction. Examples include oversight of food safety inspection programs, disease surveillance and outbreak investigation, laboratory animal care, biomedical research, and public health program management and leadership.

At the state level, each department of agriculture typically has a State Veterinarian who is responsible for protecting the livestock, poultry, and aquaculture industries directly, and the public indirectly, through the prevention, early detection, containment, and eradication of economically important livestock, poultry, and fish diseases that, in many cases, are transmissible to people. The State Veterinarian regulates the importation, transportation, and processing of animals and is responsible for the control and eradication of poultry and livestock diseases, regulation of fish farming, and emergency response programs. Welfare of farm animals is monitored, and when necessary, the Office of the State Veterinarian conducts investigations and prosecutions relating to cases of cruelty to animals.

Currently, 41 states and territories employ veterinarians in their state health departments as State Public Health Veterinarians (SPHVs). SPHVs generally work in zoonotic disease control and prevention, directly focusing on protecting public health. They typically are located in health department divisions of epidemiology, toxicology, or environmental health.

A final category of governmental activity is legislative; a relatively small number of veterinarians serve at various levels to promulgate laws, rules, and regulations that serve to protect public health, domestic preparedness, and national defense. Veterinarians serve in the United States House of Representatives, in senior leadership positions of several United States Cabinet-level departments (including USDA, DHHS, DoD, and DHS), and as legislative liaisons for professional associations such as the AVMA. They are assisted in their legislative efforts by the communicative action of practicing veterinarians across the nation. It is through this pathway that ideas and issues are effectively transmitted to legislators and translated into improved legal and policy outcomes.

SIGNIFICANT NATIONAL PUBLIC HEALTH ACHIEVEMENTS

During the 20th century, the health and life expectancy of Americans improved dramatically. Since 1900, the average

life span of people in the USA has increased by 30 yr, largely attributable to advances in public health. To commemorate these advances, the CDC named the following as the Ten Great Public Health Achievements, 1900–1999: vaccination, motor vehicle safety, safer workplaces, control of infectious diseases, mortality decline from coronary heart disease and stroke, safer and healthier foods, healthier mothers and babies, family planning, fluoridation of drinking water, and recognition of tobacco as a health hazard.

To further commemorate national advances in public health and to specifically highlight the veterinary public health contribution to the overall effort, the following were named as the Ten Great Veterinary Public Health Achievements—United States, 1901–2000.

1) Eradication of animal disease: Largely attributable to national programmatic efforts involving local, state, and federal veterinarians, the following diseases were declared eliminated from animal populations within the USA: contagious pleuropneumonia (1892), fowl plague (1929), foot-and-mouth disease (1929), glanders (1934), dourine (1942), cattle tick fever (1943), vesicular exanthema of swine (1959), screwworm myiasis (1959), sheep scabies (1973), exotic Newcastle disease (1974), and classical swine fever (hog cholera, 1978).

2) Laboratory animal science: The first professor of laboratory animal science in the USA was Dr. Carl Schlotthauer, appointed in 1945 at the University of Minnesota. Dr. Charles Griffin oversaw the development of pathogen-free animal colonies at the New York State Board of Health Laboratories from 1919 to 1954. Other veterinary pioneers in laboratory animal medicine included Dr. William Thorp at the National Institutes of Health, Dr. James Steele at the CDC, and Dr. Karl Meyer at the University of California at San Francisco.

3) Infectious disease control: In 1900, tuberculosis was the leading cause of death in people in the USA and commonly resulted in malformations in the bones of children. Of this disease burden, 40%–50% was reported to be bovine in origin, as the result of drinking unpasteurized milk. Constant public health (Pasteurized Milk Ordinance; FDA) and veterinary disease control (USDA eradication program) measures have eliminated this route of transmission in the USA. The early 1900s also saw the discovery of the etiologic agents for many prevalent animal diseases. Among these were African horse sickness (1900), rinderpest (1902), sheepox (1902), rabies (1903), hog cholera (1903), and the

first discovery of a viral cause of a cancer, fowl leukosis (1908). On a broader scale, the first cancer-preventing vaccines, which are to protect against Marek disease and feline leukemia virus, were developed by veterinarians and are contributing to development of human applications.

4) Livestock herd health and production optimization: Dr. C.L. Cole, who was at the North Central Experiment Station at Grand Rapids, Minnesota, was the first to demonstrate that large numbers of cows could be bred successfully by artificial insemination (1937–1938). The first calf sired by artificial insemination of frozen semen was born in 1953. A 10-year dairy production study published in the late 1940s noted that among the many benefits of annual physical examinations for dairy cattle was an average increase in milk production of 40%. More recently, widespread application of preventive medicine and environmental health best practices serve to maximize dairy cow health and comfort, all but eliminating milk as a source of foodborne illness. Moreover, annual milk production increased from 5,000 to 21,000 lb per cow.

5) Food safety (human): Although the 1904 publication of Upton Sinclair's provocative book *The Jungle* led to the dismissal of Dr. Daniel E. Salmon from the fledgling Bureau of Animal Industry, the resultant public furor successfully reinvigorated his mission and facilitated the promulgation of the Meat Inspection Act of 1906. Dr. Salmon's contribution to foodborne disease control was considered so valuable that the *Salmonella* spp were named for him. In 1900, the first local community instituted routine microbiologic examination of milk. In 1908, Chicago required pasteurization of dairy products and, in 1948, Michigan was the first state to require milk pasteurization. In the 1920s, veterinarians also accomplished the basic work in developing the USPHS (FDA) Pasteurized Milk Ordinance and Code. Although slow to achieve industry acceptance, irradiation of food has substantial beneficial effects on the safety and quality of many foodstuffs. Previously approved for items such as spices, fruits, vegetables, and poultry, ionizing radiation was approved for use in 1999 to reduce bacterial loads on frozen raw meat and meat by-products.

6) Recognition and enhancement of the human-animal bond: Throughout recorded history, mankind has partnered and benefited from association with domesticated animals. The dairy cow is recognized as the "foster mother of the human race," and the horse, ox, donkey, camel, water buffalo, reindeer, and yak have provided mankind with our primary

transport and tractor power for thousands of years. Indeed, the histories of all animals, including people, cannot be dissociated. That symbiotic partnership, perhaps the cornerstone of veterinary medicine, became the life work of Dr. Leo Bustad, who once stated, "One cannot have a healthy community without a strong human-animal bond." An enhanced understanding of that inextricable bond has led to relationships between people and animals, including guide dogs for the vision and hearing impaired and military working dogs and dolphins. Further, the positive physical and psychological benefits of human-animal relationships, such as the lowering of blood pressure and as companions for older, ill, and traumatized people, have been described.

7) Border inspection/surveillance: The USDA has primary responsibility for preventing the introduction or reintroduction of foreign animal diseases into the USA. The Herculean proportions of this task are exemplified by the fact that before free trade, the USA imported 1.9 million cattle, 700,000 swine, and about 28 million birds annually. Inspecting representative samples of these animals and their by-products is the direct or indirect task of USDA veterinarians. This effort has been greatly aided since 1954 by the USDA Foreign Animal Disease Diagnostic Laboratory on Plum Island, New York, which provides valuable research toward the prevention and control of these biologically and economically devastating diseases. Similarly, veterinarians employed by DHHS/CDC's Division of Global Migration and Quarantine and the U.S. Fish and Wildlife Service (Department of the Interior) oversee programs to control importation of nonhuman primates, vector species, and potentially dangerous or injurious wildlife species.

8) Surgery and medicine: Regional anesthesia via the spinal route was first introduced in the USA at the 1926 AVMA meeting. Dr. Otto Stader developed the first steel pin method for external fracture fixation. In the 1950s, Dr. H. A. Gorman developed the first prosthetic hip joint, and Dr. F. L. Earl discovered the tranquilizing effects of reserpine.

9) Uniformed services/veterinary medicine: In 1916, with the establishment of the United States Army Veterinary Corps, the USA was the last of the industrialized countries to commission a corps of military veterinarians. During World War II, army veterinarians were credited with providing higher quality rations for troops, as well as more space for armaments on cargo ships by thoroughly trimming meat products and freezing them in

compact containers. Dr. Robert A. Whitney, Jr. (USPHS) served as Deputy Surgeon General and later as the Acting Surgeon General in 1993. Today, veterinarians in the U.S. Army, Air Force, and Public Health Service contribute substantially to military and civilian public health missions, such as human and animal disease control, occupational health, food safety, medical research, deployment health surveillance, and biologic warfare/terrorism defense.

10) Integration with public health practitioners: Under the leadership of Dr. Karl Meyer, an early architect of veterinary public health, the Hooper Foundation of Medical Research became a leading institute for the study of comparative medicine and zoonotic diseases. Additionally, he developed the original curriculum for the University of California School of Public Health. One of the many important achievements by Dr. James H. Steele was the status elevation of veterinarians in the USPHS from sanitarians to veterinary medical officers. Dr. Calvin Schwabe's seminal work, *Veterinary Medicine and Human Health* (1964), provides one of the most concrete examples of this integration.

NATIONAL PUBLIC HEALTH INDICATORS

Unfortunately, there are no direct measurements of public health in a population. Therefore, it is difficult to compare overarching changes over time or against other populations, except with surrogates such as surveillance for specific diseases/events and specific population attributes. Accepted among many public health officials is some combination of the following national health indicators: 1) life expectancy at birth (years)—the average number of years that a newborn could expect to live, if he or she were to pass through life exposed to the sex- and age-specific death rates prevailing at the time of his or her birth; 2) infant mortality rate (per 1,000 live births)—the probability of a child born in a specific year dying before reaching the age of 1 yr; 3) age-standardized mortality rate (number/unit population)—a weighted average of the age-specific (ages 30–70) mortality rates per 100,000 persons, in which the weights are the proportions of persons in the corresponding age groups of the WHO standard population; 4) childhood immunization rate (%)—the percentage of children (19–35 mo old) who have received the recommended combined vaccine series; 5) annual

population growth rate (%)—average exponential rate of annual growth of the population over a given time period; 6) density of physicians (number/unit population)—number of medical doctors (physicians), including generalist and specialist practitioners, per 10,000 persons; 7) gross national income per capita (\$USD)—total annual purchasing power, standardized to the US dollar; 8) government expenditure on health as a percentage of total government expenditure (%); 9) per capita total expenditure on health (\$USD); 10) population median age (years); 11) obesity (%)—adults (>20 yr old) who have a body mass index (BMI) ≥ 30 kg/m².

ESSENTIAL PUBLIC HEALTH FUNCTIONS

Under the auspices of DHHS, the USPHS developed (and adopted in 1994) the following ten essential public health functions to assist state and local health agencies achieve their mission of promoting physical and mental health and preventing disease, injury, and disability.

1) Monitor health status to identify community health problems. A generally accepted definition of public health surveillance is “the ongoing systematic collection, analysis, interpretation, and dissemination of outcome-specific data essential to the planning, implementation, and evaluation of public health practice.” Without this type of activity over time, baseline data cannot be analyzed for adverse events and trends.

2) Diagnose and investigate health problems and health hazards in the community. As an adjunct to surveillance, public health agencies conduct targeted screening programs and/or surveys to detect problems and hazards in the community. When detected, they are investigated to determine their magnitude, and results are used to inform public education and prevention efforts.

3) Inform, educate, and empower people about health issues. Once priorities have been established through surveillance, detection, and investigation, educational activities that promote improved health should be disseminated.

4) Mobilize community partnerships to identify and solve health problems. Public health agencies at all levels can mobilize community partnerships to solve health problems. Of particular importance is identification of potential stakeholders who can contribute to or benefit from public health interventions.

5) Develop policies and plans that support individual and community health efforts. Policies and laws can effectively modify human behavior and reduce negative health outcomes. Examples include limiting access to high-calorie beverages in school-age children and “dram shop liability” to discourage overconsumption of alcoholic beverages in public establishments.

6) Enforce laws and regulations that protect health and ensure safety. The existence of policies and laws is not enough; compliance must be enforced to ensure the overall safety and health of the community. Ongoing assessment and education efforts are undertaken to ensure that these policies and laws remain relevant and known to the public.

7) Link people to needed personal health services and assure the provision of health care when otherwise unavailable. Having access to care when it is needed is important in helping individuals prevent and avoid unfavorable health outcomes and medical costs. Components of these efforts are undertaken at the local, state, and federal levels to provide a coordinated system of health care.

8) Assure a competent public health and personal health care workforce. Competent health care workers provide care more effectively and efficiently than those less competent. This is facilitated by licensing and credentialing processes, incorporating core public health competencies into personnel systems, and adopting continual quality improvement opportunities for public health workforce members.

9) Evaluate effectiveness, accessibility, and quality of personal and population-based health services. Given scarce resources, it is imperative to assess whether programs and policies achieve intended outcomes. Cost-effectiveness analyses have been proposed as one strategy to inform policymakers on how best to allocate health care resources.

10) Support/sponsor research for new insights and innovative solutions to health problems. From the evidence-based results of coordinated research programs, health and health care problems can be better understood and improved over time.

PUBLIC HEALTH FOCI OF PREVENTION

When considering opportunities and methods to address health problems, three stages of prevention are generally recognized:

1) Primary prevention—focuses on avoiding development of a disease by preventing

it before exposure. Examples of primary prevention strategies include immunization programs, health education, and smoking cessation interventions. Because disease is largely avoided by these strategies, primary prevention is generally regarded as the most cost-effective form of prevention.

2) Secondary prevention—focuses on early disease detection and intervention, ideally before the onset of clinical signs. Examples include screening programs against various forms of cancer (eg, breast, colon, prostate, etc), postexposure rabies prophylaxis, tuberculosis skin tests, and infectious disease contact investigations.

3) Tertiary prevention—focuses on the treatment and rehabilitation of individuals with disease(s). Examples include antimicrobial therapies, hypertension drugs, and heart attack and stroke rehabilitation. Because this stage focuses its efforts after a disease is established, tertiary prevention has proved the most expensive form of prevention.

BASIC PRINCIPLES OF EPIDEMIOLOGY

The definition of epidemiology is “the study of disease in populations and of factors that determine its occurrence over time.” The purpose is to describe and identify opportunities for intervention. Epidemiology is concerned with the distribution and determinants of health and disease, morbidity, injury, disability, and mortality in populations. For veterinary epidemiology, this intervention is to enhance not only health but also productivity. **Distribution** implies that diseases and other health outcomes do not occur randomly in populations; **determinants** are any factors that cause a change in a health condition or other defined characteristic; **morbidity** is illness due to a specific disease or health condition; **mortality** is death due to a specific disease or health condition; and the **population at risk** can be people, animals, or plants.

Epidemiology is applied in many areas of public health practice. Among the most salient are to observe historical health trends to make useful projections into the future, discover (diagnose) current health and disease burden in a population, identify specific causes and risk factors of disease, differentiate between natural and intentional events (eg, bioterrorism), describe the natural history of a particular disease, compare various treatment and prevention products/techniques, assess the impact/efficiency/cost/outcome of interventions, prioritize intervention strategies, and provide foundation for public policy.

Epidemiologic Terms and Concepts

The **natural history** of a disease in a population, sometimes termed the disease's ecology, refers to the course of the disease from its beginning to its final clinical endpoints. The natural history begins before infection (prepathogenesis period) when the agent simply exists in the environment, includes the factors that affect its incidence and distribution, and concludes with either its disappearance or persistence (endemicity) in that environment. Although knowledge of the complete natural history is not absolutely necessary for treatment and control of disease in a population, it does facilitate the most effective interventions.

An important epidemiologic concept is that neither health nor disease occurs randomly throughout populations. Innumerable factors influence the temporal waxing and waning of disease. A disease is considered **endemic** when it is constantly present within a given geographic area. For instance, animal rabies is endemic in the USA. An **epidemic** occurs when a disease occurs in larger numbers than expected in a given population and geographic area. Raccoon rabies was epidemic throughout the eastern USA for much of the 1980s and 1990s. A subset of an epidemic is an **outbreak**, when the higher disease occurrence occurs in a smaller geographic area and shorter period of time. Finally, a **pandemic** occurs when an epidemic becomes global in scope (eg, influenza, HIV/AIDS).

The **population at risk** is an extremely important concept in epidemiology and includes members of the overall population who are capable of developing the disease or condition being studied. This concept seems simple at first, but misinterpretations can lead to erroneous study results and conclusions. As a simple example, a study of testicular cancer among residents in a population should not include women in the population at risk (frequently expressed as the “denominator” in an epidemiologic ratio).

A **ratio** is the value obtained from dividing one quantity by another (X/Y). The numerator and denominator may be independent of each other. In fact, in epidemiology, the term ratio is applied when the numerator is not a subset of the denominator. For example, in a class of veterinary students in which 88 are female and 14 are male, the sex ratio of female students to male students is 88/14, or 6.3 to 1.

A **proportion** is a type of ratio in which the numerator is part of the denominator ($A/[A + B]$). Therefore, they are not independent. For example, suppose that, among domestic dogs testing positive for

internal parasites in Glendale, Arizona, 889 were male and 643 were female. The proportion of female dogs among those found to have parasite infections would be $643/(889 + 643)$, or 0.42.

A **rate** is another type of ratio in which the denominator involves the passage of time. This is important in epidemiology, because rates can be used to measure the speed of a disease event or to make epidemiologic comparisons between populations over time. Rates are typically expressed as a measure of the frequency with which an event occurs in a defined population in a defined time (eg, the number of foodborne *Salmonella* infections per 100,000 people annually in the USA).

Incidence is a measure of the new occurrence of a disease event (eg, illness or death) within a defined time period in a specified population. Two essential components are the number of new cases and the period of time in which those new cases appear. In an example regarding the class of veterinary students, if 13 of them developed influenza over the course of 3 mo (one quarter), the incidence would be 13 cases per quarter.

An **incidence rate** takes the population at risk into account. In the previous example, the incidence rate would be 13 cases per quarter/102 students, or 0.127 cases per quarter per student. Incidence rates are usually expressed by a multiplier that makes the number easier to conceptualize and compare. In this example, the multiplier would be 100, and the incidence rate would be 12.7 cases per quarter per 100 students (or 12.7%). An **attack rate** is an incidence rate; however, the period of susceptibility is very short (usually confined to a single outbreak).

A similar concept to incidence is **prevalence**. Prevalence (synonymous with "point prevalence") is the total number of cases that exist at a particular point in time in a particular population at risk. Again using the influenza example from above, if 7 students had influenza at the same time during the academic quarter, the prevalence would be $7/102$ or 0.069 cases per class (or 6.9%).

Measures of disease burden typically describe illness and death outcomes as **morbidity** and **mortality**, respectively. Morbidity is the measure of illness in a population, and numbers and rates are calculated in a similar fashion as with incidence and prevalence. Mortality is the corresponding measure of death in a population and can be applied to death from general (nonspecific) causes or from a specific disease. In the latter case, cause-specific mortality is expressed as the **case**

fatality rate, which is the number of deaths due to a particular disease occurring among individuals afflicted with that disease in a given time period. In another example, consider a large veterinary practice in the southwest USA that frequently sees dogs with coccidioidomycosis. The practice diagnosed 542 clinical cases in a particular year, 83 of which died from the disease in the course of that year. The month in which the most cases were diagnosed was September, in which 97 cases were diagnosed. Further, at a single point in time (perhaps based on the results of a serosurvey of dogs in the practice area), 237 dogs of 6,821 dogs with active records in the practice had the disease. In this scenario, the prevalence of coccidioidomycosis at the time of the serosurvey would be $237/6,821$ or 0.035 (3.5%); the incidence in September would be $97/6,821$ or 0.014 (1.4%). Finally, the annual mortality rate due to coccidioidomycosis would be $83/6,821$ or 0.013 (1.3%), and the case fatality rate would be $83/542$ or 0.153 (or 15.3%).

Public health surveillance is defined as the ongoing systematic collection, analysis, interpretation, and dissemination of outcome-specific data essential to the planning, implementation, and evaluation of public health practice. In epidemiology, health surveillance is accomplished in either passive or active systems. **Passive surveillance** occurs when individual health care providers or diagnostic laboratories send periodic reports to the public health agency. Because this reporting is voluntary (sometimes referred to as being "pushed" to health agencies), passive surveillance tends to underreport disease, especially in diseases with low morbidity and mortality. Passive surveillance is useful for longterm trend analysis (if reporting criteria remain consistent) and is much less expensive than active surveillance. An example of passive surveillance is the system of officially notifiable diseases routinely reported to CDC by select health departments across the USA. **Active surveillance**, in contrast, occurs when an epidemiologist or public health agency seeks specific data from individual health care providers or laboratories. In this case, the data are "pulled" by the requestor, usually during emerging diseases or significant changes in disease incidence. Active surveillance is usually much more expensive and labor intensive; it typically is limited to short-term analyses of high-impact events. An example is the 1-yr surveillance conducted by CDC of the rapid increase in incidence of coccidioidomycosis among people in Arizona in 2007–2008.

Descriptive Epidemiology

Given that neither health nor disease is equally distributed throughout a population, epidemiologists use various methods to study and describe their occurrence. In descriptive epidemiology, diseases are classified according to the variables of person, place, and time.

Person: Who is affected by this disease?

This is relevant, because certain variables may highlight changes in disease status and can be used to focus additional studies and interventions. Common person variables include age, sex, race, socioeconomic status, marital status, religion, smoker/nonsmoker, etc. In the case of animals, equivalent variables may include species, breed, reproductive status (eg, intact vs neutered, pregnant vs nonpregnant), function (eg, meat/milk/fiber production, race horse vs working horse vs pleasure horse, companion dog vs military working dog), and wild/feral vs domesticated (cats).

Place: Where does this disease occur?

Place variables commonly illustrate geographic differences in the occurrence of a particular disease. Focused studies can help epidemiologists to determine why those differences have occurred and to identify specific risk factors. Common place variables include comparisons across national, state, and municipal boundaries and between urban and rural communities. For animal populations, "place" may refer to housing (eg, indoors vs outdoors, pen number or stall) or type of herd management (eg, intensive feedlot confinement vs extensive grazing). Place may also relate to risk of exposure to infectious animals at sale barns or during shipment or to external factors such as severe weather and natural disasters.

Time: When and over what time period (hours, days, weeks, day vs night) does this disease occur? Time variables are important to describe when disease occurs in relation to various factors of potential exposure and vulnerability. In animals, time may refer to milking shift, breeding season, lambing/calving season, at weaning, during shipment, on arrival at the feedlot, dry vs wet season, etc. Common time variables include secular trends (changes over long periods of time), seasonal/cyclic periods, and specific points in time (eg, outbreaks, epidemics, clusters, etc).

When a particular disease is observed relative to the variables of person, place, and time, it is often systematically described to facilitate more in-depth study. These systematic descriptions commonly take the form of case reports, case series, or cross-sectional studies.

Case reports are accounts of single or a few noteworthy health-related incidents (eg, an epidemiologic description of a case of human rabies).

Case series are listings of a larger number of cases, usually presented consecutively (eg, a characterization of dog bite incidents in a population of veterinarians and/or technicians over time). Case series articles are useful for comparing variables of person, place, or time as they appear to affect the occurrence of a particular disease.

Cross-sectional studies are one-time assessments of the incidence or prevalence of a disease in a defined population, which is usually selected at random from a larger population at risk (eg, a serosurvey of veterinarians for the presence of antibodies to *Bartonella henselae* organisms to determine risk factors and for cat scratch disease). Cross-sectional studies are especially useful in forming hypotheses to be addressed by follow-on analytic studies.

Two main types of bias in descriptive epidemiology are **selection bias** and **observation bias**. Selection bias results from the identification of subjects/cases from a subset that is not representative of the entire population at risk. A nonmedical example of selection bias would occur in a voter survey, intended to predict the outcome of a political election, but drawn from a sample of voters from either high- or low-income status, neither of which would be representative of the overall voting population. Observation bias arises from systematic differences in the method of obtaining information from subjects/cases. Consider a study comparing library usage between students at two universities. Significant differences might result if students from one university were queried over the phone regarding library visits, whereas students at the other university were directly observed for actual usage. In general, bias in descriptive studies is not as prevalent or significant as bias in analytical studies.

In summary, descriptive epidemiology serves to describe the occurrence of disease in a population. Descriptive methods are commonly applied to little-known diseases; they use preexisting data, address the questions of who/where/when, and identify potential associations for more in-depth analytical studies.

Analytical Epidemiology

Analytical studies are applied to study the etiology of disease, to identify a causal relationship between exposures and health outcomes. They are typically used when

insights of a particular health issue are available, commonly from previous descriptive studies. In evaluating the causality of disease associations, analytical studies address the question of “why” as opposed to the “person/place/time” of descriptive studies.

Once potential associations have been observed between those who have a particular disease and those who do not, further investigations are undertaken to determine causality and identify effective interventions. The first step in an analytic study is to form some conjecture regarding observed exposures and health outcomes. In analytical studies, this conjecture is termed the **null hypothesis**, meaning that the default assumption is that there is no association between the exposure in question and the disease outcome. Note that this assumption of no association is made even though the epidemiologist often thinks that some association actually exists. Once the null hypothesis is generated, studies are designed to test it and either reject it (by finding that some association actually does exist between exposure and disease outcome) or accept it (by finding that no association exists).

Analytical epidemiology is accomplished through either observational studies or interventional studies. In the former, the investigator does not control the exposure between the groups under study and typically cannot randomly assign subjects to study groups.

Observational Studies:

Ecologic Studies: The unit under study is a group of people or animals versus an individual. The group has no size limitation but must be able to be defined. For instance, the group could be a kennel of dogs, a class of veterinary students, or the citizens of an entire country. Once defined, the group is analyzed against some exposure to see what outcome(s) ensue. Examples of ecologic studies include Dr. John Snow's analysis of the association between the incidence of cholera in London and where people obtained their drinking water, an analysis of how tobacco taxes affect tobacco usage, and an analysis of certain occupations for resultant hearing loss.

Ecologic studies have several advantages over other types of observational studies. They are relatively quick, easy, and inexpensive. Individual data are not necessary, only aggregate data for the group(s) under study. Finally, they are useful in generating information about the overall context of health, especially how it is affected by

variables such as demographics, geography, and the social environment.

Ecologic studies also have several disadvantages. First, the measurement of many exposures is imprecise, especially of large groups in which the influence(s) of those exposures is difficult to define or not equally exerted. This phenomenon of unequal variable exertion results in another potential drawback to ecologic studies. Known as ecologic fallacy, it is described by “associations observed at the group level do not necessarily hold true at the individual level.” As an example, one could determine that the average IQ of a class of veterinary students is above average (which, by definition, would be 100). If a particular student was randomly selected from that class, could it be inferred that that student's IQ was above 100? The answer is no, because of the difference between average and median. If the class had only a few people above average, but these students were significantly above average, and the rest of the students were only slightly below average, the distribution would be skewed toward a higher IQ when, in actuality, many members of the class would be below average.

Cohort Studies: In this type of study, a group of individuals (termed a cohort) is observed over time for changes in health outcomes.

When the period of the study is from the present into the future, the study is a **prospective cohort study**. In this case, the cohort is assumed to share a particular exposure and is followed over time to document the occurrence of new instances of a particular disease or outcome. Obviously, each member of the cohort must not have the disease or outcome at the beginning of the study. One of the most famous medical prospective cohort studies is the Framingham Heart Study. Researchers began the study in 1948 by recruiting 5,209 men and women, 30–62 yr old, from the town of Framingham, Massachusetts. Since that time, they have accomplished extensive serial physical examinations and surveys relating to the development of cardiovascular disease.

The major advantage of the prospective cohort study is that many different exposures can be considered and analyzed for influencing the outcome under study. Disadvantages include the high cost in terms of money and time during the period of the study and the inability to study very rare diseases or health outcomes unless the cohort is extremely large.

When the period of the study is from the past to the present, the study is a **retrospective cohort study**. The methodology is very

similar to that of the prospective cohort study, except that all the events (exposures and outcomes) have already occurred; the investigator is merely looking back rather than forward. Retrospective studies are conceived after some individuals have already developed the outcomes of interest. The investigators jump back in time to identify a cohort of individuals at a point in time before they developed the outcomes of interest, and try to establish their exposure status at that point in time. They then determine whether the subject subsequently developed the outcomes of interest. If so, they can analyze the exposure(s) that may have contributed to those outcomes.

Retrospective cohort studies have several advantages over prospective cohort studies. They typically take less time and are less expensive. Additionally, they can address rare outcomes, because the cases are selected after having already developed the disease or outcome. Disadvantages include a potentially high possibility of selection bias, the fact that individuals may have difficulty recalling certain exposures (termed **recall bias**), and the requirement for the existence of medical and/or exposure records.

Regardless of being retrospective or prospective, the measure of association of all cohort studies is the **relative risk (RR)**. Relative risk is calculated by dividing the incidence rate of the disease or outcome in the exposed individuals by the incidence rate in the unexposed individuals. An RR of 1 means there is no difference in risk between the two groups. An $RR < 1$ means that the outcome is less likely to occur in the exposed group than in the unexposed group. Conversely, an $RR > 1$ means the outcome is more likely to occur in the exposed group than in the unexposed group. Consider an example in which the incidence of prostate cancer among neutered male dogs was found to be 1.37%,

and the incidence in intact male dogs was 0.36%. In this case, the relative risk would be $1.37/0.36$ or 3.8. This could be stated as "Neutered male dogs would be nearly four times as likely as intact male dogs to develop prostate cancer."

Case-Control Studies: In this type of study, subjects are selected as either having a particular outcome (cases) or not having the outcome (controls). They are then compared in a retrospective way to identify differences in their exposures that might explain the differences in outcomes. Ideally, cases and controls should be as similar as possible in all characteristics except the outcome in order to make the comparisons simpler and more meaningful. That is why some investigators "match" cases and controls. In one notable example, a very large case-control study in 1950 studied people with lung cancer and demonstrated a very positive association between smoking and lung cancer. Although it did not prove causality alone, it was instrumental in the U.S. Surgeon General's now-standard warnings.

Case-control studies have several advantages. They are inherently retrospective, so they are relatively quick and inexpensive. Because the cases have already been identified, they are appropriate for studying rare diseases and examining multiple exposures. Disadvantages include the fact that, like cohort studies, they are prone to selection, recall, and observer bias. Additionally, their application is limited to the study of one outcome.

The most common measurement of association in case-control studies is the odds ratio. The **odds ratio (OR)** represents the odds that an outcome will occur from a particular exposure, compared with the odds of the outcome occurring in the absence of that exposure. ORs are calculated using a 2×2 frequency table (TABLE 1).

TABLE 1 CALCULATING AN ODDS RATIO

		Outcome Status	
		+	-
Exposure Status	+	a	b
	-	c	d

a = Number of exposed cases

b = Number of exposed non-cases

c = Number of unexposed cases

d = Number of unexposed non-cases

$$OR = \frac{a/c}{b/d} = \frac{ad}{bc}$$

An OR of 1 means the exposure did not affect the odds of the outcome. An OR > 1 means the exposure is associated with a higher odds of the outcome, and an OR < 1 means the exposure is associated with a lower odds of the outcome. Although a higher OR indicates a stronger association between exposure and outcome, it does not necessarily imply statistical significance and, by itself, is not enough to prove causality.

Interventional Studies: The other category of studies that comprise analytical epidemiology are interventional studies. In contrast to observational studies, the investigator using an interventional approach can intentionally change some form of exposure between several groups to determine differences in outcome(s). In medical research, these exposures typically include interventions such as vaccines, therapeutic drugs, surgical techniques, or medical devices. The results of interventional studies can be very powerful in proving causality or identifying efficacy of various interventions. Interventional studies typically take one of two forms, either a randomized controlled (clinical) trial or a nonrandomized (community) trial.

Randomized Controlled (Clinical) Trials:

In this type of study, participants are selected from a population and randomly assigned to one of two groups, one being the study group and the other being the control group. Study groups receive the intervention, and the controls do not.

Bias can be introduced in such a trial when either the participants or the investigator know which participants are in which group. This bias can be alleviated in one of two ways. First, in a single-blinded design, the participants are unaware whether they are in the study group or the control group. Additionally, in a double-blinded design, neither the investigator nor the participants are aware of the group assignments.

A major advantage of randomized controlled clinical trials is an inherently high validity for identifying differences in therapeutic efficacy of various interventions. Perhaps the major disadvantage is the high potential for ethical implications if an intervention with great potential benefit is intentionally withheld from the control group (eg, the historic Tuskegee Syphilis Study). For this reason, it can be very difficult to legally use human participants in many such trials. Additionally, this type of study is not usually applicable for discover-

ing disease etiologies; observational studies are much better suited for this purpose.

Nonrandomized (Community) Trials:

In this type of study, the units are groups (or communities) of participants assigned to treatment or control conditions. Although the communities may be selected at random, the individuals within them obviously are not. These studies are commonly undertaken to assess the quality and effectiveness of educational programs, behavioral changes, or mass interventions such as water fluoridation.

Bias

Bias is defined as the systematic deviation of results or inferences from truth. Bias is extremely difficult to completely avoid when undertaking scientific study. Therefore, studies are designed in ways that minimize the sources and effects of bias. Examples of bias are described below.

The Hawthorne effect: Participants in a study may act or behave differently because they know they are being studied. In 1924–1932, workers at the Hawthorne Works (an electric company near Chicago) were studied to see whether productivity was greater depending on how much light was provided at work. Results showed that productivity increased during the course of the study regardless of the changes in light; the workers just performed better because of the attention. When the study ended, productivity went back to prestudy levels.

Recall bias: Cases and controls may remember an exposure differently (and non-randomly). Usually, cases remember exposures more clearly than controls.

Selection bias: This occurs when selected controls are not representative of the population from which the cases were selected. In other words, there is an important characteristic of the controls that make them different from the general population. An example is the healthy worker effect, which refers to the phenomenon that employed groups have lower mortality than the general population. Therefore, if the study groups are comprised of differing fractions of employed and unemployed people, the results may very well be skewed.

Observer bias: The investigator, having knowledge of the outcome(s), might record exposures differently between cases and controls.

Confounding: In epidemiologic studies, a confounder is a variable that is not considered in the study design but is associated with the exposure and exerts

an effect on the outcome. Confounders can either produce a false association between variables or mask a true association between variables. An example of the former was a spurious conclusion drawn from a study of the relationship between alcohol consumption and heart disease. In the study, it was concluded that alcohol consumption was significantly associated with heart disease. Smoking was later identified as a confounder, because smoking was correlated both with alcohol consumption and also with heart disease. When corrected for the effects of this confounder, no association was found between alcohol consumption and heart disease.

Error

When analyzing results of an epidemiologic study, there are two categorical types of error when either accepting or rejecting the null hypothesis.

Type I error, also known as a **false positive**, is when the null hypothesis is rejected when it actually should have been accepted. In other words, this is the error of accepting an alternative hypothesis (the real hypothesis of interest) when the results can actually be attributed to chance. Type I error (which can never be zero) is generally reported as the **P value**. In scientific studies, the most common *P* value is .05, which means an error of <5% of detecting an association between a variable and an outcome is acceptable.

Type II error, also known as a **false negative**, is when the null hypothesis is accepted when it actually should have been rejected. In other words, the study did not have adequate power to detect an association between a variable and an outcome when the association actually existed.

Variable Associations and Causality

In epidemiology, variables are either associated or they are not. If the variables are not associated, there is no relationship; they are independent. If the variables are associated, that relationship can be either positive or negative. If two variables are positively associated, the values of both variables increase or decrease together. If they are negatively associated, the value of one variable increases when the other decreases. Finally, if an association exists (positive or negative), it is either causal or noncausal related to the outcome.

When two variables are associated, it is sometimes obvious as to whether it is causal. Consider the relationship between animal bites and rabies; we know they are

causally associated. However, in most epidemiologic studies, the relationship between variables (such as exposure and outcome) is much more difficult to ascertain and requires more extensive analysis. Several sets of systematic criteria for determining causality have been proposed: 1) **Strength**—Although a small association does not mean that there is not a causal effect, the larger the association, the more likely that it is causal. 2) **Consistency**—Repeatedly similar findings observed by different persons in different places with different samples strengthen the likelihood of a causal effect. 3) **Specificity**—Causation is more likely in a very specific population at a specific site and disease with no other likely explanation. The more specific the association between an exposure and an outcome, the higher the probability of causation. 4) **Temporality**—The outcome must occur after the exposure. 5) **Biological gradient**—Greater exposure generally results in greater incidence of the outcome. However, in some cases, the mere presence of the exposure, without regard to its magnitude, can trigger the effect. In yet other cases, an inverse relationship is observed when greater exposure of a protective factor leads to lower incidence of outcomes. 6) **Plausibility**—A rational, explainable mechanism between cause and effect is helpful (but may be limited by current knowledge). 7) **Coherence**—Agreement between epidemiologic and laboratory findings increases the likelihood of a causal effect. 8) **Analogy**—The effect of similar associations between other variables of exposure and outcome may be considered.

Sensitivity and Specificity

Veterinary practitioners use many diagnostic tests to determine what may be wrong with an animal and how it may be treated. The diagnostician must realize that these tests are fallible and that results are usually only close approximations of "truth." We can assume that an animal either has a medical condition or does not; however, no tests are 100% sensitive and specific. That is, no test can eliminate the potential for false-positive and false-negative results. However, there are methods to interpret test results to reduce their inherent fallibility. Those tests or diagnostic procedures known to produce the absolute best results are termed "gold standard" tests. It is against these gold standards that newer, usually faster and more convenient, tests are measured in terms of sensitivity and specificity.

Sensitivity is the probability of a positive test result when the disease is actually present. A sensitive test is "positive in disease" and minimizes false-negative results, thus minimizing type II error.

Specificity, in contrast, is the probability of a negative test result in the absence of disease, thereby correctly classifying an individual as disease-free (regarding that particular condition). A specific test is "negative in health" and minimizes false-positive results, thus minimizing type I error. To calculate the sensitivity and specificity of a test, consider the following 2×2 table (see TABLE 2).

Sensitivity and specificity are inversely proportional, ie, when one increases, the other decreases. Therefore, the accuracy of a test is a trade-off between each of these parameters. **Screening tests** tend to have higher sensitivity and lower specificity, because the purpose of such a test is to detect the maximum number of individuals with the particular disease condition. A negative test result, therefore, strongly implies that disease is absent, whereas a positive result may require additional, confirmatory testing. For that reason, positive tests are often followed up with a **confirmatory test** that displays higher specificity to identify which positive results are true and which are false. Given the high specificity of confirmatory tests, a positive result strongly implies that disease is present.

In clinical medicine, two additional diagnostic test parameters are relevant. The **positive predictive value (PPV)** of a test is the probability of a patient actually having the disease condition when the test is

positive. PPV is calculated as true positives divided by the sum of the true positives and the false positives: $a/(a + b)$. False-negative test results do not affect the PPV. Therefore, if the PPV of a test is 100%, the validity of a negative test result is still unknown.

The **negative predictive value (NPV)** is the probability of a patient not having the disease condition when the test is negative. NPV is calculated as true negatives divided by the sum of the true negatives and the false negatives: $d/(c + d)$. False-positive test results do not affect the NPV. Therefore, if a test was reported to have an NPV of 100%, the validity of a positive test result is still unknown.

PPV and NPV are clinically relevant, because they are directly related to the prevalence of disease. For diseases of high prevalence, the PPV of a test will be high and the NPV will be low. For rarer diseases, the opposite will be true, ie, the PPV will be low and the NPV will be high. For these reasons, the assumed prevalence of a disease must be taken into account when interpreting diagnostic test results.

Disease Outbreak Investigation

Public health officials investigate disease outbreaks to control them, to prevent additional illnesses, and to learn how to prevent similar outbreaks from happening in the future. Whether an outbreak is foodborne in origin or from another infectious source, the methodology is similar. The following steps in investigating disease outbreaks are used by the CDC: prepare for field work, confirm the existence of an outbreak, verify the

TABLE 2 CALCULATING TEST SENSITIVITY AND SPECIFICITY

		Gold Standard		Total
		Disease Present	Disease Absent	
Test Result	Positive	a	b	a+b
	Negative	c	d	c+d
	Total	a+c	b+d	

a = True positives; the test has correctly diagnosed the disease

b = False positives; the test is positive but disease is absent

c = False negatives; the test is negative but disease is present

d = True negatives; the test correctly diagnosed the absence of disease

Sensitivity is the true positives divided by the sum of the true positives and the false negatives: $a/(a + c)$

Specificity is the true negatives divided by the sum of the true negatives and the false positives: $d/(b + d)$

diagnosis, establish a working case definition, engage in systematic case finding, apply descriptive epidemiology, develop and test hypotheses (analytical epidemiology), implement control measures, and communicate findings.

Although these steps are accomplished in a systematic fashion, they frequently overlap or occur concurrently. For example, establishing a working case definition typically begins while the diagnosis is in the process of being verified and continues through the initial process of systematic case finding.

Establishing a working case definition is the method by which public health officials define what individuals are included as official cases in the outbreak and illustrate the boundaries of the outbreak. An effective case definition is critical because it may be confusing, especially in the absence of definitive diagnostics, to differentiate between actual disease cases and those ill from other causes. The case definition defines a case in terms of person, place, and time. Person criteria typically include vulnerability factors such as age, sex, signs/symptoms, or attendance at certain meals or public functions. Place criteria usually include a geographic boundary such as a state or local area, a school class, or a particular restaurant. Time parameters may be after an implicated meal (if foodborne) or other types of exposures. Case definitions are usually based on either clinical signs or diagnostic test results. The former is more subjective than the latter but can be just as effective, especially in field epidemiologic conditions. As the investigation ensues and more information becomes available, it may be necessary to revise the case definition. However, this is done judiciously, because changes to the case definition result in changes to the epidemic curve.

The **epidemic (epi) curve** shows progression of an outbreak over time. The horizontal axis represents the date when an individual became ill, also called the date of onset. The vertical axis is the number of individuals who became ill on each date. These are updated as new data come in and thus are subject to change. The epi curve is complex and may be limited by information deficiencies and inaccurate case definitions. Despite these potential limitations, detailed information regarding the dates and numbers of reported cases is visually useful. Moreover, in addition to the magnitude and duration of the outbreak, the shape of the

Epidemic curve common point source.

curve can show useful information regarding the nature of the outbreak.

The overall shape of the epi curve can give clues to the type of exposure that resulted in the outbreak. Typical epi curves from

common sources include 1) a common specific **point source** in which all cases were exposed at the same time and place (eg, a foodborne illness outbreak); 2) a common source with continuous exposure in which although the source is common, cases gradually rise before either peaking or plateauing and declining; and 3) a common source with intermittent exposure in which the peaks occur at irregular times corresponding to the earlier exposures. In addition to outbreaks having common sources, they can have **propagated sources**, in which cases can directly infect other cases separate from the initial source. In a propagated source outbreak, person-to-person transmission occurs, often through several cycles before declining.

Another attribute of an outbreak that can be illustrated by the epi curve is the period of incubation. For example, in a common point source outbreak, the investigation frequently identifies the event (eg, meal, social gathering, etc) when the exposure occurred. In this case, the peak of cases occur one incubation period after the exposure event. In a propagated source outbreak, the peaks of cases occur one incubation period apart.

BASICS OF FOOD SAFETY

The USA has the safest and most plentiful food supply in the world. These attributes are frequently and mistakenly taken for granted. In truth, however, they are maintained by motivations such as increases in production efficiency, reductions in market uncertainty, and the goal of higher profits.

Foodborne Pathogen Requirements

Nearly all foods contain pathogens, which originate from either the product itself or contamination during processing. As an example, CDC reports that 24% of sampled raw chicken parts were contaminated with *Salmonella* organisms. Regardless of their source, pathogens have common environmental/nutritional requirements, each of which presents various control opportunities. The acronym FAT TOM can aid in learning these common requirements.

Food (some source of energy): Controlling this requirement is perhaps the most difficult because, as the nutrient content of the food is reduced, the quality and usefulness is similarly reduced. However, certain methods of processing and preserving serve to limit

microbial access to nutrient sources. Nearly all foods are washed, rinsed, sifted, sorted, or trimmed during processing, which serves to limit the initial level of contamination. Additionally, simple packaging increases the shelf life of many foods and prevents contamination from the environment and other food items.

Acidity (measured by pH): The optimal pH range for microbial growth is 4.6–7.5. Therefore, for items such as bottled sauces/condiments and pickled foods, a common and effective preservation technique is to lower the pH (acidify) of the item below 4.6. Conversely, some food products (eg, fish, olives, eggs) can be processed with sodium hydroxide (lye) to raise the pH above this range.

Temperature: The optimal temperature range for many foodborne pathogens is 40°F–140°F. For this reason, prepared foods are held in this range for as little time as possible. As a general rule, 4 hr is considered the maximal time in this danger zone to limit microbial growth.

Time: Bacteria require time to propagate to the point of being infective and virulent. In general, 4 hr is considered the maximal time period in the temperature danger zone in retail food establishments.

Oxygen: Most foodborne pathogens are aerobic in nature, ie, they require oxygen for multiplication. Oxygen also facilitates the spoilage process. Techniques that limit available oxygen include drying, canning, bottling, vacuum packaging, adding antioxidants, and modifying the storage atmosphere by replacing oxygen with an inert gas such as nitrogen or carbon dioxide. An added benefit to a modified/controlled atmosphere is that it slows the ripening process and can extend the shelf life of many fruits and vegetables by months.

Moisture: Foods lower in water activity are more resistant to the growth of many foodborne pathogens. By definition, the water activity (*a_w*) of water is 1. Foods with an *a_w* <0.85 are considered generally safer than foods with a higher *a_w*. Techniques that lower the water activity of foods include drying, dehydrating, freezing, salt/sugar curing, and pickling.

Food Processing and Preservation

Virtually all foods are processed to some degree. Examples of minimal processing techniques include washing, peeling, slicing, juicing, freezing, drying, fermenting, and pasteurizing. More extensive processing techniques include baking, frying,

smoking, toasting, puffing, shredding, flavoring, coloring, and fortifying. Regardless of the degree, foods are processed for the purposes of preservation, safety, variety, convenience, nutritional enhancement, and increased marketability. Although these processing techniques have resulted in a safer and more plentiful supply, health concerns about food processing have been raised because of certain attributes of processed foods, such as added sugar, sodium, saturated/trans fats, refined grains, low fiber content, and their conducive nature toward unhealthy behaviors. Moreover, processing techniques such as grinding increase the surface area of foods, as in the case of hamburger, which renders them more capable of supporting the growth of pathogenic microorganisms.

In the 1960s, the National Aeronautics and Space Administration (NASA) asked the U.S. Army and the Pillsbury Company to develop safe foods for manned space flights. In a novel approach, Pillsbury required contractors to identify "critical failure areas" and eliminate them from the production system. This systematic approach became known as the Hazard Analysis Critical Control Point (HACCP) process. The underlying principle of HACCP, which focuses on health safety issues rather than quality issues, is to prevent the hazards during processing rather than merely inspecting the end product. Since that time, HACCP has been mandated by FDA and USDA for many food production sectors and also has been implemented in the cosmetics and pharmaceutical industries.

The HACCP process consists of the following seven principles: 1) Conduct a hazard analysis, ie, determine the hazards and preventive measures that could be applied to prevent them. 2) Identify critical control points, ie, any point, step, or procedure in a food manufacturing process at which controls can be applied. 3) Establish critical limits for each critical control point, ie, the maximum or minimum value to which a physical, biologic, or chemical hazard must be controlled at a critical control point. 4) Establish critical control point monitoring requirements, which are necessary to ensure that the process is under control at that point. 5) Establish corrective actions, or actions that must be taken when monitoring indicates a deviation from an established critical limit. 6) Establish procedures to ensure the HACCP system is working as intended, ie, validate the specific HACCP plan. 7) Establish record keeping proce-

dures; each plant must maintain records of the entire process, as well as records to verify the plan.

The primary purposes of food preservation are to inhibit the growth of pathogenic microorganisms and to retard organic degradation such as oxidative rancidity. Many processes involve the use of multiple techniques. In addition to extending the shelf life of food products, the quality and acceptability of many food products, such as cheese, yogurt, and pickled onions, are actually enhanced by the preservation process. These purposes are attained through one or more actions of the preservation process. They include reducing the existing pathogen load, altering the pH and temperature, lowering the oxygen content, reducing the water available for microbial growth, and providing a physical barrier to contamination.

Traditional food preservation techniques, aimed toward one or more of the above purposes, include the following: drying (reduces water necessary for microbial growth), refrigeration (slows microbial growth and enzymatic activity), freezing (preserves food for longer periods), salt or sugar curing (reduces water [especially in meats and fruit]), smoking (coats foods with natural antimicrobials), pickling and brining (reduces both aw and pH), canning and bottling (reduces oxygen and provides physical barrier to contamination), jellifying (cooking in a medium that cools to form a gel [eg, aspic]; reduces aw), jugging (meats stewed in earthenware jugs or casseroles), burying (reduces aw, oxygen, light, temperature, and pH), and fermenting (adds beneficial microbes that successfully compete with pathogens; also lowers pH and adds alcohol).

More modern food preservation techniques are listed below.

1) Pasteurization is used mainly for dairy products and other liquid foods, and it can reduce microorganisms by 99.999%. In a "high temperature, short time" process, the product is held at 161°F for 15 sec. In an "ultra-high temperature" process, pasteurization is achieved after reaching 275°F for 2 sec. In a less conventional technique, home pasteurization involves holding the product at 145°F for 30 min. Finally, an "extended shelf life" process combines heating with filtration.

2) Vacuum packaging is usually in air-tight bags or bottles.

3) Additives typically involve the addition of antimicrobials to limit the growth of microorganisms or antioxidants to inhibit

Food irradiation radura. Since 1986, all food treated with irradiation must display this radura.

spoilage. Common antimicrobials include calcium propionate, sodium nitrate, sodium nitrite, disodium EDTA, and various sulfites. Common antioxidants include butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), ascorbic acid (vitamin A), and tocopherol (vitamin E).

4) Irradiation, which is commonly termed "cold pasteurization," involves exposing the product to low-dose ionizing gamma rays from a radioactive source such as cesium-137 (Cs-137) or cobalt (Co-60). The process does not render the food radioactive but results in the killing of nearly all surface pathogens. Commonly used for products such as spices and fruits, food irradiation is endorsed by the World Health Organization and approved by the FDA. Since 1986, all food treated with irradiation must display the radura.

5) Pulsed electric field electroporation consists of brief pulses of a strong electric field that enlarges cell membrane pores, which kills microorganisms. It is commonly used for fruit juices.

6) Modified atmosphere replaces oxygen with an inert gas such as nitrogen or carbon dioxide. It is commonly used for salads, grains, apples, bananas, and fish.

7) Nonthermal plasma treats food surfaces with "flame" of helium or nitrogen.

8) High pressurization reduces microorganisms while retaining freshness. It is commonly used for deli meats and guacamole.

9) Biopreservation is the addition of beneficial microbes such as *Lactobacillus* to compete with pathogens.

10) "Hurdle" technology combines multiple techniques to produce additive benefits. An example of placing multiple hurdles in such a combination might involve high temperature and salt curing during processing, addition of antioxidants before packaging, and low temperature during storage and transportation.

INCIDENCE AND IMPACT OF FOODBORNE DISEASES

The global burden of foodborne diseases is difficult to assess, because no overarching

estimation has yet been performed. The World Health Organization has initiated this process but reports that efforts are limited by regional lack of funding, public health infrastructure, and political will. However, despite specific data, the burden seems obvious; diarrheal diseases, many of which are foodborne in origin, kill approximately 1.9 million children worldwide.

In the USA, the foodborne diseases are not generally reportable, so their burden likely is significantly underestimated. Contributing to this underestimation is that many foodborne illnesses lack the severity, duration, and specific diagnosis required for definitive identification and intervention. Recent estimates by the CDC indicate that foodborne pathogens cause approximately 9.6 million illnesses, 57,500 hospitalizations, and 1,500 deaths each year in the USA.

In an effort to maintain awareness of foodborne disease events and trends, CDC conducts the Foodborne Diseases Active Surveillance Network (FoodNet), which monitors the incidence of nine foodborne pathogens in ten USA cities, covering approximately 15% of the American population (see TABLE 3).

CDC reports that this epidemiologic situation has not changed appreciably since 2006, suggesting that there are gaps in the current food safety system and a need for better, more effective interventions.

Factors in Emerging Foodborne Illness Trends

Pathogenic organisms that contaminate food and result in foodborne illness are dynamic in that they adapt to new foods, processes, and human behaviors. The following categorical factors contribute to foodborne illness trends.

Human Demographics and Behavior:

The proportion of the USA population that is immunocompromised is increasing because of factors such as advancing age, underlying disease, and therapeutic drug regimens. Additionally, people consume more fresh fruits and vegetables, which may be more contaminated than processed or prepared foods, and consume an increasing number of meals outside the home. Finally, "organic" foods have not been shown to be microbiologically safer and in some cases may even increase the risk from certain foodborne pathogens.

Technologies Within the Food

Industry: Increasing concentration and vertical integration of many food produc-

TABLE 3 **FOODBORNE PATHOGENS IN TEN USA CITIES**

Pathogen	Incidence of Illness per 100,000 Population
<i>Salmonella</i>	15.19
<i>Campylobacter</i>	13.82
<i>Shigella</i>	4.82
<i>Cryptosporidium</i>	2.48
Shigatoxin-producing <i>E coli</i>	2.32
<i>Vibrio</i>	0.51
<i>Yersinia</i>	0.36
<i>Listeria</i>	0.26
<i>Cyclospora</i>	0.03

tion sectors have resulted in foods of higher quality and greater consistency but with certain inherent vulnerabilities. Foods (and constituent ingredients) are transported in larger batch sizes, over longer distances, and are processed into an increasing number of end products. This means that refrigeration breakdowns and cross-contamination incidents can result in more widespread effects of food recalls and illness outbreaks.

International Travel and Commerce:

The concept of “traveler’s diarrhea” is expanding because, increasingly, bulk food shipments cross international borders at least as often as people. Therefore, foodborne illnesses acquired from foreign foods can be contracted without leaving home. Additionally, when people travel, they frequently take cultural foods with them to share with extended family. Despite prohibitions against such importation practices, ~4,000 pounds of meat products are confiscated from travelers each month from Haiti to the USA. Undoubtedly, this represents only a fraction of the amount actually crossing the border.

Microbial Adaptation: Foodborne pathogens have inexorably adapted to traditional preservation techniques. Others may even be selected by various techniques. Finally, antimicrobial resistance patterns

change constantly, requiring correspondingly dynamic interventions.

Economic Development and Land Use:

USDA reports a continuing decrease in the number of farms in the USA, with the average number of livestock animals on remaining farms increasing. This concentrates the number of animals that may be affected, both by contagious pathogens and by interventions such as quarantines and depopulation efforts. Increases in ocean water temperature have been associated with increases in the number and scope of foodborne illnesses from certain seafood products such as oysters.

Lack of Food Safety Education: Health classes at the intermediate and high school levels rarely, if ever, cover food safety in favor of topics such as sexually transmitted diseases, drug abuse, and teen pregnancy. With the increasing fraction of two-worker and single-parent homes, time demands may also preclude education of children in food safety principles and further contribute to the lack of awareness.

ROLE OF FOOD ANIMAL VETERINARIANS IN CONTROL OF FOODBORNE PATHOGENS

Veterinarians in food animal practice and government service contribute

significantly to the safety of the food supply. These roles can be categorized by stage of production (eg, antemortem, postmortem, and general).

Antemortem activities include assurance of animal welfare, zoonotic disease recognition and prevention, inspection of preslaughter animals, and antibiotic residue testing.

Postmortem activities include carcass inspection and tissue residue determination.

General activities begin with herd health programs, including disease treatment and prevention, husbandry/handling/environmental advice, reproductive efficiency, vaccination regimens, nutrition, stress reduction, commodity group protocols (eg, Beef Quality Assurance), and biosecurity and biocontainment plans. In addition to herd health, other important activities include appropriate/judicious use of antimicrobials, disease surveillance, illness/outbreak/epidemic investigation and mitigation, vaccination against specific high-consequence or high-prevalence pathogens (eg, *E coli* O157:H7 and *Salmonella*), collaboration with other health professionals (One Health), food facility inspection (eg, production, retail, storage), import/export examinations, health department leadership, public health (risk) communication, food supply after disasters, and research into safer food production processes.

FOOD SAFETY REGULATION

In the USA, food safety is a shared responsibility at various governmental and private levels. Federal departments and agencies have regulatory authority over virtually all food products. State and local governments typically are responsible for sanitary inspections of restaurants and food preparation sites. Food industry sectors have internal quality control procedures to ensure both safe products and adherence to regulatory requirements. Finally, informed consumers are charged with the safe storage, preparation, and service of privately obtained foods.

At the federal level, responsibilities are shared between Congress, various regulatory agencies, and the court system. Congress enacts statutes that give agencies authority to regulate food safety and enforce those regulations. Typically, these statutes are specific in identifying individual agencies but broad in allowing discretion in how those agencies exercise their authority. Finally, the courts review challenges to

statutes, regulations, and enforcement actions.

Department of Agriculture: The Department of Agriculture consists of the Food Safety and Inspection Service (FSIS) and the Animal and Plant Health Inspection Service (APHIS). The FSIS is the primary food regulatory agency within USDA, domestic and imported (and employs most of the veterinarians in federal service). FSIS responsibilities include inspecting food animals for disease before and after slaughter; inspecting meat and poultry slaughter and processing plants; inspecting domestic and imported meat and poultry products (raw and processed); inspecting processed egg products (liquid, dried, and frozen but not eggs in shells); analyzing food products for microbial, chemical, and toxicologic agents; seeking voluntary recalls of unsafe meat and poultry products; conducting and sponsoring research on meat and poultry safety, and educating industry and consumers on safe food handling practices.

APHIS is responsible for livestock production and transport (preslaughter); inspection and quarantine at U.S. Ports of Entry; and veterinary services, including surveillance and disease control/eradication programs, as well as representing USA animal agriculture internationally.

Department of Health and Human Services (DHHS): The Food and Drug Administration (FDA) and the Centers for Disease Control and Prevention (CDC) are within DHHS.

The FDA is the primary food regulatory agency within DHHS. It is responsible for domestic and imported food sold in interstate commerce, including shell eggs (but not meat and poultry), bottled water, wine beverages <7% alcohol, livestock feeds, veterinary drugs, infant formulas, and dietary supplements; adulteration and misbranding of foods, drugs, and cosmetics; inspection of food production establishments and warehouses for contamination by microbial, chemical, and toxicologic agents; and HACCP programs for seafood products and fruit/vegetable juices. The FDA also works with industry to recall unsafe food products, as well as conducts research and educates industry and consumers.

The CDC investigates foodborne illness outbreaks (in conjunction with states), maintains nationwide disease surveillance (FoodNet), develops and advocates for

public health policies, conducts research and educational programs in foodborne illness, and trains state and local food safety personnel.

The CDC also operates the Division of Global Migration and Quarantine, which is the enforcement authority for International Health Regulations. This Division investigates deaths and disease outbreaks on all international vessels (commercial and cruise ships and aircraft) and is responsible for quarantine stations at major international ports of entry to intercept/destroy smuggled bushmeat, vector species, and other contraband of public health concern.

In addition, the CDC operates the Cruise Ship Inspection Service, which is an enforcement authority responsible for sanitary inspection of cruise ships.

Department of Defense: The DoD is responsible for emergency food supplies, research activities on military food rations (many civilian applications), and approves food and water sources for all military bases.

Department of Homeland Security: The DHS prevents terrorist attacks on USA soil (to include foodborne, crop, livestock) and ostensibly has primary authority during attack and response phases.

Department of Commerce: The DoC is responsible for management of living marine resources, including fisheries.

Environmental Protection Agency: The EPA has authority over pesticides, herbicides, and fungicides. The EPA determines the safety of pesticides and sets tolerance levels in foods, regulates toxic substances to prevent entry into food and the environment, and establishes and enforces safe drinking water standards.

PUBLIC HEALTH LAW

The U.S. Constitution makes no specific provision for health or public health. Therefore, in accordance with the Tenth Amendment, these powers are reserved by the states. However, a salient exemption from this federal exclusion is represented by the concept of legal preemption. Rooted in the "Supremacy Clause" of the Constitution (Article VI), preemption occurs when a state law is invalidated after being determined to conflict with a federal law. In the absence of a federal declaration of emergency, federal preemption is rare; one

example is the federally enacted Airline Smoking Ban.

Primary Sources of State Public Health Authority

Police Power: Authority of "police power" usually is invoked to protect the common good. Not synonymous with criminal enforcement, this authority establishes means by which a community promulgates and enforces self-protective measures. Examples include regulation of health care professionals and facilities; establishment of health and safety standards; quarantine, health, and inspection laws to limit the spread of infectious diseases; mandatory vaccination programs; age restrictions for drinking alcohol and purchasing tobacco products; and requirements for speed limits, seatbelts, and helmets.

Parens Patriae Power: This is the power of the state to serve as guardian of persons under legal disability. Examples include juveniles and the insane.

State Constitutional Power: These authorities are granted under each individual state constitution (varies by state).

After the terrorist attacks of September 11, 2001, the "Amerithrax" attacks, natural disasters such as Hurricane Katrina, the severe acute respiratory syndrome (SARS) outbreak, and pandemic influenza, the federal government strengthened its legal preparedness for all types of public health emergencies. These activities addressed a variety of concerns related to emergency declarations, quarantine and isolation, licensure and liability of health care workers, and mutual aid.

Selected General Federal Emergency Legal Authorities

Homeland Security Act of 2002:

This Act merged 22 disparate agencies and organizations into the new Department of Homeland Security (DHS), including the U.S. Coast Guard and the Federal Emergency Management Agency (FEMA). The Act charged DHS with securing the nation against terrorist attacks and carrying out the functions of all transferred entities, including acting as a focal point regarding natural and manmade crises and emergency planning.

Robert T. Stafford Disaster Relief and Emergency Assistance Act of 1988:

The Stafford Act authorizes the President to declare a "major disaster" or "emergency" in response to an event (or

threat) that overwhelms state or local government resources. Declaration under the Act triggers access to federal technical, financial, logistical, and other assistance to state and local governments. The governor of an affected state must first respond to the disaster and execute the state's emergency plan before requesting that the President declare a major disaster or emergency, and the governor must certify that the magnitude of the emergency exceeds the state's capability. As of 2013, tribal leaders can also request a Stafford Act declaration from the President. The President may declare an emergency without the request of a governor or tribal leader if the emergency involves "federal primary responsibility" (such as an event occurring on federal property, eg, the bombing of the Murrah Federal Building in 1995).

National Emergencies Act: This Act authorizes the President to declare a "national emergency." The declaration of emergency must specify the powers or authorities made available by virtue of the declaration.

Emergency Management Assistance Compact (EMAC) of 1996: Enacted by every state, this agreement facilitates resource sharing among member states during an emergency. A governor's declaration of emergency and request for assistance triggers EMAC for the requesting state. An assisting state then responds to the request by providing the needed resources. Further, EMAC establishes that the requesting state is responsible for compensating the assisting state for any expenses incurred.

Public Health Service Act: Originally enacted in 1944, this Act has been amended several times to facilitate various types of responses, listed below.

Public Health Emergencies: Authorizes the Secretary of DHHS to determine that a public health emergency exists if "1) a disease or disorder presents a public health emergency; or 2) a public health emergency, including significant outbreaks of infectious diseases or bioterrorist attacks, otherwise exists."

General Grant of Authority for Cooperation: This grant states that the Secretary of DHHS shall assist states and local authorities to prevent and suppress

communicable diseases and to help state and local authorities enforce quarantine regulations.

Strategic National Stockpile: The Stockpile (including drugs, vaccines, biologic products, medical devices, and other supplies) is maintained by the Secretary of DHHS, in collaboration with Director of the CDC, and in coordination with the Secretary of DHS, to provide for the emergency health security of the USA. The Secretary may deploy stockpile assets in response to an actual or potential public health emergency to protect public health or safety, or as required by the Secretary of DHS.

Bioterrorism Preparedness and Response Act of 2002: This Act amends the Public Health Service Act to "improve the ability of the United States to prevent, prepare for, and respond to bioterrorism and other public health emergencies." The Act requires the Secretary of DHHS to "develop and implement" a coordinated strategy in the form of a national preparedness plan.

Regulations to Control Communicable Diseases: Regulations to control communicable diseases authorize the Secretary of DHHS to make and enforce regulations "to prevent the introduction, transmission, or spread of communicable diseases" into the USA from foreign countries or from one state into another. These regulations also authorize the apprehension, detention, examination, and conditional release of individuals with certain communicable diseases that are specified in an executive order of the President.

Executive Order 13295 (Amended): Revised List of Quarantinable Communicable Diseases: This Executive Order identifies the nine communicable diseases (cholera, diphtheria, infectious tuberculosis, plague, smallpox, yellow fever, viral hemorrhagic fevers, severe acute respiratory syndrome [SARS], and pandemic influenza), for which an individual can be apprehended, detained, examined, or conditionally released by federal public health authorities.

Interstate Quarantine (42 CFR, Part 70): This allows the CDC Director to take measures to prevent the spread of communicable diseases from one state into another, including in the event the Director determines that the measures taken by the health authorities of a state are insufficient to

prevent such spread of communicable disease.

Pandemic and All-Hazards Preparedness Act of 2006: This Act identifies the Secretary of DHHS as the lead federal official for public health emergency preparedness and response. It also provides new authorities to develop countermeasures, establishes mechanisms and grants to continue strengthening state and local public health security infrastructure, and addresses surge capacity by placing the National Disaster Medical System under the purview of DHHS.

Social Security Act: Authority to Waive Requirements During National Emergencies: This authorizes the Secretary of DHHS to waive or modify certain requirements of Medicare, Medicaid, and the State Children's Health Insurance Program during certain emergencies.

Public Readiness and Emergency Preparedness Act of 2005: This Act authorizes the Secretary of DHHS to issue a declaration that provides immunity from tort liability for claims of loss (except willful misconduct) caused by, arising out of, relating to, or resulting from administration or use of countermeasures to diseases, threats, and conditions determined by the Secretary to constitute a present or credible risk of a future public health emergency.

Emergency Use Authorization: The Secretary of DHHS may, based on the request of the Secretary of either DHS, DoD, or DHS, declare that circumstances exist to justify an Emergency Use Authorization (EUA) for an unapproved drug, device, or biologic product, or for an unapproved use of an approved drug, device, or biologic product.

Pandemic and All-Hazards Preparedness Reauthorization Act of 2013: This Act established streamlined mechanisms to facilitate certain medical countermeasure preparedness and response activities without having to issue an EUA (which can be a time- and resource-intensive process). These new authorities are focused toward medical products against chemical, biologic, radiologic, and nuclear emergencies.

Volunteer Protection Act of 1997: This Act supports and promotes the activities of organizations that rely on volunteers by providing the volunteers

some protections from liability for economic damages for activities relating to the work of the organizations. Under the Act, to be found not liable for the injury caused by a negligent act or omission of the volunteer, the volunteer must have been acting within the scope of his or her responsibilities in the nonprofit or government agency. The volunteer must have appropriate licensure or certification if required for the volunteer's duties; he or she must not have acted with gross negligence, reckless disregard, willful or criminal misconduct, or flagrant indifference; and the injury cannot have occurred while the volunteer was intoxicated.

Posse Comitatus Act of 1878: This Act generally prohibits the use of federal military personnel in a law enforcement capacity within the USA unless authorized by the U.S. Constitution or an act of Congress. Certain exceptions exist, such as when the Department of Defense aids the Department of Justice in responding to an emergency situation involving a weapon of mass destruction.

Insurrection Act of 1807: This Act grants authority to the President to call the National Guard into federal service in the event of an insurrection in any state or if a state fails to uphold the constitutional rights of its citizens.

ZOOEYIA

Zooeyia is defined as "the positive inverse of zoonosis" and represents the innumerable benefits that stem from human interaction with animals. (*See also THE HUMAN-ANIMAL BOND*, p 1575.) Too often, that interaction focuses on negative issues such as disease and injury rather than on the positive contributions to our physical, mental, and social well-being. These contributions are manifested at both the individual and community levels. Documented individual benefits of interaction with animals include increased physical activity, smoking cessation, hypertension control, reduced anxiety, and treatment of post-traumatic stress disorder. Interaction with domestic animals contributes at the community level by facilitating social interaction, promoting a sense of safety, enhancing the "give and take" communication between neighbors and fellow pet owners, and perhaps even lowering overall health care costs.

ZOONOSES

Zoonotic diseases present challenges not only to veterinarians but also to all professions concerned with public health. Cooperation between veterinarians and public health physicians has been an important factor in zoonosis control programs. An example of this collaboration is the eradication of bovine tuberculosis, first in Denmark, Sweden, Finland, and Norway, and then in the USA, Canada, and other countries. Unfortunately, some zoonoses that are well controlled in developed nations, such as bovine and porcine brucellosis, bovine tuberculosis, and rabies, remain major problems in the developing world. Diseases can also reemerge in areas where they have been eradicated. Newly recognized zoonotic organisms such as Hendra and Nipah viruses are emerging, and many other zoonoses remain a constant concern.

PATHOGENS AND HOST SPECIES

Zoonotic diseases can be caused by bacteria, viruses, fungi, parasites, or prions. Because organisms are more readily transmitted between closely related hosts, most of these agents are pathogens of mammals. A particularly large number of diseases are shared by people and nonhuman primates. Birds, reptiles, amphibians, fish, and invertebrates can also be sources of infection (see TABLE 4). Many of the zoonotic agents in poikilotherms are parasitic, but these species can also carry zoonotic bacteria and viruses including *Salmonella*, West Nile virus, and opportunistic *Mycobacterium* spp. People are incidental hosts for many zoonoses; however, some agents have both human and animal reservoirs. In some cases, animal reservoirs have been revealed after a disease was controlled in people. Yellow fever, for example, is known to have a zoonotic jungle cycle in nonhuman primates, as well as an urban cycle maintained in people. Wildlife is increasingly recognized as a reservoir for zoonoses, including some that were thought to be strictly livestock pathogens. Reverse zoonoses are caused by human pathogens transmitted to animals. In some cases, these agents can later infect people. For example, *Mycobacterium tuberculosis*, the agent of human tuberculosis, can colonize the bovine udder and be shed in milk.

The occurrence of a pathogen in both people and animals does not always mean it is a significant zoonosis. Some diseases are acquired from the environment, and transmission between animal or human hosts is either absent, or occurs very rarely and under unusual conditions. These are considered infections common to people and animals rather than true zoonoses. Histoplasmosis, blastomycosis, and coccidioidomycosis, for example, are acquired by inhaling the microconidia of soil fungi, but the organisms exist as yeasts in tissues. Some agents, such as *Candida* spp, are widespread commensals in healthy people and animals and can cause disease when the host becomes debilitated. Although such organisms might be transmitted from animals to people, this transfer has little epidemiologic significance. In some cases, organisms were once thought to be zoonotic, but current knowledge, particularly the use of genetic techniques, has changed that perception. For example, *Streptococcus agalactiae* was once thought to be acquired from animals, but most strains in people are now known to be distinct from animal strains. There are also some organisms (eg, simian foamy viruses) that can be transmitted from animals to people, but with no currently known consequences.

TRANSMISSION BETWEEN ANIMALS AND PEOPLE

Zoonotic pathogens can be acquired during close contact with an animal, generally through inhalation, ingestion, or other mechanisms resulting in the contamination of mucous membranes, damaged skin, or in some cases, intact skin. Sources of organisms include body fluids, secretions and excretions, and lesions. Unprotected contact with tissues during necropsies often carries a high risk of transmission. Aerosols are occasionally involved, particularly in confined spaces. Fomites can transmit some agents; the likelihood of this route correlates with the organism's persistence in the environment. Some organisms are spread by ingestion of contaminated food or water and may infect large numbers of people. Sources of zoonotic pathogens in foodborne disease include undercooked meat or other animal tissues (including

seafood and invertebrates), unpasteurized milk and dairy products, and contaminated vegetables. Insect vectors, serving as either biologic or mechanical vectors, are important in transmitting some organisms.

The risk of acquiring a zoonosis can be affected by many factors, including the susceptibility of the host (see p 2415), the potential route(s) of transmission, the number of organisms shed by the animal, and the ability of the agent to cross species barriers. Some pathogens, such as *Bacillus anthracis*, readily infect people with appropriate exposure; others are uncommon zoonoses even when exposure is frequent. Certain occupations or activities can significantly increase the probability of exposure. Contact with soil during gardening or childhood play carries a risk of infection with pathogens that reside temporarily or permanently in the soil, such as *Toxocara* spp or *Sporothrix schenckii*. Veterinary practice, agricultural activities, and pet ownership are obvious hazards. Dogs, cats, livestock, or birds may also bring wildlife pathogens into closer proximity to people. The animal can be infected directly with the agent, either clinically or subclinically, or it may act as a transport host for infected arthropods such as ticks. Nontraditional pets have a relatively high probability of being infected with zoonotic agents, especially when captured directly from the wild. During an outbreak of monkeypox in the USA, the virus spread from exotic African rodents, imported as pets, to pet prairie dogs and then to people. Activities that bring people into closer contact with wildlife, including hunting, fishing, and camping, can result in exposure to organisms carried in wild animals (eg, *Francisella tularensis*, *Yersinia pestis*, and *Leptospira* spp) or transmitted by arthropod vectors (eg, *Borrelia burgdorferi* and West Nile virus). Hunters, in particular, may contact pathogens in animal tissues during butchering. The growing popularity of ecotourism has resulted in human exposure to some exotic wildlife diseases. The prevalence of other zoonoses may be linked to cultural practices such as eating raw fish, gastropods, or mollusks. Knowledge of a person's leisure and vocational activities, travel, and pet ownership can sometimes raise the index of suspicion for zoonoses that are uncommon in urban populations.

Once a zoonotic disease has been acquired by a person, it can sometimes be transmitted from person to person. The risk varies with the specific disease, the agent's ability to spread readily in people, and the

routes of transmission. Often, the people most at risk are health care workers and close family members. However, diseases such as plague have the potential to spread widely in human populations under some conditions. Some zoonotic diseases are not contagious during casual contact but can be spread by transfusion or organ transplantation, or from mother to fetus in utero. A particularly wide variety of agents, from encysted parasites to latent viruses, are potentially transferable in organs. Agents that were well controlled in the organ donor can be reactivated in the recipient, who is immunosuppressed by drugs taken to prevent rejection. Transfusion can also bypass normal barriers if the agent is found in the blood at the time of the donation. The bovine spongiform encephalopathy agent, for example, is ordinarily transmitted from host to host only by ingestion of tissues, but it can be acquired in transfused blood.

ROLE OF IMMUNOSUPPRESSION

The spectrum of zoonotic illness varies from skin eruptions or mild, self-limiting infections easily misdiagnosed as human influenza to serious, life-threatening disease. Some zoonoses can affect healthy people, whereas others are primarily found in individuals with debilitating illnesses and other conditions that compromise immunity. Zoonoses that are mild or asymptomatic in healthy hosts can be serious illnesses or have unusual presentations in those who are immunocompromised. In some cases, a suppressed immune response may also slow diagnosis if common tests rely on serology.

Primary immunodeficiencies, which are congenital defects, may affect humoral or cell-mediated immunity, or both. Some primary immunodeficiencies increase susceptibility to a single category of pathogens, while others broadly suppress defenses. Some may remain unnoticed except as an unusual susceptibility to certain illnesses, whereas others are obvious from infancy. Secondary immunodeficiencies can be caused by any acquired condition that compromises the immune system. Examples include splenectomy, diseases that affect metabolism (eg, diabetes), illnesses such as cancer that result in generalized debilitation, and infections such as malaria or AIDS. Some illnesses, such as chronic lung disease, can increase susceptibility by affecting innate (nonspecific) defenses. Injuries and burns can compromise the skin defenses that prevent pathogens

from entering the body, as can indwelling catheters and implanted medical devices. Drugs can suppress immunity as an intended effect (eg, drugs used to treat autoimmune diseases or prevent rejection in organ transplant patients) or as an adverse effect. Some drugs used in cancer chemotherapy are highly immunosuppressive. (See also IMMUNOLOGIC DISEASES, p 817.)

Physiologic states can also affect immunity. The immune system is relatively immature in newborns and young children, and it declines in older adults. Pregnancy may result in risks to the mother, the fetus, or both. For example, in some geographic locations, the case fatality rate for hepatitis E is ~1% in the general population but may reach 20% among pregnant women. Other pathogens, such as *Toxoplasma gondii*, may severely damage the fetus while remaining mild in the mother.

EMERGENCE AND REEMERGENCE OF ZOO NOTIC DISEASES

Emerging diseases are commonly defined as illnesses that have increased in incidence during the past two decades or are likely to increase in the near future. Many of these diseases are zoonotic. A zoonotic disease can emerge as the result of increased human contact with the animal host(s), animal tissues, vectors, or environmental sources of the pathogens. It may also result from an increased prevalence of the agent in domesticated or wild animals or in vectors. Many currently emerging and reemerging diseases have reservoirs in wildlife and/or are foodborne.

Factors that can cause emergence include altered human demographics or behavior, ranging from societal upheavals that cause people to leave urban areas to simple changes in food preferences. For example, the popularity of prewashed greens can facilitate some outbreaks of *E coli* O157:H7. Breakdowns in public health measures such as sanitation and vaccination also increase the spread of disease. Changing land use patterns may alter the number of reservoir hosts, increase the incidence of infection in these animals, encourage genetic changes in the pathogen (eg, recombination with other strains), or bring animal hosts or disease vectors into closer contact with people. Because many mosquitoes preferentially breed along the edges of forests rather than deep among the trees, deforestation can increase populations of these species. Degradation of their natural habitats, as well as the ready availability of food near human dwellings, can encourage wildlife to move into suburban areas. The growth of the

human population also exerts pressures that ultimately result in increased contact with wildlife. Climate change can be a factor in disease emergence, particularly for arthropodborne pathogens such as *Rickettsia* spp. A warmer climate not only allows vectors to survive the winter but also permits a longer transmission season. Climate changes may also favor some non-arthropodborne diseases; for example, increased rainfall has been linked to outbreaks of plague in some areas.

Technologic and industrial changes in food production can contribute to disease emergence by increasing the concentration, movement, and mixing of animals. Long-distance transport has been associated with increased shedding of enteric pathogens, including *Salmonella*. Decreased genetic diversity may eliminate species, breeds, or individuals with innate resistance to a disease. The development of large-scale farms and food-processing facilities has led to the exposure of greater numbers of people to a contaminated food source. Increased mobility of people, animals, and goods allows diseases to spread quickly. Viruses that formerly died out after affecting small numbers of animals and/or people can now find many susceptible hosts within a short period. The SARS coronavirus spread to 30 countries on 6 continents within months of the initial outbreak. Occasionally, the pathogen itself may become more virulent or better adapted to people, or it may undergo changes that affect transmission patterns. More virulent strains of the West Nile virus have emerged since the 1980s, and a new variant, which can replicate more rapidly in mosquitoes, has become established in North America.

Some diseases are emerging not because they are more common but because they are better recognized. Increased recognition can result from improved diagnostic techniques, increased use of laboratories for identification of specific pathogens, and better awareness among physicians. Some spotted fever *Rickettsia* spp are emerging, in part, because the increased use of molecular techniques facilitates their identification. Marburg virus, once thought to be a very rare and less virulent relative of ebolaviruses, was recently found to have caused hemorrhagic disease in workers at one African mine since the 1980s or earlier. This focus of bat-transmitted infections was only recognized when highly fatal outbreaks affected hundreds of people in the Democratic Republic of the Congo in 1998–2000.

Increased human susceptibility has contributed to the emergence or recognition of some opportunistic pathogens. The

number of immunocompromised people has been increased by factors such as the AIDS epidemic, the success of organ transplantation programs, and the improved survival of those with primary and secondary immunodeficiencies. Modern medicine also allows more people, many of whom develop chronic conditions, to survive to an advanced age.

TREATMENT

The treatment of zoonotic and nonzoonotic diseases of animals is similar; however, treatments that prolong the shedding of zoonotic organisms should be avoided unless there are overriding considerations. For example, antibiotic treatment is usually contraindicated in uncomplicated *Salmonella*-associated diarrhea, because these drugs may prolong shedding of this organism. Conversely, animals that carry zoonotic organisms may sometimes be treated to reduce human exposure, even when the infection is subclinical or expected to be self-limiting, such as a minor skin lesion caused by dermatophytes. During treatment of zoonotic diseases, every precaution should be taken to prevent human infection. Professional judgment is required to determine whether to keep the animal in its home environment or isolate it in a hospital ward. Factors to consider include the potential severity of the disease in people, the susceptibility of individuals in the household, and the ability of human caregiver(s) to effectively perform barrier nursing, sanitation, and hygiene protocols. The owner should always be informed if treatment is not certain to eliminate the pathogen, which could then persist in a latent or chronic, subclinical form. Zoonotic concerns may dictate euthanasia of the animal, especially when the disease is likely to be fatal.

People who may have contracted a zoonotic disease should be referred to their physician for diagnosis and treatment. The physician should be given any information necessary to facilitate diagnosis, particularly if the disease is unusual and would not ordinarily be among the differential diagnoses. Simultaneous elimination of the pathogen from both animal and human hosts is ideal, to prevent it from cycling between the hosts. Public health authorities must be contacted when a reportable zoonotic disease (eg, rabies) is found in an animal.

PREVENTION

People can be protected from some zoonoses by eliminating the pathogen from

its animal reservoir(s). In some countries, livestock diseases such as bovine and porcine brucellosis and bovine tuberculosis have been eradicated, and the prevalence of *Salmonella* in poultry has been significantly reduced. Vaccination (eg, rabies), treatment of clinical cases, flea and tick control, periodic testing for enteric parasites or other pathogens, and other disease control measures in domestic animals can also protect people. Human vaccines are available for a few diseases, and arthropod control measures decrease the risk of vectorborne infections.

Foodborne zoonoses can often be interrupted by using good sanitation and hygiene during food preparation, eliminating cross-contamination of foods, cooking all foods of animal origin (including invertebrates such as mollusks and snails) to safe temperatures, and thoroughly washing vegetables shortly before eating. Prions cannot be destroyed by cooking; meat inspection and elimination of the pathogen from animals remain the only ways to reduce the risks from these agents. Modern water treatment procedures eliminate most waterborne zoonoses. Where such facilities are unavailable, drinking water should be boiled, filtered, or otherwise treated to remove pathogens. Accidental ingestion of lake or stream water should be avoided. The contamination of irrigation water used for agriculture has become an increasing concern with the rise of pathogens such as enterohemorrhagic *Escherichia coli* (eg, *E coli* O157:H7). Measures such as composting livestock manure before spreading it on fields may lower the risks from this source. However, post-harvest procedures to eliminate contamination are also critical.

It is often difficult to avoid diseases acquired from the environment. However, measures to eliminate skin contact with soil, such as wearing gloves when gardening and avoiding dust inhalation, are helpful.

During contact with apparently healthy animals, good hygiene (including hand washing) is an important preventive measure. Hand washing is particularly important before eating or any other hand-to-mouth contact. In fairs, petting zoos, or other environments where the public may contact animals, hand-washing facilities should be provided, and eating or drinking in the animal areas should be discouraged. Children <5 yr old should be supervised closely; their immune systems are generally more vulnerable to pathogens, they are less likely to follow sanitary precautions, and they are more likely to engage in risky behaviors such as tasting dirt. Detailed zoonosis

control programs for various types of facilities have been published.

Protective measures in veterinary hospitals include barrier precautions (including gloves, protective outerwear, and other personal protective equipment as appropriate), good hygiene, sanitation and disinfection, appropriate disposal of infectious material, and use of isolation units for animals with known zoonoses.

Prevention in Immunocompromised Populations:

Counseling immunocompromised owners must strike a balance between awareness of the risks from zoonoses and acknowledgement of the human-animal bond and the psychologic benefits of animal companionship. If the person chooses to have a pet, the veterinarian can help make that decision as safe as possible. Topics to discuss include the risks from feeding raw meat or eggs, the prevention of garbage eating and coprophagia in dogs, the importance of flea and tick control, and the dangers of allowing cats and dogs to hunt. Pets should not be allowed to drink nonpotable water, including water from lakes or streams and water from toilet bowls. Claws should be kept clipped short to reduce the risk of scratches, and rough play that might encourage biting or scratching should be avoided. Regular and thorough cleaning of bedding and cages prevents the accumulation of debris that can shelter microorgan-

isms. Owners should be counseled to avoid any direct contact with feces, as well as to practice excellent hygiene when handling the pet. The litter box should be cleaned daily, preferably by a household member who is not immunocompromised, to reduce the risk of toxoplasmosis. Similarly, cleaning aquariums carries the risk of exposure to *Mycobacterium marinum* and is best done by a healthy individual. Regular veterinary visits, with periodic screening for intestinal parasites and/or other zoonotic pathogens as appropriate, are essential for all pets. Pets that develop diarrhea or other diseases should be brought in promptly for diagnosis.

Any new pet should be examined by a veterinarian to ensure it is not carrying intestinal parasites, mites, dermatophytes, or other zoonotic pathogens. A healthy, unstressed adult dog or cat with a known history and no recent exposure to environments with high concentrations of pathogens is preferable to a puppy or kitten. Immunocompromised persons should avoid contact with reptiles, baby chicks, or ducklings, all of which may shed *Salmonella*. Some amphibians and exotic mammalian pets may also have a higher likelihood of carrying *Salmonella*. Avoidance of strays, wildlife, nonhuman primates, and animals with diarrhea or any other illness is particularly important. It is also prudent to stay away from animals in fairs, petting zoos, farms, schools, and

TABLE 4 GLOBAL ZOONOSES^a

Disease	Causative Organism	Animals Involved
BACTERIAL DISEASES		
Actinomycosis (see p 590)	<i>Actinomyces bovis</i> and other species in animals may affect people, but most human infections are caused by commensals of people, especially <i>Actinomyces israelii</i>	Mammals
Anthrax (see p 593)	<i>Bacillus anthracis</i>	Mainly in cattle, sheep, goats, horses, wild herbivorous animals; virtually all mammals and some birds are susceptible to high dose

similar settings, and to take additional precautions if avoidance is impractical.

Veterinarians have a vital role in educating immunocompromised owners on the risks from zoonotic diseases, as well as the steps that can be taken to decrease risk. Educational materials such as signs and brochures may prompt owners to ask for advice. Educational materials can also be used to warn pregnant women of the risks from toxoplasmosis and other zoonotic pathogens, or to remind owners that their veterinarian can provide help with safe pet selection and zoonosis prevention in households with children. Guidelines on zoonosis prevention for therapy animals used in hospitals and convalescent homes have also been published.

ZOO NOTIC DISEASES

TABLE 4 lists zoonotic bacterial, viral, fungal, and parasitic diseases, grouped by category. Many proven zoonoses, including some diseases that are rare in people, organisms that are maintained primarily in people, some primate diseases, and diseases caused by fish and reptile toxins have been omitted. The table is intended to give a general clinical picture of each disease; current medical texts or review articles should be consulted for a more complete description. Clinical signs are listed; asymptomatic infections can also be assumed to occur in

most cases. An indication of the mortality rate among healthy individuals has been provided for many infections. However, there is almost always a chance of death whenever lesions can become generalized, vital organs may be affected, secondary infections occur, and/or the patient is immunosuppressed. The mortality rate is often influenced by the availability of medical care, and it is generally lower when advanced medical support is available. The risk of death from some bacterial diseases with high mortality rates can be nearly eliminated with prompt antibiotic treatment.

If a disease is known to have unusual manifestations or to be particularly common and/or severe in immunocompromised people, this has been noted. In addition to these diseases, many pathogens can cause more severe disease and/or unusual signs in immunocompromised patients. Information on the geographic range of an organism should be taken as a rough guide. The precise ranges of many pathogens have not been completely determined. Organisms may also expand their range or be eradicated from areas where they were once abundant. In this table, "worldwide" indicates those organisms that are widespread and found on all major continents, although they may be absent from some areas (eg, polar regions or some islands). In some cases, organisms indicated as being present on a continent may nevertheless have a limited distribution.

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
BACTERIAL DISEASES		
Worldwide; very rare in people	Probably contact; actinomycosis usually disseminates from endogenous human flora	Granulomas, abscesses, skin lesions; chronic bronchopneumonia; abdominal mass that may mimic a tumor; endocarditis; sepsis
Worldwide but distribution is focal; common in Africa, Asia, South America, Middle East, parts of Europe	Occupational contact exposure (abraded skin, mechanical transmission by biting flies, other routes); ingestion/foodborne, rarely airborne	Early signs vary with route of inoculation; papule to ulcerative skin lesions; mild to severe gastroenteritis ± hematemesis, bloody diarrhea, ascites (abdominal GI form); sore throat, dysphagia, fever, neck swelling, mouth lesions (oropharyngeal GI form); pneumonia; all may progress to sepsis, meningitis; untreated cases fatal in 5%-20% (cutaneous) to 100% (inhalation)

(continued)

TABLE 4 GLOBAL ZOONOSES^a (continued)

Disease	Causative Organism	Animals Involved
BACTERIAL DISEASES (continued)		
<i>Arcobacter</i> infections	<i>Arcobacter butzleri</i> , <i>A. cryaerophilus</i> , <i>A. skirrowii</i> , possibly others	Poultry, cattle, pigs, sheep, horses, shellfish; some studies detected these organisms in dogs and/or cats
Bordetellosis (see p 1464 and p 1491)	<i>Bordetella bronchiseptica</i>	Dogs, rabbits, cats, pigs, guinea pigs, other mammals
Borreliosis (see p 659)		
—Lyme disease	<i>Borrelia burgdorferi</i> sensu lato complex (<i>B. burgdorferi</i> sensu stricto, <i>B. garinii</i> , <i>B. afzelii</i> , <i>B. spielmanii</i> , <i>B. japonica</i>)	Wild rodents, insectivores, hedgehogs, hares, other mammals; birds are reservoirs for agent; deer are hosts for tick vector only (blood meals)
—Tickborne relapsing fever	<i>B. recurrentis</i> , <i>B. crocidurae</i> , <i>B. turicatae</i> , <i>B. hermsii</i> , <i>B. persica</i> , <i>B. hispanica</i> , others; some species such as <i>B. duttoni</i> are human pathogens and not zoonotic	Wild rodents, insectivores, possibly birds
—Southern tick-associated rash illness	Etiology uncertain; various <i>Borrelia</i> spp suggested	
Brucellosis (see p 1348 and p 1402)	<i>Brucella abortus</i>	Cattle, bison, water buffalo, African buffalo, elk, deer, sheep, goats, camels, South American camelids; other mammalian spillover hosts
	<i>B. melitensis</i>	Goats, sheep, camels; other mammalian spillover hosts
	<i>B. suis</i> biovars 1–4; biovar 5 has not been reported in people	Swine and wild pigs (biovars 1, 2, 3), European hares (biovar 2), reindeer and caribou (biovar 4); <i>B. suis</i> also in some other mammals

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
BACTERIAL DISEASES (continued)		
Worldwide	Ingestion of contaminated water, undercooked meat (especially poultry) has been suggested	Gastroenteritis; bacteremia, mainly in patients with chronic illnesses; endocarditis, peritonitis; emerging and incompletely understood
Worldwide; uncommon in people	Exposure to saliva or sputum, aerosols	Sinusitis, bronchitis, pertussis-like illness; pneumonia and disseminated disease (eg, endocarditis, peritonitis, meningitis), usually in immunocompromised; wound infection
Agents exist worldwide where <i>Ixodes</i> ticks are found; human cases have been reported in North America, Europe, Australia, parts of Asia, Amazon region of South America	<i>Ixodes</i> spp bites	Nonspecific febrile illness early; target skin lesions in many; may progress to arthritis, neurologic, cardiac, and/or skin signs (acrodermatitis chronica atrophicans); syndromes may vary with infecting agent
Africa, Asia, Europe, Americas; species varies with region	Tick bites (mainly <i>Ornithodoros</i> spp)	High fever, malaise, headache, myalgia, chills; neurologic signs or abortion possible; recurring episodes, often milder, after a symptom-free period; death in 2%-5%
USA; most cases in southeast	Tick bite (<i>Amblyomma americanum</i>)	Resembles Lyme disease
Once worldwide, now eradicated from domestic animals in some countries or regions; reservoirs in wildlife in some disease-free areas	Ingestion (especially unpasteurized dairy products or undercooked meat), contact with mucous membranes and broken skin; strain 19 vaccine	Extremely variable, subacute and undulant to sepsis; often nonspecific febrile illness with drenching sweats early; arthritis, spondylitis, epididymo-orchitis, endocarditis, neurologic, other syndromes if chronic; case fatality 5% in untreated
Asia, Africa, Middle East, Mexico, Central and South America, some parts of Europe	Ingestion (including unpasteurized dairy products or undercooked meat), contact with mucous membranes and broken skin; Rev 1 vaccine	As above; this species highly pathogenic for people
Biovars 1 and 3 worldwide in swine-raising regions except eradicated or nearly eradicated from domestic pigs in some countries; biovar 2 in wild boar in Europe; biovar 4 in Arctic	Ingestion, direct contact with mucous membranes and broken skin	As above

TABLE 4 GLOBAL ZONOSSES^a (continued)

Disease	Causative Organism	Animals Involved
BACTERIAL DISEASES (continued)		
Brucellosis (continued)	<i>B canis</i>	Dogs; evidence of infection in wild canids including coyotes, foxes
	<i>B pinnipedialis</i> and <i>B ceti</i>	Marine mammals
<i>Campylobacter</i> enteritis (see p 191)	<i>C jejuni</i> , <i>C coli</i> , occasionally other species; some strains of <i>C jejuni</i> seem to have broader host ranges than others	Poultry, cattle, swine, dogs, cats, rodents, other mammals, wild birds
<i>Campylobacter fetus</i> infection	<i>C fetus</i> subsp. <i>fetus</i> (most cases), <i>C fetus</i> subsp. <i>testudinum</i> (proposed name); possibly <i>C fetus</i> subsp. <i>venerealis</i>	<i>C fetus</i> subsp. <i>fetus</i> and <i>C</i> subsp. <i>venerealis</i> in cattle, sheep, goats; <i>C fetus</i> subsp. <i>testudinum</i> in reptiles
<i>Capnocytophaga</i> infection	<i>C canimorsus</i> , <i>C cynodegmi</i>	Dogs, cats
Cat scratch disease	<i>Bartonella henselae</i> ; <i>B clarridgeiae</i> and other <i>Bartonella</i> species also implicated rarely in cat scratch disease or other conditions (eg, endocarditis)	Cats and other felids; other <i>Bartonella</i> spp in canids, rodents, rabbits, other animals
Chlamydiosis (see also PSITTACOSIS, p 2428)	<i>Chlamydia</i> (<i>Chlamydophila</i>) <i>abortus</i> , <i>C felis</i>	<i>C abortus</i> in sheep, goats, cattle, other mammals; <i>C felis</i> in cats
Clostridial diseases (see p 601)	<i>Clostridium difficile</i> ; some ribotypes found in animals have been implicated as potential zoonoses	Ribotypes from some calves, pigs, dogs are identical to some ribotypes found in people

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
BACTERIAL DISEASES (continued)		
Worldwide; rare in people	Probably via ingestion or contact with mucous membranes, broken skin; close contact, especially with animals that recently aborted or gave birth	Probably as above
Atlantic, Arctic, and Pacific oceans; Mediterranean sea	Laboratory exposure; sources of other infections unknown (possibly contact with animals or exposure to seawater); rare or underdiagnosed in people	Few cases known: mild to severe febrile illness, similar to that caused by other <i>Brucella</i> spp; neurobrucellosis with headache and chronic neurologic signs; spinal osteomyelitis
Worldwide	Foodborne (especially poultry and other meats, unpasteurized dairy products); waterborne; contact with infected animals (fecal/oral)	Gastroenteritis from mild cases to fulminating or relapsing colitis; occasional sequelae such as reactive arthritis; occasionally, other syndromes, including sepsis
Worldwide	Probably direct contact or ingestion; often unknown	Opportunist; sepsis, meningitis, endocarditis, abscesses, other systemic infections in elderly, immunocompromised, or infants; abortions, preterm births in pregnant women, neonatal sepsis; gastroenteritis not prominent in most cases
Probably worldwide	Bites or scratches	Fever, localized infections to bacteremia or sepsis, endocarditis, meningitis; often in immunocompromised or elderly
Worldwide	Often associated with scratches, bites, especially from cats; potential for other exposures to broken skin via saliva; exposure of conjunctiva	Lymphadenopathy (may be absent in elderly), fever, malaise, skin lesions at inoculation site in immunocompetent, usually self-limiting with complications (eg, endocarditis, neuroretinitis, neurologic disease) uncommon; inoculation into eye results in conjunctivitis ± ocular granuloma and local lymphadenopathy; risk of bacteremia, disseminated disease, bacillary angiomatosis in immunosuppressed
<i>C. felis</i> worldwide; <i>C. abortus</i> in most sheep-raising areas but not Australia or New Zealand	Contact with animals; <i>C. abortus</i> probably contact with pregnant or aborting ruminants	<i>C. abortus</i> : abortions, septicemia; <i>C. felis</i> suspected agent of keratoconjunctivitis, also implicated in other conditions (controversial)
Worldwide	Possible zoonosis; from contact or ingestion in contaminated meat; also from environment and contact with infected people	Gastroenteritis, varying in severity from diarrhea to fulminant colitis, usually in conjunction with antibiotic use

(continued)

TABLE 4 GLOBAL ZOONOSES^a (continued)

Disease	Causative Organism	Animals Involved
BACTERIAL DISEASES (continued)		
Clostridial diseases (continued)	<i>Clostridium perfringens</i> , type A (most common), C, or D; environmental or endogenous source, with some potential for zoonotic transmission	Domestic and wild animals, people
<i>Corynebacterium ulcerans</i> and <i>C pseudotuberculosis</i> infections	<i>C ulcerans</i> , <i>C pseudotuberculosis</i>	<i>C ulcerans</i> in cattle, pigs, small ruminants, dogs, cats, ferrets, other domestic and wild animals; <i>C pseudotuberculosis</i> in sheep, goats, cattle, horses, camelids, other mammals
Dermatophilosis (see p 858)	<i>Dermatophilus congolensis</i>	Cattle, horses, deer, sheep, goats, other mammals
Enterohemorrhagic <i>Escherichia coli</i> infections ^b	<i>E coli</i> O157:H7; also implicated are types O157:H, and members of serogroups O26, O103, O104, O111, O145, and others	Especially cattle, sheep; also goats, bison, deer, pigs, other species of mammals, birds
Erysipeloid (see p 625)	<i>Erysipelothrix rhusiopathiae</i>	Swine, sheep, cattle, rodents, marine mammals; many other domestic and wild mammals and marsupials, birds (including poultry), reptiles, fish, mollusks, crustaceans
Glanders (see p 706)	<i>Burkholderia mallei</i>	Equids are reservoirs; felids, many other domesticated and wild mammals also susceptible
<i>Helicobacter</i> infection	<i>H pullorum</i> , <i>H suis</i> , other species suspected as zoonoses	Poultry (<i>H pullorum</i>), rodents (<i>H pullorum</i> and other species), pigs (<i>H suis</i>), dogs (<i>H canis</i>), many other mammals

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
BACTERIAL DISEASES (continued)		
Worldwide	Foodborne (usually type A); nonfood-associated intestinal infection; wound contaminant, usually environmental; may be endogenous in debilitated from GI or urogenital tract	Foodborne gastroenteritis, usually brief, self-limited except in debilitated; nonfood-related intestinal infection with prolonged diarrhea, sometimes bloody, mainly in elderly after antibiotics; life-threatening necrotic enteritis, often in debilitated; gas gangrene, sepsis; necrotic enteritis, gas gangrene, sepsis are fatal if not treated
Probably worldwide; uncommon in people but may be increasing	Direct contact, consumption of unpasteurized milk products	Acute upper respiratory illness with sinusitis, sore throat, tonsillitis, or more severe pharyngitis resembling diphtheria (pseudomembranous pharyngitis); cardiorespiratory complications possible; peritonitis; isolated skin infection; some cases serious or fatal
Worldwide, especially in warmer regions	Usually direct contact with lesions; mechanical transmission on arthropod vectors, fomites possible	Pustular desquamative dermatitis, other skin lesions
Worldwide	Ingestion of undercooked meat (especially ground beef), vegetables or water contaminated with feces; direct contact with feces or contaminated soil	Diarrhea or hemorrhagic colitis; up to 15% of patients with hemorrhagic colitis progress to hemolytic uremic syndrome (HUS); case fatality rate for HUS is 3%-5%, higher in some populations (eg, 5%-10% in children, up to 50% in elderly)
Worldwide	Contact with animal products; via skin, usually after scratch or puncture wound; contaminated soil (survives for weeks to months)	Localized cellulitis, usually self-limiting, often on hands; generalized skin lesions (uncommon); arthritis, often in finger joints near skin lesion; endocarditis (with high mortality, 38%); generalization with sepsis, other syndromes uncommon and often in immunocompromised
Middle East, Asia, Africa and South America	Contact with infected animals, tissues through broken skin, mucous membrane; ingestion; inhalation	Mucous membrane or skin lesions; pneumonia and pulmonary abscess; sepsis; chronic abscesses, nodules, ulcers in many organs, weight loss, lymphadenopathy; case fatality rate varies with form, but >95% in untreated septicemia
	Uncertain; possibly ingestion of undercooked meat or direct contact	Gastroenteritis or diarrhea, liver disease; bacteremia in immunosuppressed patients

(continued)

TABLE 4 GLOBAL ZONNOSES^a (continued)

Disease	Causative Organism	Animals Involved
BACTERIAL DISEASES (continued)		
Leprosy (see p 692)	<i>Mycobacterium leprae</i>	Armadillos; nonhuman primates (rare)
Leptospirosis (see p 646)	<i>Leptospira</i> spp	Domestic and wild animals; reservoir hosts include rodents, dogs, cattle, pigs, farmed red deer, others
Listeriosis (see p 656)	<i>Listeria monocytogenes</i> (types most often associated with disease are 1/2a, 1/2b, 4b), <i>Listeria ivanovii</i> (rare)	Numerous mammals, birds, fish, crustaceans
Melioidosis (Pseudoglanders, see p 661)	<i>Burkholderia pseudo-mallei</i> (other species of soil-associated <i>Burkholderia</i> , such as <i>B. oklahomensis</i> sp nov in North America, rarely linked to human infections)	Sheep, goats, swine; occasional cases in many other terrestrial and aquatic mammals; also reptiles, some birds including parrots, tropical fish
Methicillin-resistant <i>Staphylococcus aureus</i> (MRSA) infections	<i>S. aureus</i> that carry <i>mecA</i> gene; some strains maintained in animals (eg, livestock associated CC398), other strains mainly in people but animals can become carriers	Pigs (major reservoirs for livestock-associated strain CC398, also carry ST9); cats, dogs mainly acquire strains from people; MRSA also reported in other mammals, including horses, cattle; birds, including poultry, psittacines; turtles
Mycobacteriosis (see p 687)	<i>Mycobacterium avium</i> complex	Many species of mammals, some birds

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
BACTERIAL DISEASES (continued)		
Armadillos in parts of southern USA, Mexico, South America; non-human primates in Africa, possibly other locations; only human reservoirs in other areas	Transmission of animal leprosy to people likely	Various skin lesions, sensory nerve lesions and deficits, nasal mucosal lesions; mild, self limiting to progressive destruction
Worldwide	Occupational and recreational exposure, or exposure to rodent-contaminated material in urban locations; especially skin, mucous membrane contact with contaminated urine, infected fetuses, or reproductive fluids; water- and foodborne	Asymptomatic to severe, sometimes biphasic; nonspecific febrile illness followed by aseptic meningitis or icteric form (especially liver, kidney, CNS involvement, hemorrhages possible); pulmonary hemorrhage and edema, other syndromes; uveitis can be sequela; case fatality rate varies with syndrome (uncommon in aseptic meningitis, 5%–15% in icteric form, 30%–60% in severe pulmonary form)
Worldwide	Foodborne, especially unpasteurized dairy products, raw meat and fish, vegetables, processed foods contaminated after processing; ingestion of contaminated water, soil; direct contact with infected animals; nosocomial in hospitals, institutions	Acute, self limited febrile gastroenteritis or mild, flu-like illness; ocular disease, conjunctivitis; abortion, premature or septicemic newborn if infected during pregnancy; meningitis, meningoencephalitis, septicemia in elderly, immunosuppressed, and infants; papular or pustular rash ± fever, chills in healthy adults after handling infected fetuses
Asia, Africa, Australia, South America, Middle East, Caribbean	Wound infection, inhalation, and ingestion; organisms live in soil and surface water; most cases are acquired from environment, but direct transmission from animals is possible	Mimics many other diseases; acute localized infections, including skin lesions, cellulitis, abscesses, corneal ulcers; pulmonary disease, septicemia, internal organ abscesses; often occurs in immunocompromised; case fatality rate varies with form, >90% in untreated septicemia
Worldwide; can be reverse zoonosis or zoonosis; major strains in animals can vary with region	Usually by direct contact (typically with asymptomatic carrier animals); other routes also described; can be nosocomial in hospitals	Opportunist; localized skin and soft-tissue infections, invasive disease including septicemia, toxic shock syndrome; mortality varies with syndrome and success in finding antibiotic
Worldwide	Environmental, mainly from water, and/or soil; infection common to people and animals	Soft-tissue and bone infections; cervical lymphadenitis; pulmonary disease, often in immunocompromised or those with preexisting lung conditions; disseminated in immunocompromised, especially AIDS patients with uncontrolled disease

(continued)

TABLE 4 GLOBAL ZONONOSES^a (continued)

Disease	Causative Organism	Animals Involved
BACTERIAL DISEASES (continued)		
Mycobacteriosis (continued)	<i>M avium</i> <i>paratuberculosis</i>	Cattle, sheep, goats, camelids, deer, other ruminants; rabbits and other nonruminants; corvids
	Mycobacteria other than tuberculosis (includes <i>M simiae</i> , <i>M kansasii</i> , <i>M xenopi</i> , <i>M scrofulaceum</i> , <i>M szulgai</i> , <i>M chelonae</i> , <i>M marinum</i> , <i>M ulcerans</i> , others)	Cattle, other ruminants; swine, cats, dogs, koalas, other mammals, amphibians, reptiles (uncommon), fish; predominant <i>Mycobacterium</i> spp vary with host
<i>Mycoplasma</i> infections	<i>Mycoplasma</i> spp	Livestock, nonhuman primates, marine mammals, cats, dogs, rodents, other mammals
Pasteurellosis (see p 765 and p 1944)	<i>Pasteurella multocida</i> and other species	Many species of domestic and wild animals, including dogs, cats, livestock, rabbits, birds
Plague (see p 677)	<i>Yersinia pestis</i>	Rodents (eg, squirrels, prairie dogs, rats) and lagomorphs (pikas in Asia) are main reservoir; many mammals can be incidental hosts; cats and wild felids especially susceptible
Psittacosis and ornithosis (see p 2808)	<i>Chlamydia</i> (<i>Chlamydophila</i>) <i>psittaci</i>	Psittacine birds (especially parakeets, cockatiels), pigeons, turkeys, ducks, geese, and other domestic or wild birds; mammalian strains of <i>C psittaci</i> also exist (zoonotic potential still undetermined)
Rat bite fever	<i>Streptobacillus moniliformis</i>	Rodents; might also be transmitted by carnivores (eg, dogs, cats, ferrets), which are probably infected or transiently colonized from rodents
	<i>Spirillum minus</i>	Rodents; might also be transmitted by carnivores, which are probably infected or transiently colonized from rodents

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
BACTERIAL DISEASES (continued)		
Worldwide	Ingestion; accidental injection of vaccine	Postulated involvement in Crohn's disease after ingestion (controversial); severe local reaction if vaccine accidentally injected
Worldwide; distribution varies with the organism	Environmental, from water and/or soil	Same syndromes as <i>M avium</i> complex; some organisms tend to be associated with certain syndromes (eg, <i>M marinum</i> , <i>M ulcerans</i> , with ulcerative or nodular dermatitis)
Worldwide; zoonotic infections rare	Direct contact; bites; wound contamination, including accidental inoculation	Asymptomatic carriage; cellulitis; other syndromes, including respiratory disease, septic arthritis, septicemia have been reported, especially in immunocompromised
Worldwide	Wounds, scratches, bites, close contact with mucus membranes	Wound infections, cellulitis most common; other syndromes possible, including osteomyelitis, septic arthritis, sepsis, meningitis, respiratory disease; systemic conditions more common in immunocompromised
Foci in North and South America, Asia, Middle East, and Africa	Flea bites, aerosols, handling infected animals or tissues (contact with broken skin or mucous membranes), bites or scratches, eating uncooked infected tissues	Febrile flu-like syndrome with swollen, very painful draining lymph node(s) (buboes); pneumonia; sepsis can occur in either bubonic or pneumonic form; case fatality rate in untreated 40%–70% (bubonic) to 100% (pneumonic); < 5% mortality if bubonic form treated early
Worldwide	Inhalation of respiratory secretions or dried guano	Influenza-like febrile illness with nonproductive cough that may progress to pneumonia; complications, including endocarditis, myocarditis, meningoencephalitis, hepatitis, glomerulonephritis, and other organ dysfunction; sepsis; some cases fatal if untreated, < 1% with treatment
Probably worldwide	Bites and scratches; handling or kissing a rodent, exposure to rodent urine; can be waterborne or foodborne	Fever, severe myalgia and joint pain, headache, rash, sometimes GI signs; complications, including polyarthritis (usually but not always sterile), hepatitis, endocarditis, focal abscesses, sepsis possible if untreated; overall case fatality rate 10%–13% if untreated
Organism is common only in Asia	Mainly bites and scratches	As above, but indurated, often ulcerated lesion at inoculation site; can relapse; some (minority) may have distinctive rash (large violaceous or reddish macules); polyarthritis is rare; overall case fatality rate 7%–10% if untreated

TABLE 4 GLOBAL ZONNOSES^a (continued)

Disease	Causative Organism	Animals Involved
BACTERIAL DISEASES (continued)		
Salmonellosis (see p 195)	<i>Salmonella enterica</i> and <i>S bongori</i> (>2,500 serovars)	Widespread in mammals, birds, reptiles, amphibians, including domestic species; also in crustaceans; higher risk pets for human exposure may include reptiles, amphibians, young poultry, some exotic mammals
Streptococcal infections	<i>Streptococcus</i> spp, including <i>S suis</i> , <i>S equi zooepidemicus</i> , <i>S canis</i> , <i>S iniae</i> , possibly others	<i>S suis</i> in swine; <i>S equi zooepidemicus</i> in horses; <i>S canis</i> in dogs, cats; <i>S iniae</i> in fish; each species can also be found in other animals
Tuberculosis (see also MYCOBACTERIOSIS, p 2426, p 2869, and p 687)	<i>Mycobacterium bovis</i>	Cattle, bison, African buffalo, cervids, brushtail opossums, badgers, kudu can be reservoirs; swine and many other mammals can be spillover hosts
	<i>Mycobacterium caprae</i>	Mainly goats, also infects other ruminants; can occur in other mammals, including pigs, horses, cervids, camels, carnivores
	<i>Mycobacterium microti</i>	Rodents thought to be reservoir; can occur in domestic animals, including cats, dogs, ferrets, livestock
Tularemia (see p 692)	<i>Francisella tularensis</i> subsp <i>tularensis</i> more virulent, <i>F tularensis</i> subsp <i>holarctica</i> (<i>F tularensis</i> type B) less virulent, <i>F tularensis</i> subsp <i>mediasiatica</i> , <i>F tularensis</i> subsp <i>novicida</i>	Rabbits, rodents, cats, sheep, other mammals, birds, reptiles, fish; often in wild animals
Vibriosis	<i>Vibrio parahaemolyticus</i>	Marine and estuarine shellfish, fish; also environmental in aquatic environments

TABLE 4 GLOBAL ZONOOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
BACTERIAL DISEASES (continued)		
Worldwide	Foodborne infection or fecal-oral; some cases of occupational and recreational exposure	Gastroenteritis to sepsis; focal infections possible; especially severe in the elderly, young children, or immunocompromised
Worldwide	Ingestion, especially of unpasteurized dairy products, pork; direct contact often through broken skin; the human pathogen <i>S pyogenes</i> can also colonize bovine udder and be transmitted in milk	Skin and soft-tissue infections; pharyngitis; other conditions, including pneumonia, meningitis, arthritis, endocarditis, streptococcal toxic shock syndrome, sepsis
Once worldwide, now eradicated or rare in some countries	Ingestion (unpasteurized dairy products, undercooked meat including bushmeat), inhalation, contamination of breaks in the skin	Skin lesions, cervical lymphadenitis (scrofula), pulmonary disease; genitourinary disease; can affect bones and joints, meninges; gastroenteritis
Reported mainly in Europe	Thought to be ingestion or direct contact with livestock, similarly to <i>M bovis</i>	Extrapulmonary conditions, including skin lesions, meningitis, lymphadenitis, pericarditis, urinary, dissemination; also pulmonary disease
Appears to be rare human zoonosis		Most reported cases have been pulmonary; can also cause extrapulmonary disease
<i>F tularensis</i> subsp <i>tularensis</i> almost exclusively in North America; <i>F tularensis</i> subsp <i>holarctica</i> in North America, Europe, Asia; <i>F tularensis</i> subsp <i>mediasiatica</i> in Central Asia; <i>F tularensis</i> subsp <i>novicida</i> reported in North America, Australia, Spain	Contact with mucous membranes, broken skin; insect bites (tabanids, mosquitoes, hard ticks); fomites; ingestion in food or water; inhalation	Nonspecific febrile illness, lymphadenitis; ulcerative skin lesions, exudative pharyngitis and stomatitis, conjunctivitis, gastroenteritis, respiratory signs or pneumonia, sepsis; case fatality rate 5% (localized disease, untreated) to >50% (untreated typhoidal form or severe respiratory disease)
Worldwide	Ingestion; wound infections	Gastroenteritis; dysentery (especially in some geographic regions); wound infections (mild to severe, including necrotizing fasciitis); sepsis; severe wound infections and sepsis usually in immunocompromised or those with liver disease (case fatality rate for sepsis 29%)

(continued)

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Disease	Causative Organism	Animals Involved
BACTERIAL DISEASES (continued)		
Vibriosis (continued)	<i>V vulnificus</i>	Marine shellfish, crustaceans (eg, shrimp), fish; also environmental in aquatic environments
	<i>V cholerae</i> O1/O139 (epidemic strains)	Oysters, crabs, shrimp, mussels; most cases acquired from people
	<i>V cholerae</i> non-O1/O139 (nonepidemic strains)	Oysters, other seafood; also environmental in aquatic environ- ments
Yersiniosis	<i>Yersinia pseudotubercu- losis</i>	Many species of mammals, including swine, dogs, cats, rodents, wild mammals, birds
	<i>Y enterocolitica</i> ; not all serotypes are pathogenic	Many domestic and wild mammals, including rodents; some birds, reptiles, amphibians; zoonotic serotypes most common in pigs (major zoonotic source), pathogenic types also occur in dogs, cats
RICKETTSIAL DISEASES		
Human ewingii ehrlichiosis (formerly granulo- cytic ehrlichiosis)	<i>Ehrlichia ewingii</i>	Dogs, deer proposed
Human monocytic ehrlichiosis (see p 803)	<i>Ehrlichia chaffeensis</i>	Deer are probably major reservoir in North America, dogs and other canids, lemurs, other mammals can also be infected

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
BACTERIAL DISEASES (continued)		
Worldwide; human cases have been reported in North America, Europe, Asia	Ingestion (often raw oysters); wound infection from water or handling hosts	Wound infections from mild, self-limited lesions, bullae to cellulitis, myositis; necrotizing fasciitis; gastroenteritis; sepsis, usually in immunocompromised or those with liver disease, other debilitating illnesses; case fatality rate for sepsis >50%, and up to 25% for wound infections
Rare/absent to epidemic in different regions; one focus along USA Gulf Coast in shellfish	Ingestion	Mild to severe, voluminous diarrhea, vomiting, dehydration; severe cases fatal if untreated, but low mortality if treated
Worldwide	Ingestion; wound infection	Gastroenteritis, usually mild and self-limited; wound infections; septicemia, usually in immunosuppressed or those with liver disease (case fatality rate for sepsis 47%–60% or higher)
Agent probably worldwide; prevalence may vary between regions	Ingestion of contaminated water, food (including meat [especially pork], vegetables); fecal-oral (animal contact); dog bite (rare)	Gastroenteritis (enterocolitis); pseudoappendicitis (with mesenteric lymphadenitis, terminal ileitis, fever, abdominal pain); severe GI bleeding possible in some cases of colitis; pharyngitis; sequelae may include erythema nodosum, reactive arthritis; sepsis, especially in elderly or immunocompromised
Worldwide; prevalence of human disease may vary between regions (commonly reported in Europe)	Ingestion	Gastroenteritis with watery diarrhea especially in young children, bloody feces uncommon; pseudoappendicitis; sequelae may include erythema nodosum, reactive arthritis; sepsis, other syndromes
RICKETTSIAL DISEASES		
Southeastern and south central USA; has been detected in South America	Ticks, including <i>Amblyomma americanum</i>	Few cases described; fever, headache, malaise, myalgia, nausea, vomiting; many patients were immunosuppressed
North America; also reported in South America, Asia, and Africa	Ticks, including <i>Amblyomma americanum</i>	Asymptomatic to nonspecific febrile illness; rash in many pediatric cases, some adults; may progress to prolonged fever, renal failure, respiratory distress, hemorrhages, cardiomyopathy, neurologic signs, multiorgan failure; more severe in immunosuppressed, elderly; estimated case fatality rate 2%–3%

(continued)

TABLE 4 GLOBAL ZOOSES^a (continued)

Disease	Causative Organism	Animals Involved
RICKETTSIAL DISEASES (continued)		
Human granulocytic anaplasmosis (formerly human granulocytic ehrlichiosis)	<i>Anaplasma phagocytophilum</i> (formerly <i>Ehrlichia phagocytophilum</i> and <i>E equi</i>)	Wild rodents, deer may be reservoirs in North America; livestock, wild ungulates, wild rodents may be reservoirs in Europe; many other animals (eg, equids, ruminants, dogs, cats, birds) can also be infected
Infection by other <i>Ehrlichia</i> species	<i>E canis</i> , <i>E muris</i> -like organism implicated rarely in human illness	Dogs and other canids thought to be reservoirs for <i>E canis</i> , might also occur in felids; rodents may be reservoirs for <i>E muris</i>
Q fever (Query fever, see p 623)	<i>Coxiella burnetii</i>	Sheep, cattle, goats, cats, dogs, rodents, other mammals, birds, ticks
Sennetsu fever	<i>Neorickettsia sennetsu</i>	Uncertain, possibly fish
Spotted fever group of <i>Rickettsia</i>		
—African tick bite fever	<i>R africae</i>	Ungulates
—Mediterranean spotted fever; Boutonneuse fever; Tick bite fever;	<i>R conorii</i> subsp <i>conorii</i>	Dogs, rabbits implicated as reservoirs; other animals can be infected
—Israeli spotted fever, Astrakhan spotted fever, Indian tick typhus	<i>R conorii</i> subsp <i>israelensis</i> (Israeli spotted fever), <i>R conorii</i> subsp <i>caspia</i> (Astrakhan spotted fever), <i>R conorii</i> subsp <i>indica</i> (Indian tick typhus)	Reservoir hosts uncertain
—Fleaborne spotted fever; Cat flea typhus	<i>R felis</i> (synonym ELB agent)	Unknown; dogs have been suggested as possible amplifying hosts

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
RICKETTSIAL DISEASES (continued)		
Worldwide	Tick bites (<i>Ixodes</i> spp)	Resembles human monocytic ehrlichiosis; often asymptomatic to mild in immunocompetent; rash uncommon; estimated case fatality rate <1%
<i>E. canis</i> worldwide; <i>E. muris</i> Eastern Europe to Asia; <i>E. muris</i> -like organism in North America	Ticks (<i>E. canis</i> transmitted by <i>Rhipicephalus sanguineus</i> , <i>E. muris</i> by <i>Haemaphysalis flava</i> and <i>Ixodes persulcatus</i> complex)	Rare cases of febrile illness, in both healthy and immunosuppressed
Worldwide	Mainly airborne; exposure to placenta, birth tissues, animal excreta; occasionally ingestion (including unpasteurized milk); tickborne infections probably rare or nonexistent in people	Febrile influenza-like illness; atypical pneumonia, hepatitis, endocarditis in some; possible pregnancy complications; overall case fatality rate 1%-2% if untreated
Japan, Malaysia, Laos, possibly other Asian countries	Thought to be ingestion of raw fish	Relatively mild, nonspecific, febrile illness, resembles infectious mononucleosis
Sub-Saharan Africa, eastern Caribbean	Bite of infected tick (mainly <i>Amblyomma hebraeum</i> , <i>A. variegatum</i> , also <i>A. lepidum</i> , possibly <i>Rhipicephalus decoloratus</i> , <i>Rhipicephalus appendiculatus</i>)	Nonspecific febrile illness; painful regional lymphadenopathy in many; eschars often multiple; nuchal myalgia; sometimes sparse maculopapular and/or vesicular rash; deaths do not seem to occur
Europe, especially Mediterranean; cases reported in sub-Saharan Africa	Bite of infected ticks (mainly <i>Rhipicephalus sanguineus</i> , also others), crushing tick	Nonspecific febrile illness; eschar (typically single) may or may not be present; rash, often maculopapular, in most; life-threatening disseminated disease or neurologic signs possible but uncommon; case fatality rate 1%-3% if untreated
Israeli spotted fever in Middle East, reported in Europe; Astrakhan spotted fever in Russia, Kazakhstan; Indian tick typhus in Asia (Indian subcontinent)	Bite of infected ticks (mainly <i>Rhipicephalus</i> spp), crushing tick	Astrakhan spotted fever and Indian tick typhus resemble Mediterranean spotted fever, but Israeli spotted fever may be more severe
North and South America, Europe, Asia, Africa, probably worldwide	Flea bites; mainly associated with <i>Ctenocephalides felis</i> (cat flea), also infects <i>C. canis</i> and other fleas	Few clinical cases have been described but resembles other spotted fevers; febrile illness; rash in most; eschar may be uncommon; most cases seem to be mild but CNS involvement, pneumonia possible

(continued)

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Disease	Causative Organism	Animals Involved
RICKETTSIAL DISEASES (continued)		
—Queensland tick typhus	<i>R australis</i>	Bandicoots, rodents
—Rickettsial pox	<i>R akari</i>	Mice; also rats, Korean voles
— <i>Rickettsia parkeri</i> rickettsiosis	<i>R parkeri</i>	
—Rocky Mountain spotted fever (see p 806)	<i>R rickettsii</i>	Rodents, rabbits, opossums, and other small mammals might amplify; dogs can be infected
—Tickborne lymphadenopathy; <i>Derma-centor</i> necrosis-erythema-lymphadenopathy	<i>R slovaca</i> , <i>R raoultii</i>	Uncertain; wild boar may be involved
—Other tickborne species in spotted fever group	<i>R sibirica</i> , <i>R japonica</i> , <i>R helvetica</i> , <i>R honei</i> , <i>R heilongjiangensis</i> , <i>R aeschlimannii</i> , <i>R massiliae</i> , <i>R monacensi</i> , <i>R amblyomii</i> , others	Various vertebrates
Typhus group of <i>Rickettsia</i>		
—Murine typhus; Fleaborne typhus	<i>R typhi</i> (formerly <i>R mooseri</i>)	Rats are major reservoir; cats, opossums, possibly dogs, other species in peridomestic cycle

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
RICKETTSIAL DISEASES (continued)		
Australia	Bite of infected <i>Ixodes</i> tick, especially <i>I holocyclus</i> , <i>I tasmani</i>	Febrile illness, eschar may be present, rash (either maculopapular or vesicular) in most; mild in most, but serious disseminated disease, complications, death possible
Organism may be cosmopolitan; human cases seem to be uncommon	Bite of infected rodent mites, <i>Liponyssoides sanguineus</i>	Eschar (single) in most; febrile illness; maculopapular rash progresses to vesicular, pustular, resembles chickenpox; self-limiting
North America, detected in parts of South America	Bite of infected ticks, <i>Amblyomma maculatum</i> ; also found in other <i>Amblyomma</i> spp	Resembles Rocky Mountain spotted fever (RMSF) but seems to be milder in most cases; differs from RMSF in that eschars occur in most cases (may be multiple), petechial rash does not seem to be characteristic
Western hemisphere	Bite of infected ticks, especially <i>Dermacentor variabilis</i> , <i>D andersoni</i> (<i>D variabilis</i> in USA); <i>Amblyomma cajennense</i> , <i>A aureolatum</i> in South America; <i>Rhipicephalus sanguineus</i> in Arizona, Mexico, and South America; also from crushing tick	Moderate to severe febrile illness; macular to generalized petechial rash; edema in some; usually no eschar; neurologic, pulmonary, hemorrhagic, and kidney signs in some; sepsis; gangrene; case fatality rate 15%–30% or higher (up to 85%) if untreated, ~3% or less with treatment in North America but higher in parts of Brazil
Europe to Central Asia	Bites of infected ticks; <i>R slovaca</i> especially in <i>Dermacentor marginatus</i> , <i>D reticulatus</i> ; <i>R raoultii</i> in <i>Rhipicephalus pumilio</i> , <i>D nuttalli</i> , other <i>Dermacentor</i> spp	Eschar, local lymphadenopathy; localized alopecia at bite site; mild illness, fever and rash uncommon; no deaths reported
Worldwide; distribution varies by species	Bites of ixodid ticks; specific vector varies by species	Inoculation site eschar (most); febrile illness with headache, myalgia, sometimes other signs; rash; local lymphadenopathy (some species); major signs, risk of complications, severity vary with species of <i>Rickettsia</i>
Worldwide, especially warmer regions	Infected rodent fleas, usually via flea feces; cat fleas seem to be involved in some cycles	Fever, severe headache, central rash (not always observed); other signs, including arthralgia, cough, nausea/vomiting in some; mortality rate 4% without treatment

(continued)

TABLE 4 GLOBAL ZONNOSES^a (continued)

Disease	Causative Organism	Animals Involved
RICKETTSIAL DISEASES (continued)		
—Scrub typhus; Chigger-borne rickettsiosis	<i>Orientia tsutsugamushi</i> and related species	Rodents, insectivores
—Typhus	<i>R. prowazekii</i>	Flying squirrels
FUNGAL DISEASES		
Aspergillosis; Allergic bronchopul- monary aspergillosis (see p 2901)	<i>Aspergillus</i> spp	Birds and mammals
Blastomycosis (see p 634)	<i>Blastomyces dermatitidis</i>	Dogs, cats, horses, marine mammals, other mammals
Coccidioidomycosis (see p 637)	<i>Coccidioides immitis</i> , <i>C. posadasii</i>	Cattle, sheep, horses, llamas, dogs, many other mammals
Cryptococcosis (see p 637)	<i>Cryptococcus neoformans</i> var <i>grubii</i> , <i>C. neoformans</i> var <i>neoformans</i> , <i>C. gattii</i>	Birds including pigeons, psittacines (mainly grows in guano; temporary colonization of intestinal tract also possible); clinical cases in cats, other mammals

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
RICKETTSIAL DISEASES (continued)		
Asia, Australia, islands of southwestern Pacific Ocean; cases are usually concentrated regionally in "typhus islands"	Bite of infected larval trombiculid mites (chiggers)	Eschar in some; rash, headache, fever, painful lymphadenopathy, body aches, interstitial pneumonitis, GI signs; pneumonia, neurologic signs or cardiac complications in some; mild to severe; convalescence prolonged; case fatality rate up to 30%–50% if untreated
Eastern USA	Squirrel lice or fleas suspected	Nonspecific febrile illness, rash; GI signs in some; sepsis possible; appears to be somewhat milder than non-zoonotic typhus, which has a mortality rate of 20%–60% if untreated
FUNGAL DISEASES		
Worldwide	Environmental exposure (decaying vegetation or grains); infection common to people and animals, insignificant as zoonosis	Allergic respiratory signs, especially in people with certain respiratory conditions or immunodeficiencies; allergic sinusitis; pneumonia sometimes with dissemination in immunocompromised (can be fatal); chronic pulmonary disease ± aspergilloma (fungus ball); localized infections of other organs, tissues
Distribution in environment uncertain; clinical cases focal; locally acquired cases reported in parts of North America, Africa, Middle East, India	Environmental exposure, organism is most common in moist soil; infection common in people and animals; also reported rarely by animal exposure	Acute to chronic pulmonary disease; skin or bone lesions; meningitis, other syndromes, disseminated disease possible; course mild to severe, some cases fatal
Especially southwestern USA, Mexico, Central and South America; in arid or semiarid foci; some cases might be acquired outside usual foci	Principally environmental exposure (inhalation of arthrospores), including fungal cultures; infection common in people and animals, one unusual case reported after necropsy of horse with disseminated disease	Self-limited, febrile, flu-like illness, sometimes with cough, chest pain in healthy host; serious, possibly life-threatening pulmonary disease or disseminated infection with cutaneous/subcutaneous lesions, persistent meningitis or osteomyelitis, especially in immunocompromised
Worldwide	Principally environmental exposure, especially pigeon nests for <i>C. neoformans</i> , trees for <i>C. gattii</i> ; via inhalation or through the skin; infection common in people and animals, insignificant as zoonosis	Respiratory signs, mild to severe, often self-limiting in healthy host but more likely to be severe in immunocompromised; dissemination with CNS disease, ocular signs, other syndromes, most often in immunocompromised; skin lesions, either localized from inoculation (uncommon) or from disseminated disease

(continued)

TABLE 4 GLOBAL ZONONOSES^a (continued)

Disease	Causative Organism	Animals Involved
FUNGAL DISEASES (continued)		
Histoplasmosis (see p 639)	<i>Histoplasma capsulatum</i> var <i>capsulatum</i>	Dogs, cats, bats, cattle, sheep, horses, many other domestic and wild mammals, birds
	<i>H. capsulatum</i> var <i>duboisii</i>	As above
Malassezia infection	<i>Malassezia</i> spp	Dogs, cats, other animals
Ringworm (Dermatophytosis, see p 872)	<i>Microsporum</i> and <i>Trichophyton</i> spp	Dogs, cats, hedgehogs, cattle, sheep, goats, horses, rodents, other mammals, birds, very rarely reptiles
Sporotrichosis (see p 644)	<i>Sporothrix schenckii</i>	Cats, other mammals, birds
PARASITIC DISEASES—PROTOZOANS		
Babesiosis (see p 21)	<i>Babesia microti</i> complex, <i>B. duncani</i> (formerly WA-1), and other species	Rodents, insectivores, lagomorphs, some other mammals; reservoirs uncertain for some species
	<i>B. divergens</i>	Cattle; <i>B. divergens</i> or closely related organism in farmed reindeer, wild cervids
	<i>B. bovis</i> ; uncertain zoonosis; some historical cases were probably <i>B. divergens</i>	Cattle, water buffalo, African buffalo, possibly other species

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
FUNGAL DISEASES (continued)		
Worldwide; clinical cases often cluster in regional foci	Principally environmental exposure, avian or bat feces encourage growth of organism; infection common in people and animals; insignificant as zoonosis	Flu-like, febrile illness, usually self-limiting in healthy hosts; skin lesions; chronic pulmonary disease, usually with preexisting lung disease; dissemination in very young, elderly, immunocompromised
Africa	As above	Usually skin and subcutaneous lesions, osteolytic bone lesions but can disseminate
Worldwide	Exposure to symptomatic animals; normal levels on skin not thought to be a significant risk	Dermatitis; zoonotic strains might be implicated in fungemia in preterm neonates, other immunocompromised
Worldwide	Direct skin/hair contact with infected animals, fomites	Skin and hair lesions, usually pruritic; rare skin dissemination in immunocompromised
Worldwide; epizootics in cats in South America	Primarily environmental in vegetation, wood, soil; inoculation from environment in penetrating wounds (splinters, bites, pecks), skin contact with lesions, especially in cats; bites, scratches, other close contact implicated during feline epidemics; inhalation rare	Papules, pustules, nodules, ulcerative skin lesions, may follow course of draining lymphatics; mucosa can be affected; extracutaneous involvement, especially bones, joints; disseminated disease (including meningitis) can be seen in immunocompromised; acute or chronic pulmonary disease resembling tuberculosis after inhalation, especially with underlying lung disease (rare)
PARASITIC DISEASES—PROTOZOANS		
<i>Babesia</i> spp worldwide in wild animals, many agents not identified to species; human illness due to <i>B microti</i> complex reported in North America (most), Europe, Asia, Australia	Bite of infected <i>Ixodes</i> ticks for <i>B microti</i>	Many immunocompetent patients may have mild to moderate flu-like, febrile illness; mild to severe hemolytic anemia, especially severe in immunocompromised and elderly; respiratory, hepatic, renal, and other organ dysfunction; recurrent or chronic infection may develop; dual infection with <i>B burgdorferi</i> may worsen both diseases; death possible in severe cases
Europe, possibly North Africa; similar organisms might be present in North America; reported in Asia (China)	Tick bites (<i>Ixodes ricinus</i>)	Usually in splenectomized; acute, severe hemolysis; persistent high fever, headache, myalgia, abdominal pain, sometimes GI signs; shock and renal failure; cases progress rapidly; usually fatal if untreated; milder flu-like cases have been reported in immunocompetent patients
Africa, Asia, Central and South America, Mexico, Australia, parts of Europe	Tick bites (<i>Rhipicephalus microplus</i> and <i>R annulatus</i>)	

(continued)

TABLE 4 GLOBAL ZONOSSES^a (continued)

Disease	Causative Organism	Animals Involved
PARASITIC DISEASES—PROTOZOANS (continued)		
Balantidiasis	<i>Balantidium coli</i> and related species	Swine, rats, nonhuman primates, other animals
Chagas' disease (American trypanosomiasis, see p 38)	<i>Trypanosoma cruzi</i>	Opossums, lagomorphs, rodents, armadillos, dogs, cats, other wild and domestic mammals
Cryptosporidiosis (see p 209)	<i>Cryptosporidium parvum</i> , <i>C. canis</i> , <i>C. felis</i> , <i>C. meleagridis</i> , <i>C. cuniculus</i> , <i>C. viatorum</i> , <i>C. muris</i> , and other species (<i>C. hominis</i> and likely some genotypes of <i>C. parvum</i> are adapted mainly to people)	Cattle and other ruminants, dogs, cats, rabbits, other domestic and wild mammals, birds, reptiles, fish
Giardiasis (see p 211)	<i>Giardia intestinalis</i> , also known as <i>G. duodenalis</i> (formerly <i>G. lamblia</i>); only some genotypes seem to have zoonotic potential	Many domestic and wild mammals, including dogs, cats, ruminants, aquatic mammals such as beavers
Leishmaniasis —Visceral (Kalaazar; see p 800)	<i>Leishmania infantum</i>	Wild canids and dogs are primary reservoirs, also in other mammals
—Cutaneous and mucocutaneous	<i>L. tropica</i> complex (except <i>L. tropica</i> , which is maintained in people), <i>L. braziliensis</i> complex, <i>L. mexicana</i> complex, others	Dogs (<i>L. peruviana</i>), rodents, various wild mammals act as reservoir hosts; other mammals can be infected

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
PARASITIC DISEASES—PROTOZOANS (continued)		
Worldwide	Ingestion, especially of water contaminated with feces	Asymptomatic to mucoid, bloody feces; intestinal hemorrhage and perforation possible; rare extraintestinal cases
Western hemisphere—southern USA, Mexico, Central and South America	Fecal material of reduviid bug in family Triatomidae contaminates bite wounds, abrasions, or mucous membranes; ingestion in contaminated food	Acute disease—erratic fever, adenopathy, headache, myalgia, hepatosplenomegaly, swelling at inoculation site and eyelid; myocarditis or encephalitis in some; worse in immunocompromised Chronic form (in 10%–30% of patients)—cardiomyopathy, megaesophagus, megacolon, other forms; reported annual mortality rate in chronic form 0.2%–19% (higher rates from studies that include only cardiac patients)
Worldwide	Fecal-oral; ingestion of contaminated food and water; inhalation	Self-limiting gastroenteritis in healthy; can be cholera-like and persistent in immunocompromised, with weight loss, wasting; cholecystitis; respiratory signs, pancreatitis, other syndromes mainly in immunosuppressed
Worldwide	Ingestion of water and less often food; direct fecal-oral (hands or fomites)	Gastroenteritis, may be persistent
Asia, South America, Caribbean, Africa, the Middle East, Europe (Mediterranean spreading north), North America	Bite of sand flies <i>Phlebotomus</i> and <i>Lutzomyia</i> spp	Undulating fever, hepatosplenomegaly; some have cough, diarrhea, lymphadenopathy, weight loss, petechiae or hemorrhages on mucous membranes, nodular lesions or darkening of skin; pancytopenia; mild cases with only a few signs may resolve on their own, but most other cases fatal if untreated
Mediterranean, Asia, Africa, Middle East, Mexico to South America, Caribbean; localized focus in USA (Texas and Oklahoma)	As above	Papules to ulcers or nodules on skin ± mucous membranes; single or multiple lesions; localized or disseminated; may persist or recur; atypical forms in immunosuppressed; cutaneous form rarely fatal, mucocutaneous form can be disfiguring and may be fatal if pharynx affected

(continued)

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Disease	Causative Organism	Animals Involved
PARASITIC DISEASES—PROTOZOANS (continued)		
Malaria of nonhuman primates	Nonhuman primate-associated <i>Plasmodium</i> spp, <i>P knowlesi</i> , rarely <i>P cynomolgi</i> , others also potential zoonoses	Old and New World monkeys, apes
Microsporidiosis	Microsporidia of <i>Enterocytozoon bienersi</i> , <i>Encephalitozoon cuniculi</i> , <i>E intestinalis</i> , <i>E hellem</i> , others; both zoonotic and anthroponotic transmission reported for some agents	Widespread in vertebrates, including primates, rabbits, rodents, dogs, cats, cattle, pigs, goats, birds, fish; also in invertebrates
Rhinosporeidiosis (see p 644)	<i>Rhinosporeidium seeberi</i> ; some strains may be host specific	Natural hosts thought to be fish and amphibians; also found in various mammals, including horses, cattle, mules, dogs, and cats; birds
Sarcocystosis (Sarcosporidiosis, see p 1058)	<i>Sarcocystis suis hominis</i> , also called <i>S meischeriana</i>	People, nonhuman primates are definitive hosts; swine are intermediate host
	<i>S hominis</i> , also called <i>S fusiformis</i>	People, nonhuman primates are definitive hosts; cattle are intermediate host
	<i>Sarcocystis</i> spp; <i>S nesbitti</i> may be one cause	People are intermediate host; species of <i>Sarcocystis</i> and definitive host(s) are often unknown; definitive host for <i>S nesbitti</i> thought to be snakes
Toxoplasmosis (see p 685)	<i>Toxoplasma gondii</i>	Felidae, including domestic cats, are definitive hosts; essentially all other mammals (including livestock) and birds thought to be susceptible as intermediate hosts
Trypanosomiasis (African sleeping sickness, see p 35)	<i>Trypanosoma brucei</i> ; <i>T brucei rhodesiense</i> is zoonotic; <i>T brucei gambiense</i> is primarily a human pathogen, although some animals (eg, pigs) can be infected and might serve as minor reservoirs	<i>T brucei rhodesiense</i> reservoirs may include cattle, sheep, antelope, hyenas, lions, other wildlife, people; also isolated from other mammals

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
PARASITIC DISEASES—PROTOZOANS (continued)		
<i>P. knowlesi</i> in Asia; other species exist in Central and South America, Asia, Africa	Bite of anopheline mosquitoes	Febrile episodes with chills; headache, myalgia, malaise, cough, nausea, vomiting, and other symptoms in some; cases range from mild, self-limiting to fatal (3% case fatality rate for <i>P. knowlesi</i>)
Worldwide	Fecal-oral; direct contact; ingestion of contaminated food or water; aerosols; possibly vector-transmitted	Keratitis; acute diarrhea (traveler's diarrhea); chronic diarrhea in immunocompromised; may disseminate to systemic disease with variable symptoms in immunocompromised
Worldwide, especially in tropics; endemic in South America, Asia, and Africa	Environmental exposure, probably water	Nasal and other mucous membrane masses and polyps (mainly nose, nasopharynx, eye); may cause obstruction; rare disseminated disease with osteolytic lesions or affecting viscera; rare skin and subcutaneous lesions
Worldwide	Ingestion of raw pork	Gastroenteritis, usually mild, or asymptomatic
Worldwide	Ingestion of raw beef	Gastroenteritis, usually mild or asymptomatic
Worldwide; symptomatic cases mainly in Asia, probably because of distribution of definitive host	Assumed to be ingestion of oocysts shed in feces of definitive host(s) or sporocysts	Main syndrome is myositis, acute and self-limited to chronic, moderately severe; also cough, arthralgia, transient pruritic rashes, headache, malaise, lymphadenopathy in some
Worldwide	Ingestion of oocysts shed in feces of infected cats (including contaminated soil, food, water) or ingestion of tissue cysts in undercooked meat or unpasteurized milk	Lymphadenopathy or mild, febrile, flu-like syndrome or uveitis in immunocompetent, nonpregnant host; often severe in immunocompromised, with neurologic disease, chorioretinitis, myocarditis, pneumonitis, or disseminated disease; infection of fetus may result in CNS damage or generalized infection; abortions and stillbirths
Africa; common below the Sahara desert	Bite of infected tsetse fly (<i>Glossina</i> spp)	Painful chancre at bite site in some patients; intermittent fever, headache, adenopathy, rash, arthralgia; neurologic signs such as somnolence, seizures; cardiac complications possible; <i>gambiense</i> disease may last years; <i>rhodesiense</i> disease acute, may last weeks to months; both usually fatal without treatment

(continued)

TABLE 4 GLOBAL ZOONOSES^a (continued)

Disease	Causative Organism	Animals Involved
PARASITIC DISEASES—TREMATODES (FLUKES)		
Clonorchiasis	<i>Clonorchis sinensis</i> (Chinese liver fluke)	Dogs, cats, swine, rats, other mammals are definitive hosts; fish (and snails) are intermediate hosts
Dicrocoeliasis	<i>Dicrocoelium dendriticum</i> , possibly <i>D hospes</i> (lancet flukes)	Ruminants, especially sheep, goats, cattle, occasionally other domestic and wild mammals are definitive hosts; land snails (first) and ants (second) are intermediate hosts
Echinostomiasis	<i>Echinostoma revolutum</i> , <i>E ilocanum</i> , <i>E hortense</i> , and other <i>Echinostoma</i> spp; <i>Echinochasmus japonicus</i> and other members of Echinostomatidae can also be zoonotic	Cats, dogs, rodents, pigs, other mammals; birds, including poultry, are definitive hosts; fish, shellfish, tadpoles, snails are intermediate hosts
Fascioliasis	<i>Fasciola hepatica</i>	Cattle, sheep, water buffalo, horses, rabbits, other herbivores are definitive hosts; snails are intermediate hosts
	<i>F. gigantica</i>	Cattle, buffalo, goats, sheep, zebras, other mammals are definitive hosts; snails are intermediate hosts
Fasciolopsiasis	<i>Fasciolopsis buski</i>	Swine, people are definitive hosts; snails are intermediate hosts
Gastrodiscoidiasis	<i>Gastrodiscoides hominis</i> ; uncertain whether people and swine carry the same strains	Swine, people, nonhuman primates, rodents, other mammals are definitive hosts; snails are intermediate hosts
Heterophyiasis	<i>Heterophyes</i> spp, <i>Haplorchis</i> spp, other heterophids	Cats, dogs, foxes, wolves, cattle, other mammals, fish-eating birds are definitive hosts (host varies with species of parasite); fish (and snails) are intermediate hosts
Metagonimiasis	<i>Metagonimus yokogawai</i> , <i>M miyatai</i> , <i>M takahashii</i> , and other <i>Metagonimus</i> spp	Cats, dogs, rats, other fish-eating mammals, possibly birds are definitive hosts; fish (and snails) are intermediate hosts

TABLE 4 GLOBAL ZONOOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
PARASITIC DISEASES—TREMATODES (FLUKES) (continued)		
Asia	Ingestion of undercooked infected freshwater fish or shrimp containing encysted larvae	Cholecystitis symptoms, indigestion, diarrhea, mild fever; chronic infections associated with cirrhosis, pancreatitis, or cholangiocarcinoma
<i>D dendriticum</i> on all major continents (may be focal); <i>D hospes</i> in Africa south of Sahara desert	Ingestion of infected ants	Abdominal discomfort, flatulent indigestion; occasionally GI signs (diarrhea, constipation, vomiting, pain); weight loss, fatigue; biliary obstruction, cholangitis, hepatomegaly, or acute urticaria possible
Most human cases in Asia, Western Pacific; this group of parasites is widely distributed, including Europe, Americas, Middle East	Ingestion of undercooked fish, shellfish, snails, or amphibians (frogs)	Abdominal discomfort; diarrhea, especially in heavy infestation; malnutrition, anemia, edema may occur, especially in children; intestinal perforation has been reported
Worldwide or nearly worldwide; previously thought to be mainly in temperate areas but may be more widely distributed	Ingestion of contaminated greens, eg, watercress, or water that contains metacercariae	Gastroenteritis, hepatomegaly, fever, urticaria possible acutely; biliary colic and obstructive jaundice in chronic cases; aberrant migration with extrahepatic signs (eg, pulmonary infiltrates, neurologic signs, lymphadenopathy, skin lesions or subcutaneous swelling) in some
Thought to occur mainly in tropical areas: Africa, Asia, Middle East, and western Pacific	As above	Signs resemble fascioliasis caused by <i>F hepatica</i>
Asian pig-raising regions	Ingestion of aquatic vegetables or contaminated drinking water containing metacercariae	Often asymptomatic; gastroenteritis; intestinal bleeding, obstruction, or perforation possible; facial, abdominal, extremity edema may occur
Asia (including the Philippines), also reported in Africa, Volga delta in Russia	Possibly ingestion of water or aquatic plants	Mild diarrhea if high parasite burden
Middle East (especially Nile delta), Turkey, Asia	Ingestion of undercooked fish containing encysted larvae	Diarrhea with mucus, colicky pain; heart or CNS involvement possible; severity of signs may vary with species
Human illness mainly in Asia, also reported in Siberia; parasites have been found in Europe	Ingestion of undercooked freshwater fish containing encysted larvae	Diarrhea with mucus, anorexia, mild epigastric pain or abdominal cramps; malabsorption, weight loss if high parasite burden

(continued)

TABLE 4 GLOBAL ZOONOSES^a (continued)

Disease	Causative Organism	Animals Involved
PARASITIC DISEASES—TREMATODES (FLUKES) (continued)		
Metorchiasis	<i>Metorchis conjunctus</i> , Canadian liver fluke	Dogs, foxes and other canids, cats, raccoons, muskrats, mink, other fish-eating mammals are definitive hosts; fish (and snails) are intermediate hosts
Nanophyetiasis	<i>Trogloremia salmincola</i> (also called <i>Nanophyetus salmincola</i>)	Raccoons, foxes, dogs, cats, skunks, and other fish-eating mammals and birds are definitive hosts; salmonid and some non-salmonid fish (and snails) are intermediate hosts
Opisthorchiasis	<i>Opisthorchis felineus</i> (cat liver fluke)	Cats, dogs, foxes, swine, seals, other fish-eating mammals are definitive hosts; fish (and snails) are intermediate hosts
	<i>O. viverrini</i> (small liver fluke); zoonotic transmission can occur, but people are important hosts	People, dogs, cats, rats, pigs, fish-eating mammals are definitive hosts; fish and snails are intermediate hosts
	<i>Amphimerus pseudofelineus</i>	Various mammals, birds, reptiles are definitive hosts; fish suspected as intermediate hosts
Paragonimiasis (Lung fluke disease)	<i>Paragonimus westermani</i> , <i>P. heterotremus</i> , <i>P. africanus</i> , <i>P. mexicanus</i> , and other species	Dogs, cats, swine, wild carnivores, opossums, and other mammals are definitive hosts; snails and freshwater crustaceans are intermediate hosts; wild boars, sheep, goats, rabbits, birds, other animals are paratenic hosts
Schistosomiasis, intestinal and hepatic	<i>Schistosoma japonicum</i>	Many mammals, including cattle, water buffalo (important host in Asia), swine, dogs, cats, deer, horses, nonhuman primates, and rodents, are definitive hosts; snails are intermediate hosts

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
PARASITIC DISEASES—TREMATODES (FLUKES) (continued)		
North America; human infection rare	Ingestion of undercooked freshwater fish containing encysted larvae	Fever, abdominal pain (mainly epigastric), anorexia during acute stage; effects of chronic infection uncertain
North America along Pacific coast, Russia	Ingestion of undercooked fish or roe	Mild gastroenteritis
Europe, Kazakhstan, Russia, Ukraine	Ingestion of undercooked freshwater fish containing encysted larvae	Acute febrile illness with arthralgia, lymphadenopathy, skin rash; suppurative cholangitis and liver abscess in subacute, chronic stages; possible increased risk of cholangiocarcinoma
Southeast Asia	Ingestion of undercooked freshwater fish containing encysted larvae	Upper abdominal pain, diarrhea, fever, jaundice possible acutely; chronic infections with cirrhosis, pancreatitis, high incidence of cholangiocarcinoma
North and South America	Undetermined but probably ingestion of undercooked fish	
Flukes are world-wide (distribution varies with species); most human infections in Asia, Africa, tropical America	Ingestion of undercooked, infected freshwater crustaceans (crabs, crayfish); metacercariae on contaminated hands, fomites after preparing crustaceans, or undercooked meat from paratenic hosts such as wild boars	Chills, fever possible during migration to lungs; pulmonary disease resembling tuberculosis with cough, blood-tinged sputum; abdominal form with dull pain, tenderness, possibly diarrhea; less often, neurologic signs, migratory skin nodules, other organ-specific symptoms; predominant signs vary with species of fluke
Asia	Penetration of unbroken skin by cercariae from infected snails in water	Acute disease can include urticarial rash, mild signs, isolated pulmonary signs, or Katayama syndrome (occurs especially after first infection; febrile illness, sometimes with cough, diarrhea, abdominal pain, hepatosplenomegaly, and/or rash/urticaria); apparent clinical recovery may be followed by chronic intestinal schistosomiasis with abdominal pain/discomfort, diarrhea $\pm$ blood; chronic hepatic schistosomiasis with hepatosplenomegaly followed by liver fibrosis, ascites, portal hypertension with hematemesis and/or melena, portocaval shunting with pulmonary signs; ectopic parasites can cause seizures, paralysis, meningoencephalitis; intestinal and hepatic lesions tend to progress rapidly; death can occur

(continued)

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Disease	Causative Organism	Animals Involved
PARASITIC DISEASES—TREMATODES (FLUKES) (continued)		
Schistosomiasis, intestinal and hepatic (continued)	<i>S mansoni</i>	People, nonhuman primates are major reservoir (definitive) hosts; also in rodents, insectivores, cattle, dogs; snails are intermediate hosts
	<i>S mattheei</i> ; <i>S bovis</i> and <i>S margrebowiei</i> might also be zoonotic	Definitive hosts are artiodactylid ruminants (cattle, sheep, goats, waterbuck, wildebeest, antelope, buffalo), also found in nonhuman primates; snails are intermediate hosts
	<i>S mekongi</i>	People are reservoir (definitive) hosts; also found in dogs, pigs; snails are intermediate hosts
	<i>S intercalatum</i> , <i>S guineensis</i>	Primarily people, rodents may also be definitive hosts; some other mammals, including nonhuman primates, susceptible to infection; snails are intermediate hosts
Schistosomiasis, urinary	<i>S haematobium</i>	People are main reservoir (definitive host); occasionally infects nonhuman primates, pigs, buffalo, sheep, rodents, or other mammals; snails are intermediate hosts
Swimmer's itch (Cercarial dermatitis)	Schistosome cercariae from <i>Schistosoma</i> spp (mammals); <i>Gigantobilharzia</i> , <i>Trichobilharzia</i> , and <i>Austrobilharzia</i> spp (birds)	Birds, mammals are definitive hosts; snails are intermediate hosts
PARASITIC DISEASES—CESTODES (TAPEWORMS)		
Bertielliasis	<i>Bertiella studeri</i> , <i>B mucronata</i>	Nonhuman primates are usual hosts; other mammals, including dogs, people can be infected
Coenuriasis (Coenurosis)	<i>Taenia multiceps</i>	Definitive hosts are canids; intermediate hosts are sheep, other herbivores
	<i>T serialis</i>	Definitive hosts are canids; intermediate hosts are lagomorphs, rodents, occasionally other mammals

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
PARASITIC DISEASES—TREMATODES (FLUKES) (continued)		
Africa, Middle East, South America, Caribbean	Penetration of unbroken skin by cercariae from infected snails in water	Acute disease in some; intestinal (most often) and/or hepatic schistosomiasis similar to <i>S japonicum</i> but not as rapidly progressive; glomerulonephritis a possible complication; ectopic CNS parasites tend to cause transverse myelitis; also causes genital schistosomiasis with reproductive problems; death can occur
Southern Africa; seems to be rare in people, and some infections may have been misidentified	Penetration of unbroken skin by cercariae from infected snails in water	Suggested agent in intestinal and hepatic schistosomiasis
Southeast Asia	Penetration of unbroken skin by cercariae from infected snails in water	Acute disease absent or very rare; intestinal and hepatic schistosomiasis; death can occur
Africa	Penetration of unbroken skin by cercariae from infected snails in water	Intestinal schistosomiasis only, often mild or asymptomatic; occasionally bloody feces, diarrhea
Africa (including Madagascar, Mauritius), the Middle East	Penetration of unbroken skin by cercariae from infected snails in water	Acute disease in some; chronic disease—hematuria, dysuria, kidney failure; calcification of bladder wall, ureter, and bladder can lead to bladder cancer; ectopic CNS parasites tend to cause transverse myelitis; genital schistosomiasis; death can occur
Worldwide	Penetration of unbroken skin by cercariae from infected snails in fresh- and saltwater	Self-limiting urticaria, pruritus, rash; fever, local lymph node swelling possible in some cases
PARASITIC DISEASES—CESTODES (TAPEWORMS)		
Asia, South America, Africa; can occur in imported primates in other areas	Ingestion of infected oribatid mites in food	Most cases asymptomatic; abdominal pain, vomiting, diarrhea, constipation, weight loss
Worldwide in scattered foci; mainly reported from Europe, Asia	Ingestion of tapeworm eggs in canine feces, may be via water, vegetables, soil	Painless skin swelling; possible CNS involvement (signs of mass lesion in brain) or larva in eye
Africa, Europe, North America, Australia; rare in people	As above	Painless skin swelling; also in muscles and retroperitoneally; CNS involvement possible

(continued)

TABLE 4 GLOBAL ZOONOSES^a (continued)

Disease	Causative Organism	Animals Involved
PARASITIC DISEASES—CESTODES (TAPEWORMS) (continued)		
Coenuriasis (Coenurosis) (continued)	<i>T brauni</i>	Definitive hosts are canids; intermediate hosts are gerbils, wild rodents, also people
Cysticercosis	<i>Taenia solium</i> (see also Taeniasis)	People are definitive hosts; swine, other mammals are intermediate hosts (people can be both definitive and intermediate hosts)
	<i>T crassiceps</i>	Foxes, also other canids and carnivores, including dogs, are definitive hosts; rodents, insectivores, rabbits, occasionally other mammals are intermediate hosts
Diphyllobothriasis (Fish tapeworm infection)	<i>Diphyllobothrium latum</i> (<i>Dibothriocephalus latus</i>), <i>D nihonkaiense</i> , <i>D pacificum</i> , <i>D dendriticum</i> , and other <i>Diphyllobothrium</i> spp	Dogs, bears, seals, sea lions, gulls, and other fish-eating mammals and birds are definitive hosts; freshwater or marine fish (and copepods) are intermediate hosts
Dipylidiasis (Dog tapeworm infection)	<i>Dipylidium caninum</i>	Dogs, cats, wild canids, some other wild carnivores are definitive hosts; fleas are intermediate hosts
Echinococcosis	<i>Echinococcus granulosus sensu lato</i>	Dogs, other canids, hyenas are definitive hosts; sheep, goats, cattle, water buffalo, swine, camels, cervids, rodents, other mammals, or marsupials are intermediate or aberrant hosts; strains of parasite can be adapted to different intermediate hosts
	<i>E multilocularis</i>	Foxes and other wild canids and felids are usual definitive hosts, but parasite can also mature in dogs, cats; intermediate hosts are usually rodents, insectivores, some other mammals
	<i>E oligarthrus</i>	Wild felids are definitive hosts, can mature in cats; agouti, pacas, spiny rats are intermediate hosts
	<i>E vogeli</i>	Bush dogs are usual definitive host, can mature in other canids, including dogs; pacas, agouti, nutria, nonhuman primates, and other mammals can be intermediate hosts
Hymenolepiasis	<i>Hymenolepis nana</i> (dwarf tapeworm); most human infections probably transmitted from people, but zoonoses possible	People, nonhuman primates, rodents are definitive hosts; insects, including fleas, flour beetles, cereal beetles are intermediate hosts

TABLE 4 GLOBAL ZONOSSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
PARASITIC DISEASES—CESTODES (TAPEWORMS) (continued)		
Africa	As above	Most often in subcutaneous tissues (skin swelling) or eye, also CNS
Worldwide where swine are reared; most cases seen in Africa, Asia, Central and South America	Ingestion of eggs (including autoinfection from adult parasite in human intestine)	Inflammation in CNS caused by death of small larva or growth to large size (often years after infection); can cause seizures, other CNS signs; less often in eye or heart; massive numbers in muscles can also be symptomatic
North America, Europe, Asia, and other areas where foxes are present	Ingestion of eggs	Tissue invasion (mainly subcutaneous, muscle), ocular; one paravertebral pseudohematoma with local bleeding, one CNS larva; many but not all cases in immunocompromised
Worldwide; distribution of species varies	Ingestion of undercooked infected fish	Usually asymptomatic; may cause mild abdominal distress, diarrhea (chronic relapsing diarrhea possible in some cases)
Worldwide; uncommonly reported in people	Ingestion of dog or cat fleas	Usually in children; asymptomatic or mild abdominal distress, diarrhea; proglottids in feces resemble cucumber seeds
Worldwide, strains differ in distribution	Ingestion of tapeworm eggs in food or water, to mouth on hands; eggs stick to fur and hands	Cause space-occupying lesions of organs, especially lung, liver, also other organs, rarely CNS; cyst grows slowly, can cause death if untreated; rupture can cause allergic reactions, dissemination of cysts
North America (mainly Canada to north central USA), northern and central Eurasia	Ingestion of tapeworm eggs in food or water, to mouth on hands; eggs stick to fur and hands	Usually involves liver with mass lesions, occasionally lung or CNS; primary lesion can metastasize to many organs; without treatment, 70%–100% cases are fatal
Central and South America; rare in people	Ingestion of tapeworm eggs in food or water, to mouth on hands; eggs stick to fur and hands	Has been seen in a variety of internal organs, eyes
Central and South America	Ingestion of tapeworm eggs in food or water, to mouth on hands; eggs stick to fur and hands	Usually involves liver, may invade adjacent tissues; mortality high in advanced cases, even with treatment (22% in one study)
Worldwide	Accidental ingestion of tapeworm eggs or infected insects; autoinfection possible	Mainly in children; mild abdominal distress, decreased appetite, irritability are most common; weight loss, flatulence, diarrhea possible

(continued)

TABLE 4 GLOBAL ZONONOSES* (continued)

Disease	Causative Organism	Animals Involved
PARASITIC DISEASES—CESTODES (TAPEWORMS) (continued)		
Hymenolepiasis (continued)	<i>H diminuta</i> (mouse tapeworm, rat tapeworm)	Rats, mice are definitive hosts; insects, including fleas and cereal beetles are intermediate hosts
<i>Inermicapsifer</i> infection	<i>Inermicapsifer</i> spp	Rodents, people are definitive hosts in Africa; people may be exclusive host outside Africa
<i>Raillietina</i> infection	<i>R celebensis</i> , <i>R demerariensis</i> ; most <i>Raillietina</i> spp have not been reported in people	Rodents, nonhuman primates are definitive hosts for <i>R celebensis</i> , <i>R demerariensis</i> ; other species in birds, mammals; arthropods, including ants, are intermediate hosts
Sparganosis	<i>Spirometra</i> spp (pseudophyllidean tapeworms, second larval stage)	Dogs, cats, wild canids and felids are definitive hosts; copepods are first intermediate host; fish, frogs, reptiles are second intermediate hosts; primates, pigs, weasels, rodents, insectivores, other mammals, birds are paratenic hosts
Taeniasis		
—Asian taeniasis	<i>Taenia asiatica</i> (also called <i>T taiwanensis</i> , <i>T saginata asiatica</i>)	Domestic and wild pigs, occasionally cattle, goats, monkeys are intermediate hosts; people are definitive hosts
—Beef tapeworm disease	<i>T saginata</i>	Cattle, water buffalo, llamas, reindeer, camels, other domestic and wild ruminants are intermediate hosts; people are definitive host
—Pork tapeworm disease; cysticercosis and neurocysticercosis	<i>T solium</i>	People are definitive host; swine, occasionally other mammals, including people, are intermediate hosts
PARASITIC DISEASES—NEMATODES (ROUNDWORMS)		
Angiostrongyliasis	<i>Angiostrongylus costaricensis</i> , also called <i>Parastrongylus costaricensis</i>	Cotton rats and other rodents are definitive hosts; slugs are intermediate hosts

TABLE 4 GLOBAL ZONONOS^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
PARASITIC DISEASES—CESTODES (TAPEWORMS) (continued)		
Worldwide	Ingestion of infected insects in food	Mild abdominal symptoms of short duration
Africa, southeast Asia, tropical America	Probably ingestion of infected arthropods	Mild abdominal symptoms, if any
<i>R demerariensis</i> in tropical America (human cases mainly Ecuador, Cuba, Guyana, Honduras); <i>R celebensis</i> in Asia, Australia, Africa	Probably ingestion of infected arthropods in food	Vague discomfort, many cases asymptomatic; gastroenteritis, possibly other signs; mainly in children
Worldwide; human cases most common in Asia	Ingestion of infected cyclops (in water) or undercooked intermediate or paratenic host; application of contaminated tissues to skin (eg, as poultice)	Nodular, itchy skin lesions that can migrate; conjunctival and eyelid lesions; urticaria, painful edema; other organ involvement, including CNS, eye
Asia	Ingestion of undercooked animal products, usually visceral organs such as liver and lung	Vague abdominal complaints and proglottid passage; anal pruritus; possible that ingestion of eggs may be followed by larval migration and disseminated disease (uncertain/controversial)
Worldwide	Ingestion of undercooked meat containing larvae	Mild abdominal discomfort and proglottid passage; gravid proglottids may travel to ectopic sites and cause symptoms; eggs do not cause disseminated disease
Worldwide where swine are reared; most cases seen in Africa, Asia, Central and South America	Ingestion of undercooked pork containing larvae causes taeniasis; ingestion of eggs (including autoinfection from adult worm in intestine) causes cysticercosis	Adult stage in intestine (taeniasis) mild or asymptomatic; cysticercosis usually asymptomatic for years until cysticercus becomes large or death of small cysticerci result in inflammation in CNS (seizures, other CNS signs) or infrequently in eye or heart; massive numbers in muscles can also be symptomatic
PARASITIC DISEASES—NEMATODES (ROUNDWORMS)		
Mainly in Central and South America, Caribbean parasite has also been reported in North America	Accidental ingestion of slugs or possibly plants contaminated by their secretions	Acute abdominal angiostrongyliasis; severe pain resembles appendicitis, especially in children; rarely, more insidious disease with liver involvement; complications can include intestinal ischemia, perforation; fatalities possible

(continued)

TABLE 4 GLOBAL ZONONOSES^a (continued)

Disease	Causative Organism	Animals Involved
PARASITIC DISEASES—NEMATODES (ROUNDWORMS) (continued)		
Angiostrongyliasis (continued)	<i>Angiostrongylus cantonensis</i> , also called <i>Parastrongylus cantonensis</i>	Rodents (rats, including <i>Rattus</i> and <i>Bandicota</i> spp) are definitive hosts; snails, slugs are intermediate hosts; land planarians, crustaceans (crabs, shrimp, prawns), amphibians, fish, reptiles are paratenic hosts
Anisakiasis	<i>Anisakis</i> , <i>Pseudoterranova</i> , and <i>Contracaecum</i> spp	Marine mammals (cetaceans and pinnipeds) and fish-eating birds are definitive hosts; fish, crustaceans, and cephalopod mollusks are intermediate or paratenic hosts
Ascariasis	<i>Ascaris suum</i> ; potentially zoonotic (controversial)	Pigs, also reported occasionally in other mammals, including nonhuman primates, sheep, cattle
Capillariasis		
—Hepatic capillariasis	<i>Capillaria hepatica</i> (also called <i>Calodium hepaticum</i>)	Rodents major host, also in many other wild and domestic mammals
—Intestinal capillariasis	<i>C. philippinensis</i> (also called <i>Paracapillaria philippinensis</i>)	Aquatic birds, people can be definitive hosts; freshwater fish are intermediate host
—Pulmonary capillariasis	<i>C. aerophila</i> (also called <i>Eucoleus aerophilus</i>)	Dogs, cats, other carnivores
Diectophymosis (Giant kidney worm infection)	<i>Diectophyma renale</i>	Mink, dogs, and other carnivores are definitive hosts; annelids are intermediate hosts; frogs, fish are paratenic hosts
Dracunculiasis (Guinea worm infection)	<i>Dracunculus medinensis</i> ; people are most important host but possible role for zoonotic transmission in some locations	People, nonhuman primates are definitive hosts; infections have also been reported in animals, but parasite identification sometimes uncertain; domestic animals not thought to maintain parasite but possible exceptions (eg, dogs in Chad); copepods are intermediate hosts
Filariasis		
—Dirofilariasis	<i>Dirofilaria immitis</i>	Dogs, cats, other mammals especially carnivores, mustelids, primates are definitive hosts (mainly patent in dogs and wild canids); mosquitoes are intermediate hosts

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
PARASITIC DISEASES—NEMATODES (ROUNDWORMS) (continued)		
● Originated in Asia, spread to many other regions, mainly tropics, including Americas, Caribbean, Middle East, Australia	Ingestion of raw/ undercooked intermediate or paratenic host (or accidental ingestion on vegetables); possibly ingestion of plants contaminated by secretions of intermediate host	Eosinophilic meningitis or meningoencephalitis, spinal cord involvement; ocular involvement with decreased vision; transient abdominal pain, pruritus in some; most cases relatively mild and self-limiting, but some fatal
Worldwide but many cases in northern Asia and western Europe	Ingestion of undercooked marine fish, squid, octopus	Gastroenteritis with upper quadrant pain; parasite usually in stomach; small-intestinal infections unusual but can occur; colon, esophagus rarely involved; oropharyngeal worm can cause hematemesis, cough; urticaria and other allergic signs after ingestion of live or dead worms
Worldwide, prevalence varies	Ingestion of eggs from environment (shed in feces)	Visceral larva migrans (respiratory signs, fever during larval migration); GI signs
Worldwide in scattered foci	Ingestion of embryonated eggs in soil	Acute or subacute hepatitis with marked eosinophilia; subclinical to fatal
Philippines, Thailand, also reported occasionally in other parts of Asia, Middle East, Cuba	Ingestion of undercooked infected fish	Enteropathy with protein loss and malabsorption; diarrhea, abdominal pain; weight loss can be severe; death possible
Worldwide; rare in people	Accidental ingestion of infective eggs in soil or contaminated food	Fever, cough, bronchospasm, bronchitis, dyspnea; can mimic bronchial carcinoma
Worldwide; rare in people	Ingestion of infected fish, frog, or annelid	Renal colic, hematuria, pyuria, ureteral obstruction, various kidney complications can be fatal; subcutaneous nodule
Asia (mainly Indian subcontinent) and Africa	Ingestion of infected cyclops in water	No symptoms until just before larviposition (~1 yr); papule to vesicular skin lesion to ulcer that opens in water to reveal worm; allergic reaction common at this time, and secondary infection may occur
Worldwide	Bite of infected mosquitoes	Fever, cough acutely, larvae result in infarct or coin lesion in the lungs; often asymptomatic; rarely involves eye or other body sites

(continued)

TABLE 4 GLOBAL ZONOOSES^a (continued)

Disease	Causative Organism	Animals Involved
PARASITIC DISEASES—NEMATODES (ROUNDWORMS) (continued)		
Dirofilariasis (continued)	<i>D tenuis</i> , <i>D repens</i> , rarely other species	<i>D tenuis</i> in raccoons; <i>D repens</i> mainly patent in dogs and some wild canids (eg, foxes); also infects cats but not usually patent
—Malayan filariasis	<i>Brugia malayi</i> ; subperiodic form is of uncertain origin, thought to be zoonotic or maintained in both animals and people; periodic form is exclusive to people	Cats, wild felids, pangolins, other carnivores, nonhuman primates susceptible
Filariasis caused by other <i>Brugia</i> species	<i>Brugia</i> spp other than <i>B malayi</i> , including <i>B pahangi</i>	Various domestic and wild mammals, including dogs and cats, are definitive hosts
Gnathostomiasis	<i>Gnathostoma spinigerum</i> , <i>G binucleatum</i> , and some other <i>Gnathostoma</i> spp	Dogs, cats, wild carnivores are definitive hosts (<i>G doloresi</i> and <i>G hispidum</i> in pigs and wild boars); copepods, freshwater fish, eels, frogs, snakes, chickens, snails, pigs are intermediate or paratenic hosts
Gongylonemiasis	<i>Gongylonema pulchrum</i>	Ruminants, domestic and wild swine, other mammals, birds are definitive hosts; coprophagous insects (eg, beetles, cockroaches) are intermediate hosts
Larva migrans, cutaneous (see also GNATHOSTOMIASIS, above)	<i>Ancylostoma braziliense</i> , <i>A caninum</i> , <i>A ceylanicum</i> , <i>Uncinaria stenocephala</i>	Cats, dogs, wild carnivores are definitive hosts
	<i>Bunostomum phlebotomum</i>	Cattle
	<i>Strongyloides stercoralis</i> and other <i>Strongyloides</i> spp found in animals	<i>S stercoralis</i> in dogs, cats, primates, including people; other species in swine, sheep, goats, cattle, horses, raccoons, and other domestic and wild mammals

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
PARASITIC DISEASES—NEMATODES (ROUNDWORMS) (continued)		
<i>D tenuis</i> in North America; <i>D repens</i> in Asia, Europe, Africa	Bite of infected mosquitoes	Subcutaneous nodule or submucosal swelling, some migratory and/or painful; subconjunctival (rarely intraocular); internal location (mainly lung but also brain, other organs) possible
Asia; subperiodic form limited to peninsular Malaysia, Thailand, and parts of Indonesia, Vietnam, and the Philippines in swamp-forest environments	Bite of infected mosquitoes, <i>Mansonia</i> spp mainly associated with subperiodic form	Lymphatic filariasis: recurrent painful lymphadenitis, lymphangitis, often preceded by prodromal illness with malaise or urticaria; may progress to elephantiasis, usually of legs; hypersensitivity syndrome with cough, chest pain, asthmatic attacks especially at night
Asia, Africa, Americas	Mosquitoes	Occasional zoonotic infections (eg, cutaneous nodules, granuloma in lymph nodes)
Worldwide; most human cases from Asia; emerging along Pacific coast of Mexico, Ecuador, Peru, Argentina	Ingestion of undercooked fish, poultry, or other intermediate or paratenic host, drinking water contaminated with copepods containing larvae; handling meat that contains larvae	Fever, malaise, gastroenteritis, urticaria, soon after ingestion; migratory skin lesions (intermittent swelling, often painful or pruritic, or linear erythematous lesions) after weeks to years; may involve viscera, eye, or CNS; CNS involvement can be fatal or result in permanent damage with reported case fatality rates of 7%–25%
Worldwide; rare in people	Ingestion of infected beetles, probably on vegetables; possible inhalation of small beetles	Movement of parasite in submucosa of mouth is sensed; local irritation; pharyngitis, stomatitis possible
Worldwide; distribution varies with the species	Contact with infective larvae that penetrate skin, usually via soil	Itchy, serpiginous, migrating skin lesions; papules, nonspecific dermatitis, vesicles; wheezing, cough, and urticaria may occur; myositis or ocular lesions possible; eosinophilic enteritis after ingestion of <i>A caninum</i> ; <i>A ceylanicum</i> can also become patent in intestine, causing GI signs, anemia
Temperate regions	As above	As above
Worldwide, more common in tropics and subtropics	Contact with infective larvae that penetrate skin, from soil or direct contact with feces; autoinfection possible with <i>S stercoralis</i>	Larva currens (linear, serpiginous urticarial inflammation, often rapidly progressive); <i>S stercoralis</i> may also mature in intestine, causing enteritis and other signs (see below)

(continued)

TABLE 4 GLOBAL ZOOONOSES^a (continued)

Disease	Causative Organism	Animals Involved
PARASITIC DISEASES—NEMATODES (ROUNDWORMS) (continued)		
Larva migrans, visceral (<i>see also</i> ANGIOSTRONGYLIASIS, p 2454, and ANISAKIASIS, p 2456)	<i>Toxocara canis</i> , <i>T cati</i> , possibly others	Dogs and wild canids (<i>T canis</i>), cats and wild felids (<i>T cati</i>) are definitive hosts; many species can be paratenic hosts
	<i>Baylisascaris procyonis</i> , possibly other species of <i>Baylisascaris</i>	Raccoons, kinkajous are definitive hosts; dogs can be definitive or intermediate host; many mammals (including people), marsupials, and birds are intermediate or paratenic hosts
Oesophagostomiasis, Ternidensiasis	<i>Oesophagostomum</i> spp, <i>Ternidens deminutus</i> ; zoonotic potential may vary with parasite species/strain and geographic area	Primates, including people
Onchocercosis	<i>Onchocerca gutturosa</i> , <i>O cervicalis</i> , <i>O jakutensis</i> , <i>O dewittei japonica</i> , <i>O reticulata</i> , <i>O lupi</i> , others	Definitive hosts include cattle, horses, cervids, wild boars, dogs and other canids, camels, other species
Strongyloidiasis	<i>Strongyloides stercoralis</i> ; most human infections thought to be from strains adapted to people; frequency of maturation of canine <i>S stercoralis</i> in people undetermined, thought to be rare	<i>S stercoralis</i> in dogs, cats, foxes, primates, including people
	<i>S fuelleborni</i>	Primates, including people
Thelaziasis (Eyeworms)	<i>Thelazia callipaedia</i> , <i>T californiensis</i> , possibly <i>T rhodesii</i>	Definitive hosts are dogs and other canids, cats (<i>T callipaedia</i>); dogs, wild mammals, occasionally cats (<i>T californiensis</i>); flies are intermediate hosts
Trichinosis (Trichinellosis)	<i>Trichinella spiralis</i> and subspecies, <i>T nativa</i> , <i>T britovi</i> , <i>T nelsoni</i> , <i>T pseudospiralis</i> , possibly others	Main reservoir may be wild carnivores (foxes, badgers, wolves, lynx), omnivores (bears, boars); also in any mammal that eats (or is fed) meat, including domestic swine, rodents, cats, dogs, horses, marine mammals; also birds (<i>T pseudospiralis</i>); <i>T zimbabwensis</i> (zoonotic potential unknown) can infect reptiles

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
PARASITIC DISEASES—NEMATODES (ROUNDWORMS) (continued)		
Worldwide	Ingestion of embryonated eggs shed in feces of dogs and cats; via soil, water, food, fomites	Fever, wheezing cough, upper abdominal discomfort; other symptoms, including neurologic signs, skin rashes also possible; may wax and wane for months; eye involvement (ocular migrans) may resemble retinoblastoma
North America, Europe, Japan	Accidental ingestion of embryonated eggs in soil, water, or fecal-contaminated material	Nonspecific signs, including fever, lethargy; hepatomegaly, pneumonitis, parasitic meningoencephalitis (may be fatal in infants, young children), ocular disease; other syndromes, including cardiac disease
Parasites found in Africa, Asia, South America; human cases mainly reported in Africa	Ingestion of infective larvae in soil, often in food or water	Abdominal pain and one or more masses $\pm$ mild fever; intestinal obstruction or abscessation possible; multinodular form (less common) with abdominal pain, persistent diarrhea, weight loss; rarely ectopic in omentum, liver, or skin
Distribution varies with species	Probably transmitted by blackflies (Diptera: Simuliidae), possibly other vectors	Ocular disease, subcutaneous nodules
<i>S. stercoralis</i> worldwide; more common in tropical and subtropical climates	Contact with infective larvae that penetrate skin, in soil or direct contact with feces; autoinfection possible	Frequently asymptomatic in healthy; possible larva currens (see LARVA MIGRANS, p 2458); respiratory signs in some (cough to bronchopneumonia), especially in elderly, immunocompromised; abdominal pain, diarrhea, sometimes with periodic urticarial or maculopapular rash; disseminated strongyloidiasis, neurologic complications, septicemia, and death may occur in immunocompromised
Africa, Asia, and in captive primates in other areas	As above	Associated with abdominal pain, occasional diarrhea, not well studied
<i>T. callipaeda</i> in Asia, Europe; <i>T. californiensis</i> in North America (western USA); rarely in people	Flies release parasite larvae on conjunctiva	Conjunctivitis; corneal scarring, opacity in chronic cases
Worldwide, especially in temperate regions; some species are limited in their distribution	Ingestion of undercooked pork, horse meat, game, and other tissues containing viable cysts	Gastroenteritis in some; followed by fever, headache, severe myalgia, facial swelling (especially eyelids); ocular pain, rashes, or pruritus possible; pneumonitis, CNS, or myocardial involvement can occur; inapparent to fatal

(continued)

TABLE 4 GLOBAL ZOONOSES^a (continued)

Disease	Causative Organism	Animals Involved
PARASITIC DISEASES—NEMATODES (ROUNDWORMS) (continued)		
Trichostrongyliasis	<i>Trichostrongylus</i> spp	Cattle, sheep, other domestic and wild ruminants, sometimes other mammals
Trichuriasis (Whipworm infection)	<i>Trichuris suis</i> , possibly <i>T vulpis</i> and other species; main species in people is <i>T trichiura</i> , but zoonotic infections are unusual	<i>T vulpis</i> in canids; <i>T suis</i> in domestic and wild swine
PARASITIC DISEASES—ACANTHOCEPHALANS		
Acanthocephaliasis, Macracanthorhynchosis	<i>Macracanthorhynchus hirudinaceus</i> and other species	Hosts vary with parasite species; definitive hosts include domestic and wild pigs, rodents, muskrats, arctic foxes, dogs, sea otters, other terrestrial and marine mammals; intermediate hosts are beetles, cockroaches, crustaceans; fish are paratenic hosts
PARASITIC DISEASES—ANNELIDS (LEECHES)		
Hirudiniasis (internal)	<i>Limnatis nilotica</i> and other aquatic leeches	Cattle, buffalo, other domestic and wild mammals, probably frogs
ARTHROPOD DISEASES		
Acariasis (Mange)	Mites of <i>Sarcoptes</i> , <i>Cheyletiella</i> , <i>Dermanyssus</i> , and <i>Ornithonyssus</i> spp, <i>Notoedres cati</i> , <i>Trixacarus caviae</i> , <i>Liponyssoides sanguineus</i> ; possibly others (uncommon)	Mammals and birds
Myiasis	<i>Cochliomyia hominivorax</i> and <i>Chrysomya bezziana</i> (screwworms)	Mammals; rare in birds
	<i>Cordylobia anthropophaga</i> , rarely <i>C rodhaini</i> (Tumbu flies)	Mammals, often found in dogs, rodents

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
PARASITIC DISEASES—NEMATODES (ROUNDWORMS) (continued)		
Worldwide	Ingestion of infective larvae on vegetables or in contaminated water, soil	Asymptomatic or mild gastroenteritis
Worldwide, especially warm, humid climates	Ingestion of embryonated eggs on plant foods, water, or in soil	<i>T suis</i> can colonize people, who develop GI signs; rare larva migrans or intestinal infections suggested from <i>T vulpis</i> (controversial identification)
PARASITIC DISEASES—ACANTHOCEPHALANS		
Worldwide	Ingestion of infected beetles, other intermediate hosts, or fish	Gastroenteritis, may lead to gut perforation or intestinal obstruction; some cases asymptomatic
PARASITIC DISEASES—ANNELIDS (LEECHES)		
Africa, Asia, southern Europe, Middle East	Drinking unfiltered water (leech enters nares or mouth), wading in deep water (enters genitourinary tract)	Attaches to nasopharynx, pharynx, esophagus, occasionally deeper in respiratory tract, or in genitourinary tract; pressure and/or pain at attachment site; bleeding (eg, hemoptysis, hematemesis, epistaxis, vaginal bleeding), anemia (can be severe); other signs depend on location
ARTHROPOD DISEASES		
Worldwide	Contact with infected animals, fomites	Itchy skin lesions
<i>C hominivorax</i> in South America, Caribbean; <i>C bez-ziana</i> in Asia, Africa, Middle East	Flies lay eggs on host, larvae enter wounds (as small as a tick bite), mucous membranes	Painful, pruritic, foul-smelling, enlarging dermal and subdermal wounds or nodules, often with serosanguineous discharge; some infestations in cavities, including nasal cavity; larvae can invade living tissue, locally destructive (including bone, eye, sinuses, or cranial cavity); can be fatal if untreated
Africa, Middle East; also reported in Mediterranean region of Europe	Larvae from environment invade unbroken skin	Furuncular swelling at site of invasion, often feet; fever, malaise, focal lymphadenopathy possible

(continued)

TABLE 4 GLOBAL ZOONOSES^a (continued)

Disease	Causative Organism	Animals Involved
ARTHROPOD DISEASES (continued)		
Myiasis (continued)	<i>Cuterebra</i> spp	Rodents, lagomorphs, occasionally other mammals
	<i>Dermatobia hominis</i> (human botfly)	Mammals, some birds
	<i>Gasterophilus</i> spp (equine botfly)	Equids, occasionally other mammals
	<i>Hypoderma lineatum</i> , <i>H bovis</i> (warbles), and other <i>Hypoderma</i> spp	<i>H bovis</i> and <i>H lineatum</i> in cattle, sometimes other mammals; other species primarily parasites of deer, caribou, or yaks
	<i>Oestrus ovis</i> , <i>Rhino- estrus purpureus</i>	<i>O ovis</i> mainly in sheep, goats, also other mammals; <i>R purpureus</i> mainly in equids
Pentastomid infections	<i>Wohlfahrtia</i> spp, <i>Wohlfahrtia vigil</i> , <i>W magnifica</i>	<i>W vigil</i> in rabbits, rodents, mink, foxes, dogs, and other carnivores, other mammals; <i>W magnifica</i> in sheep, cattle, dogs, other mammals, some birds, especially geese
	<i>Armillifer</i> spp (tongue worms)	Definitive hosts are snakes; intermediate hosts are rodents and other wild animals

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
ARTHROPOD DISEASES (continued)		
North America	Larvae from vegetation enter host in natural cavities or invade intact skin	Subcutaneous furunculoid nodule(s); creeping skin eruption (uncommon); ocular lesions; rarely larvae might be found in upper respiratory tract
South and Central America, Mexico	Eggs carried by other insects (eg, mosquitoes); larvae hatch and penetrate skin of mammalian host when insect lands	Nonmigratory larvae in furuncles; episodes of pain, intense pruritus, sometimes with lymphangitis or lymphadenitis; can invade eyelids, eye sockets, mouth, especially in children
Worldwide	Accidental exposure to larvae	Serpiginous, pruritic red stripes on skin resembling cutaneous larva migrans; very rarely might reach stomach (nausea, vomiting)
North America, Europe, Asia; species distribution varies	Eggs laid on host, larvae invade skin	Usually subcutaneous (slowly moving furuncles that can appear and disappear) or similar to cutaneous larva migrans; endophthalmitis uncommon; <i>H lineatum</i> may also cause an eosinophilic syndrome with fever, muscle pain, sometimes respiratory, cardiac, or neurologic signs
<i>O ovis</i> worldwide, usually in warmer climates; <i>R purpureus</i> in Asia, Africa, Europe	Larvae are deposited in nares, conjunctiva, occasionally lips/mouth by adult fly	Conjunctival form, with lacrimation and sensation of irritating foreign body in eye, ocular destruction rare; nasal form with localized pain or pruritus, congestion, headache; also reported in pharynx (inflammation, vomiting, dysphagia), rarely ear; usually self-limiting (except inside eye), because larvae cannot develop beyond first stage in people
<i>W vigil</i> in North America; <i>W magnifica</i> in Europe (mainly Mediterranean), north Africa, Asia	Larvae deposited on host or nearby, penetrate lesions (both agents) or intact skin (<i>W vigil</i>) and natural orifices	<i>W vigil</i> causes subcutaneous abscesses, furuncles; <i>W magnifica</i> has been reported from skin, eye, vulva, ear, orotracheal region
Africa, Asia	Ingestion, via water or vegetables contaminated with eggs (from feces or saliva of snakes); undercooked snake meat; contaminated hands, fomites after handling snake meat	Usually asymptomatic; large numbers of parasites can cause multifocal abscesses, masses, or obstruction of ducts in internal organs; symptoms vary with location; death rare

(continued)

TABLE 4 GLOBAL ZOONOSES^a (continued)

Disease	Causative Organism	Animals Involved
ARTHROPOD DISEASES (continued)		
Pentastomid infections (continued)	<i>Linguatula serrata</i>	Definitive hosts are dogs and other canids, felids; intermediate hosts are herbivores (especially sheep, goats, lagomorphs) and people
Tick paralysis (see p 1314)	More than 40 species of ticks are capable of causing this disease; <i>Dermacentor andersoni</i> , <i>D. variabilis</i> most common in North America	Various animals carry ticks
<i>Tunga</i> infections	<i>Tunga penetrans</i> (sand fleas, jiggers)	People, dogs, pigs, other mammals
VIRAL DISEASES		
Alkhurma virus infection	Alkhurma virus (family Flaviviridae, genus <i>Flavivirus</i>); may be a variant or strain of Kyasanur Forest virus	Sheep, goats, camels
Barmah Forest virus infection; epidemic polyarthritis	Barmah Forest virus (family Togaviridae, genus <i>Alphavirus</i>)	Natural hosts unknown; horses, brushtail possums may be hosts
Buffalopox virus infection	Vaccinia virus, Buffalopox virus strain (family Poxviridae, genus <i>Orthopoxvirus</i>)	Water buffalo, cattle
California encephalitis virus serogroup (California serogroup) infections	California encephalitis virus serogroup (family Bunyaviridae, genus <i>Orthobunyavirus</i>); includes California, La Crosse, Tahyna, Inkoo, Jamestown Canyon, Morro Bay, Snowshoe hare, Guaroa, Lumbo, Chatanga, and other viruses	Many wild and domestic mammals

TABLE 4 GLOBAL ZONONOS^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
ARTHROPOD DISEASES (continued)		
Worldwide	Ingestion of water or vegetables contaminated with eggs (from feces, saliva, or nasal discharge of definitive host); ingestion of larvae in undercooked liver or lymph nodes from intermediate hosts	Ingestion of eggs—usually asymptomatic; ocular or pulmonary signs, abdominal pain, icterus, and other symptoms possible from invasion of internal organs Ingestion of larvae—throat irritation, pain; edema, congestion of nasopharynx may cause dyspnea, difficulty swallowing; most severe cases are probably in people who have been sensitized
Worldwide	Tick attachment	Ascending flaccid paralysis, may be preceded by prodromal flu-like illness (malaise, weakness); can cause respiratory paralysis, also paresthesia; ends when tick is removed
Africa, Central and South America, Caribbean, south Asia	Skin contact with contaminated soil	Penetration of skin and burrowing result in pain and itching around discrete sores, often on feet; may be secondarily infected
VIRAL DISEASES		
Middle East, mainly reported in Saudi Arabia, also Egypt	Ticks (<i>Ornithodoros</i> and <i>Hyalomma</i> spp); direct contact with animal meat via broken skin or ingestion of unpasteurized camel milk linked to some cases	Febrile illness, often with GI signs (eg, vomiting, abdominal pain); encephalitic/neurologic and hemorrhagic signs in some; case fatality up to 25% in early reports, recently <1%
Australia	Mosquito bites; <i>Culex annulirostris</i> and <i>Aedes</i> spp implicated	Resembles disease caused by Ross River virus (see p 2478) but seems to persist longterm in fewer patients, rash more common
Indian subcontinent (south Asia), Egypt, Indonesia	Skin contact with infected animals, often when milking	Pox skin lesions mainly on hands, face, legs, buttocks; occasionally lymphadenopathy, fever, malaise
North and South America, Europe, Africa, Asia; possibly worldwide; distribution of each virus varies	Mosquito bites	Syndromes, severity vary with the virus; flu-like illness, meningitis, or encephalitis common with North American viruses

(continued)

TABLE 4 GLOBAL ZONNOSES^a (continued)

Disease	Causative Organism	Animals Involved
VIRAL DISEASES (continued)		
—La Crosse encephalitis	La Crosse virus (California encephalitis virus serogroup)	Chipmunks, squirrels are major amplifying hosts; rabbits, foxes, and other mammals can be infected
—Tahyna fever	Tahyna virus (California encephalitis virus serogroup)	Hares, rabbits, rodents, hedgehogs, and other mammals
Camelpox	Camelpox virus	Old World camelids, possibly other species
Chikungunya virus infection	Chikungunya virus (family <i>Togaviridae</i> , genus <i>Alphavirus</i>)	Sylvatic cycle in nonhuman primates, possibly rodents in Africa; virus thought to be maintained in people in Asia, but sylvatic cycle may also exist
Colorado tick fever	Colorado tick fever virus (family <i>Reoviridae</i> , genus <i>Coltivirus</i> ; Salmon River virus and California hare coltivirus may be variants	Rodents; also found in porcupines, lagomorphs, deer, elk, and other mammals
Contagious ecthyma (Orf, see p 866)	Orf virus (family <i>Poxviridae</i> , genus <i>Parapoxvirus</i>)	Sheep, goats, camelids, reindeer, wild ungulates; rare cases in dogs
Cowpox (see p 868)	Cowpox virus (family <i>Poxviridae</i> , genus <i>Orthopoxvirus</i>)	Rodents are usual reservoir host; also in domestic and wild cats, occasionally cattle, other mammals

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
VIRAL DISEASES (continued)		
North America	Mosquito bites	Many cases mild and flu-like; meningitis or encephalitis with seizures, paralysis, and focal neurologic signs possible; most cases in children; estimated case fatality rate <1% in cases with encephalitis
Europe, Asia, Africa	Mosquito bites (culicine and anopheles)	Influenza-like illness, sometimes including GI signs; arthritis or respiratory signs, including bronchopneumonia in some; meningitis possible; most often in children; does not appear to cause fatal disease
Middle East, Asia, Africa, possibly other areas; human cases recently described in India in camel handlers, rare unconfirmed cases suggested in other locations	Direct contact	Skin lesions similar to cowpox, variola virus infections
Asia, Africa	Mosquito bites (especially <i>Aedes</i> spp)	Febrile illness, may have rash and/or GI signs; arthralgia, especially in small joints, and myalgia prominent, may persist for months; myocarditis, neurologic signs, hemorrhages reported in a few cases
Rocky Mountain region of North America	Tick bites (primary vector is <i>Dermacentor andersoni</i>)	Nonspecific febrile illness; pharyngitis, rash, or GI signs possible; biphasic or triphasic in some; complications (eg, neurologic signs, hemorrhages, pericarditis, myocarditis, orchitis) uncommon but can occur in severe cases; deaths rare
Worldwide	Occupational exposure via contact with broken skin (both live animals and meat processing)	Papule(s) that umbilicate and ulcerate, usually on hands; dissemination rare; large lesions refractory to treatment can be seen in immunosuppressed
Parts of Europe and Asia	Contact exposure via broken skin, bites, scratches	Papules, vesicles that become pustular, to ulcerative nodules, scars; single or multiple lesions, often on hands; regional adenopathy and malaise, flu-like symptoms in some; lesions remain localized in healthy people; more extensive or generalized disease may be seen in children, people with eczema, immunocompromised; severe cases can involve respiratory mucosa; rare fatal cases (eg, complications of encephalitis)

(continued)

TABLE 4 GLOBAL ZONONOSES^a (continued)

Disease	Causative Organism	Animals Involved
VIRAL DISEASES (continued)		
Crimean-Congo hemorrhagic fever (see p 751)	Crimean-Congo hemorrhagic fever virus (family <i>Bunyaviridae</i> , genus <i>Nairovirus</i>)	Cattle, rodents, sheep, goats, hares, other manunals, some birds
Eastern equine encephalomyelitis (see p 1291)	Eastern equine encephalomyelitis virus (family <i>Togaviridae</i> , genus <i>Alphavirus</i>); North American lineage 1 strains more virulent than South American lineages	Birds are principal reservoir hosts in North America, snakes might have role in overwintering virus; rodents, marsupials might be reservoir hosts in South America; clinical cases seen in equids and occasionally other mammals and birds; mammals are almost always dead-end hosts
Ebola hemorrhagic fever	Zaire ebolavirus, Sudan ebolavirus, Ivory Coast ebolavirus, Bundibugyo ebolavirus (family <i>Filoviridae</i> , genus <i>Ebolavirus</i>); Reston ebolavirus does not seem to affect people	Bats are reservoir hosts for Zaire ebolavirus and suspected reservoir hosts for others; primates, duikers, possibly other mammals can be infected
Encephalomyocarditis	Encephalomyocarditis virus (family <i>Picornaviridae</i> , genus <i>Cardiovirus</i>); thought to be zoonotic	Rodents may be reservoir hosts; also in swine, nonhuman primates, elephants, other mammals, and wild birds
Foot-and-mouth disease (see p 629)	Foot-and-mouth disease virus (family <i>Picornaviridae</i> , genus <i>Aphthovirus</i> , types A, O, C, SAT 1, SAT 2, SAT 3, and Asia 1)	Cattle, swine, sheep, goats, other cloven-hoofed animals (<i>Artiodactyla</i>), a few mammals in other orders
Hantaviral diseases		
—Hantaviral pulmonary syndrome	Sin Nombre, Black Creek Canal, Bayou, Andes, Bermejo, Choclo, Araraquara, <i>Juquitiba</i> , Laguna Negra, and Castelo dos Sonhosviruses, others (family <i>Bunyaviridae</i> , genus <i>Hantavirus</i>)	Rodents; each virus tends to be associated with a single reservoir host
—Hemorrhagic fever with renal syndrome	Hantaan virus, Dobrava virus, Puumala virus, Seoul virus, Saaremaa virus, others (family <i>Bunyaviridae</i> , genus <i>Hantavirus</i>)	Rodents; each virus tends to be associated with a single reservoir host, but Seoul virus is carried by both <i>Rattus norvegicus</i> and <i>R. rattus</i>

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
VIRAL DISEASES (continued)		
Africa, Middle East, central Asia, southeastern Europe; appears to be spreading	Tick bites, especially <i>Hyalomma</i> but also <i>Rhipicephalus</i> , <i>Dermacentor</i> ; other species; skin contact with animal or human blood or tissues or crushed ticks; ingestion of unpasteurized milk	Fever, headache, pharyngitis, abdominal symptoms, petechial rash, hemorrhage, hepatitis, other organ involvement in some cases; very severe in pregnant women; case fatality rate 3%–50%, varies with region
Western hemisphere	Mosquito bites; <i>Culiseta melanura</i> important in maintenance cycle in birds in North America; various mosquito species (<i>Aedes</i> , <i>Coquilleltidia</i> , <i>Culex</i>) can transmit to people	Nonspecific febrile illness may be followed by severe encephalitis, especially with North American lineage; neurologic sequelae common after encephalitis; case fatality rate 30%–70% with North American lineage; more severe in infants and elderly
Africa	Contact with infected tissues (especially nonhuman primates and duikers); probable transmission from bats in caves	Initially nonspecific febrile illness; maculopapular rash with desquamation; mild to severe bleeding tendency develops a few days after onset; mortality rate 36%–90%, varies with isolate
Worldwide in animals	Uncertain	Nonspecific febrile illness, sometimes with GI signs, and/or decreased reflexes have been reported in adults, with recovery within several days; CNS signs, including paralysis, have been reported in children
Asia, Africa, Middle East, South America	Contact exposure, often in laboratories or other high concentrations of virus	People may become temporary nasal carriers of virus but do not usually become ill; mild influenza-like disease with vesicular lesions occurs very rarely
North and South America	Aerosols from rodent excretions and secretions; contact with broken skin and mucous membranes; rodent bites	Prodromal stage with nonspecific febrile illness; followed by respiratory failure, cardiac abnormalities; hemorrhagic signs possible with South American viruses; significant kidney disease uncommon; mortality rate varies with the virus, but can reach 40%–60%
Europe, Asia; Seoul virus is worldwide	Aerosols from rodent excretions and secretions; contact with broken skin and mucous membranes; rodent bites	Prodromal stage with abrupt onset of fever, headache, back pain, sometimes petechiae, GI signs (maybe severe); followed by hypotension, renal signs to renal failure with oliguria; hemorrhage, other syndromes in some; mortality rate varies with the virus, from <1% (Puumala virus) to 10%–15% (Hantaan virus)

(continued)

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Disease	Causative Organism	Animals Involved
VIRAL DISEASES (continued)		
Hendra virus infection (see p 707)	Hendra virus (family Paramyxoviridae, genus <i>Henipavirus</i>)	Fruit bats are normal reservoir host; horses can be infected
Hepatitis E	Hepatitis E virus, mammalian isolates (family Hepeviridae, genus <i>Hepevirus</i>); genotypes 3 and 4 zoonotic; genotypes 1 and 2 maintained in people	People; animals, including swine, wild boar, deer, rabbits, ferrets, rats, mongoose, others; swine and probably other hosts are reservoirs for human infections
Herpes B virus disease	Cercopithecine herpesvirus 1 (McHV, Herpesvirus simiae, B virus) (family Herpesviridae, genus <i>Simplexvirus</i>)	Carried in genus <i>Macaca</i> (Old World macaques), with lifelong latency and potential for periodic shedding after infection; other nonhuman primates susceptible; cell cultures
Influenza virus infections		
—Avian influenza	Influenza A virus (family Orthomyxoviridae, genus <i>Influenzavirus A</i>); avian influenza viruses; many severe human cases linked to Asian lineage H5N1 highly pathogenic avian influenza (HPAI) viruses, but other viruses also cause illness	Avian influenza viruses in wild and domestic birds, especially poultry; uncommon in mammals
—Swine influenza	Influenza A virus (family Orthomyxoviridae, genus <i>Influenzavirus A</i>); swine influenza viruses	Usually in pigs; also turkeys; can infect mink, ferrets
Japanese encephalitis (Japanese B encephalitis)	Japanese encephalitis virus (family Flaviviridae, genus <i>Flavivirus</i>)	Swine, wild birds are important maintenance hosts; horses ill but epidemiologically unimportant in amplification; other mammals, reptiles, amphibians may be infected, usually asymptotically
Kyasanur Forest disease	Kyasanur Forest virus (family Flaviviridae, genus <i>Flavivirus</i>)	Rodents, shrews, other small mammals might be reservoirs (uncertain); affects monkeys; possible infections in other mammals, birds

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
VIRAL DISEASES (continued)		
Australia	Direct contact with infected animals (all human cases have been linked with horses) or contaminated tissues	Respiratory infection, encephalitis (including recurrent encephalitis); few cases described but several were fatal
Worldwide; human and zoonotic genotypes may differ in prevalence between areas	Fecal-oral spread; consumption of raw or undercooked meat and liver; waterborne, contact with animal reservoirs	Mild, self-limiting hepatitis to liver failure, more severe in pregnancy and can result in abortion, death of newborn, premature birth; usually acute, but can be chronic in organ-transplant patients; case fatality rate <1% to 4% in general population, up to 20% in pregnant
Worldwide, can be common, especially in closed groups of macaques; human cases rare	Monkey bites and scratches, contamination of mucous membranes with infected saliva, secretions	Influenza-like symptoms; vesicular skin lesions, pain, or itching around wound, followed by severe encephalitis with seizures, paralysis, coma; 85% mortality rate
Worldwide, distribution of strains varies	Usually by contact with infected poultry; avian viruses may be shed in respiratory secretions and feces	Avian influenza viruses can cause conjunctivitis, human influenza-like illness, or severe disease with multiorgan dysfunction, death; severity of disease varies with influenza strain
Worldwide	Usually by contact with infected animals; swine influenza viruses occur in respiratory secretions	Seems to resemble human influenza; severity of disease varies; fatal cases have been reported uncommonly
Asia, Australia, Papua New Guinea, Pacific islands from Japan to the Philippines	Mosquito bites (<i>Culex tritaeniorhynchus</i> important in maintenance cycle, other <i>Culex</i> and <i>Aedes</i> spp can transmit); also through broken skin or mucous membranes after direct contact with infected tissues	Fever, chills, myalgia, severe headache, GI symptoms; can progress to severe encephalitis; neurologic sequelae very common in survivors of encephalitis; case fatality rate 15%–30%
India	Tick bites (especially <i>Haemaphysalis spinigera</i> , also others)	Nonspecific febrile illness; course may be biphasic; hemorrhagic signs (eg, ecchymoses, purpura, petechiae, GI bleeding, epistaxis) and/or neurologic signs possible in second stage; prolonged convalescence in many; case fatality rate ~3%

(continued)

TABLE 4 GLOBAL ZONONOSES^a (continued)

Disease	Causative Organism	Animals Involved
VIRAL DISEASES (continued)		
Lassa fever	Lassa virus (family Arenaviridae, genus <i>Arenavirus</i>)	Wild rodents, usually multimammate mouse
Louping ill (Ovine encephalomyelitis, see p 1299)	Louping ill virus (family Flaviviridae, genus <i>Flavivirus</i>)	Sheep, goats, also in llamas, cattle, horses, other domestic and wild mammals, grouse, ptarmigan
Lymphocytic choriomeningitis	Lymphocytic choriomeningitis virus (family Arenaviridae, genus <i>Arenavirus</i>)	Reservoir mainly house mouse; can be maintained in some other mice, hamster populations; also infects guinea pigs, chinchillas, rats, nonhuman primates, some other mammals
Marburg hemorrhagic fever	Marburg virus (family Filoviridae, genus <i>Marburgvirus</i>)	Bats are reservoir hosts; primates can be infected
Menangle virus infection	Menangle virus (family Paramyxoviridae)	Fruit bats are normal reservoir host; pigs can also be reservoir
Middle East respiratory syndrome (MERS)	MERS coronavirus	Unknown reservoir host, possibly bats; source of infection for people uncertain, camels implicated
Milker's nodules (Pseudocowpox, see p 868)	Pseudocowpox virus (family Poxviridae, genus <i>Parapoxvirus</i>)	Cattle
Monkeypox	Monkeypox virus (family Poxviridae, genus <i>Orthopoxvirus</i>); Congo Basin clade causes more severe illness than West African clade	Nonhuman primates, some wild and pet rodents, including Gambian rats, dormice, prairie dogs, African squirrels, some other mammals such as opossums; full host range uncertain

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
VIRAL DISEASES (continued)		
West Africa	Contact with rodent excretions, secretions, or tissues; aerosols	Gradual onset of nonspecific febrile illness, may be followed by chest pain, cough, GI signs, hepatitis; severe swelling of head and neck, hypotension/shock can develop; pleural/pericardial effusions; hemorrhagic syndrome less common; overall mortality rate 1% in endemic areas; case fatality rate 20% among hospitalized patients
UK, Northern Ireland; also reported in Norway, Spain; uncommon in people	Tick bites (<i>Ixodes ricinus</i>); aerosol exposure in laboratory, contamination of skin wounds, contact with infected animals; possibly ingestion of milk	Biphasic influenza-like illness, sometimes followed by meningitis or meningoencephalitis, paralysis, joint pain in second phase; not usually fatal
Worldwide	Contact with host excretions and secretions; bites; possibly ingestion	Ranges from mild flu-like illness to biphasic with meningitis in second phase; complications (eg, arthritis, parotitis, orchitis) possible; can cause congenital defects (CNS defects, chorioretinitis, and other ocular lesions) or abortion; rarely fatal in immunocompetent (overall case fatality rate <1%)
Africa	Contact with infected tissues (especially nonhuman primates); probable transmission from bats in caves	Initially nonspecific febrile illness; maculopapular rash with desquamation; hepatitis; mild to severe bleeding tendency develops a few days after onset; mortality rate 20%–88%, varies with isolate
Australia	Close direct contact with tissues, amniotic fluid or blood of pigs reported in human cases	Severe illness with fever, severe headache, myalgia, lymphadenopathy, drenching sweats, macular rash
Middle East		Pneumonia, more likely in people with coexisting illness or immunosuppression but also in healthy; ~50% of known cases were fatal
Worldwide	Skin contact (especially broken skin) with lesions on cow's udder or mouth of calf; also from fomites	Papular to nodular red skin lesions; self-limiting
West and central Africa	Contact with lesions, blood or body fluids, fomites; bites; aerosols during close contact	Smallpox-like disease; flu-like symptoms followed by maculopapular rash, which develops into vesicles, pustules, scabs; lymphadenopathy prominent; respiratory signs, encephalitis possible; case fatality rate varies with strain, <1% to 10%–17% or higher; milder in those vaccinated for smallpox

(continued)

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Disease	Causative Organism	Animals Involved
VIRAL DISEASES (continued)		
Murray Valley encephalitis	Murray Valley encephalitis virus (family Flaviviridae, genus <i>Flavivirus</i>)	Wild water birds
Newcastle disease	Newcastle disease virus/ Avian paramyxovirus 1 (family Paramyxoviridae, genus <i>Avulavirus</i>)	Domestic and wild birds
New World hemorrhagic fever (Argentinean, Bolivian, Venezuelan and Brazilian hemorrhagic fevers [HF])	Arenaviruses in Tacaribe complex (family Arenaviridae, genus <i>Arenavirus</i>): Junin virus (Argentine HF), Machupo virus (Bolivian HF), Guanarito virus (Venezuelan HF), Sabiá virus (Brazilian HF), Chapare virus; possibly others	Rodents
Nipah virus infection (see p 721)	Nipah virus (family Paramyxoviridae, genus <i>Henipavirus</i>)	Fruit bats are normal reservoir; swine can be reservoir; occasionally in other mammals (spillover hosts)
Omsk hemorrhagic fever	Omsk hemorrhagic fever virus (family Flaviviridae, genus <i>Flavivirus</i>)	Voies, muskrats; also found in other animals
Powassan virus encephalitis	Powassan virus (family Flaviviridae, genus <i>Flavivirus</i>); two closely related lineages in different reservoirs	Rodents (groundhog, squirrels, mice) and other small mammals thought to be reservoirs

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
VIRAL DISEASES (continued)		
Australia, New Guinea	Mosquito bites (<i>Culex annulirostris</i>)	Asymptomatic or mild nonspecific febrile illness in majority; encephalitis, often with neurologic sequelae, or poliomyelitis-like flaccid paralysis in small number of patients; case fatality rate 15%–30% in encephalitic form
Mildly virulent (lentogenic, mesogenic strains) are found worldwide; highly virulent (velogenic) strains found in Asia, the Middle East, Africa, Central and South America, parts of Mexico; also in cormorants in USA	Occupational exposure, usually after contact with large amounts of virus	Highly virulent (velogenic) strains can cause self-limiting conjunctivitis, possibly other syndromes
South America, related viruses might exist among rodents in Mexico	Viruses found in rodent excretions, secretions, tissues; inhalation of aerosolized virus or direct contact with mucous membranes or broken skin	Gradual onset of nonspecific signs, including myalgia, headache, and fever; may develop petechial or ecchymotic hemorrhages, bleeding, CNS signs, hypotension/shock; case fatality rate in untreated Bolivian hemorrhagic fever 5%–30%, untreated Argentine hemorrhagic fever 15%–30%
Malaysia, Bangladesh, and Northern India; virus is probably endemic in southeast Asia, but outbreaks seem to cluster in certain geographic areas	Direct contact with infected pigs or contaminated tissue; direct or indirect (eg, contaminated fruit juice) bat-to-human transmission	Initial signs flu-like with fever, headache, myalgia, sometimes vomiting; encephalitis and meningitis; respiratory disease, including acute respiratory distress syndromes in some; septicemia; other complications in severely ill; case fatality rate 33%–75%
Siberia	Tick bites (<i>Dermacentor</i> spp); direct contact with body fluids or carcasses of muskrats and possibly other animal hosts	Biphasic febrile illness with headache, GI signs, ± hemorrhages (nose, gums, lungs, uterus); CNS signs in minority of patients; mortality rate <3%
North America, eastern Russia	<i>Ixodes</i> spp ticks, also found in <i>Dermacentor andersoni</i>	Nonspecific febrile illness; may progress to neurologic signs, which may be severe; some cases fatal

(continued)

TABLE 4 GLOBAL ZONNOSES^a (continued)

Disease	Causative Organism	Animals Involved
VIRAL DISEASES (continued)		
Rabies and rabies-related infections (see p 1302)	Lyssaviruses: rabies virus (family Rhabdoviridae, genus <i>Lyssavirus</i>) and the related lyssaviruses, Duvenhage virus, Mokola virus, Australian bat lyssavirus, European bat lyssaviruses 1 and 2, Irkut virus, possibly others	Wild and domestic canids, Mustelidae, Viverridae, Procyonidae, and order Chiroptera (bats) are important reservoir hosts; all mammals are susceptible; bats are reservoir hosts for Duvenhage virus, Australian bat lyssavirus, and European bat lyssaviruses; Mokola virus carried in rodents and shrews
Rift Valley fever (see p 768)	Rift Valley fever virus (family Bunyaviridae, genus <i>Flavivirus</i>)	Sheep, goats, cattle, buffalo, African buffalo, camels, nonhuman primates; squirrels and other rodents; puppies and kittens
Ross River virus infection, Ross River fever; epidemic polyarthritis	Ross River virus (family Togaviridae, genus <i>Alphavirus</i>)	Marsupials, including wallaby, brushtail possum, might be natural hosts; dusky rat also proposed; people, horses, ruminants, pigs, rabbits, other mammals (minor hosts) may also be a source of virus during epidemics
St. Louis encephalitis	St. Louis encephalitis virus (family Flaviviridae, genus <i>Flavivirus</i>)	Wild birds, domestic fowl; rodents, bats, other mammals might also maintain viruses in South America
Severe acute respiratory syndrome (SARS)	SARS coronavirus (family Coronaviridae, genus <i>Coronavirus</i>)	Bats are thought to be reservoir hosts; can also infect palm civets, raccoon dogs, cats, pigs, ferrets, rodents, nonhuman primates, other mammals
Sindbis virus disease	Sindbis virus (family Togaviridae, genus <i>Alphavirus</i>)	Birds (passeriforms suspected as main reservoirs/amplifying hosts); occasionally found in other vertebrates
Tanapox	Tanapox virus (family Poxviridae, genus <i>Tatapoxvirus</i>); Yaba-like disease virus may be a variant of tanapox virus	Nonhuman primates

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
VIRAL DISEASES (continued)		
Rabies is worldwide with some exceptions: completely absent from some islands; countries also considered rabies-free if no cases in people or domestic animals for 2 yr; rabies-related lyssaviruses found only in Eastern Hemisphere (distribution varies)	Bites of diseased animals; aerosols in closed environments	Paresthesias or pain at bite site; nonspecific prodromal signs such as fever, myalgia, malaise; mood changes progress to paresthesias, paresis, seizures, and many other neurologic signs; survival in clinical cases thought to be very rare
Africa, foci on Arabian peninsula, Indian subcontinent	Mosquito bites (<i>Aedes</i> spp and <i>Culex tritaeniorhynchus</i>); contact with tissues	Influenza-like febrile illness in most; complications, including hemorrhagic fever, meningoencephalitis in <5%; ocular disease in 1%–10%; other syndromes include acute renal failure or thrombosis; death uncommon except with hemorrhagic syndrome
Australia, South Pacific Islands	Mosquito bites (especially <i>Culex annulirostris</i> and <i>Aedes</i> spp)	Mild fever, arthralgia ± arthritis, headache, rash; small joints most affected but large joints can also be involved; arthralgia, myalgia, lethargy may persist for months
Western hemisphere	Mosquito bites (<i>Culex tarsalis</i> , <i>C pipiens quinquefasciatus</i> complex, <i>C nigripalpus</i> , also reported in other genera)	Flu-like illness sometimes followed by meningitis or encephalitis, focal neurologic signs, dysuria; more severe in elderly and those with debilitating diseases; case fatality rate of 5%–20% reported in epidemics
China, southeast Asia	Contamination of mucous membranes with respiratory droplets or virus on fomites; possibly aerosol transmission	Fever, myalgia, headache, diarrhea, cough; viral pneumonia with rapid deterioration; case fatality rate 15%
Virus widespread in Eastern hemisphere; human cases tend to occur in limited geographic regions	Mosquito bites; <i>Culex</i> and <i>Culiseta</i> , also others	Fever, arthritis, rash, prominent myalgia; nausea, vomiting, mild jaundice in some; joint pain can persist for months; seems to be mild or asymptomatic in most children; no fatal cases reported
Asia, Africa, and in monkey colonies	Direct contact through broken skin; mosquitoes suspected to be vector in Africa	Nonspecific febrile illness and papulovesicular or nodular lesions (lesions may be pruritic or tender), often on extremities; more than one or two skin lesions uncommon

(continued)

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Disease	Causative Organism	Animals Involved
VIRAL DISEASES (continued)		
Tickborne encephalitis (Far eastern tickborne encephalitis, Russian spring-summer encephalitis, Central European tickborne encephalitis)	Tickborne encephalitis virus (TBEV) (family <i>Flaviviridae</i> , genus <i>Flavivirus</i>); three subtypes: European (TBEV-Eu [least virulent]), Siberian (TBEV-Sib), Far Eastern (TBEV-FE)	Small mammals especially rodents; also in goats, sheep, dogs, and other mammals; birds
Usutu virus infections	Usutu virus (family <i>Flaviviridae</i> , genus <i>Flavivirus</i>)	Birds
Vaccinia-related poxviruses	Vaccinia or vaccinia-like viruses (family <i>Poxviridae</i> , genus <i>Orthopoxvirus</i>) of uncertain origin	Reservoir uncertain; found in wild rodents, cattle, horses, nonhuman primates
Venezuelan equine encephalomyelitis	Venezuelan equine encephalitis virus (family <i>Togaviridae</i> , genus <i>Alphavirus</i>)	Enzootic subtypes maintained in rodents, other small mammals, bats; epizootic subtypes amplified in equids; occasionally in other mammals and birds
Vesicular stomatitis	Vesicular stomatitis Indiana virus, vesicular stomatitis New Jersey virus, vesicular stomatitis Alagoas virus, and Cocal virus (family <i>Rhabdoviridae</i> , genus <i>Vesiculovirus</i>)	Swine, cattle, horses; occasionally in South American camelids, sheep, and goats; also rodents; serologic evidence of infection in many wild mammals, especially bats
Wesselsbron fever	Wesselsbron virus (family <i>Flaviviridae</i> , genus <i>Flavivirus</i>)	Ruminants, especially sheep, goats; also evidence of infection in other mammals, including lemurs; can infect birds
West Nile fever and neuroinvasive disease (see p 1291)	West Nile virus (family <i>Flaviviridae</i> , genus <i>Flavivirus</i>); lineage 1 and lineage 2 viruses are both pathogenic	Birds are primary reservoir hosts; also affects horses, other mammals, alligators, possibly other reptiles and amphibians

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
VIRAL DISEASES (continued)		
Eurasia; TBEV-Eu mainly Europe to former USSR; TBEV-FE mainly Asia to former USSR; TBEV-Sib mainly in Siberia	Tick bites (mainly <i>Ixodes ricinus</i> and <i>I. persculturatus</i> ; also other species); may be ingested in milk	Often biphasic, with flu-like febrile illness in initial stage; neurologic signs from mild meningitis to severe encephalitis in some; myelitis or flaccid poliomyelitis-like paralysis (usually arms, shoulders, levator muscles of head); possibility of chronic and progressive forms, especially with TBEV-Sib; case fatality rate <2% (TBEV-Eu), 2%-3% (TBEV-Sib); case fatality rate 20%-30% in TBEV-FE may be based on severe cases
Africa, Europe	Mosquito bites (<i>Culex</i> spp)	Very few cases identified: fever with rash, fever with jaundice, or meningoencephalitis
Appear to be endemic in Brazil	Direct contact	Pox skin lesions (papules, pustules, ulcerative nodules), may be accompanied by fever, lymphadenopathy
Western hemisphere; enzootic strains Florida to South America; epizootic strains emerge in South America, spread	Mosquito bites (<i>Aedes</i> , <i>Culex</i> , and <i>Psorophora</i> spp); exposure to aerosolized debris from infected laboratory rodents; laboratory accidents	Most have nonspecific febrile illness, can be followed by neurologic signs; <5% children, <1% adults progress to encephalitis with case fatality rate of 10%-35% (highest rates in children <5 yr old)
North and South America; most likely not endemic north of Mexico but sporadic outbreaks	Contact with animals or in laboratory, probably also from insect bites, including mosquitoes and biting flies (<i>Phlebotomus</i> spp, <i>Lutzomyia</i> spp, and black flies)	Usually asymptomatic; may develop acute, febrile, flu-like illness; vesicles can be found in mouth, pharynx, or inoculation site (eg, hands); self-limiting
Southern Africa, southeast Asia	Mosquito bites (mainly <i>Aedes</i> spp, possibly others); also by contact with contaminated material	Nonspecific febrile illness ± maculopapular rash or ocular signs in some; few cases described but seems to be self-limiting
Eastern and Western hemisphere	Mosquito bites (primarily <i>Culex univittatus</i> , <i>Culex</i> spp); also by handling infected birds or reptiles or their tissues	Nonspecific febrile illness, occasionally with rash; some cases progress to encephalitis, meningitis, and/or acute flaccid paralysis that resembles poliomyelitis; occasionally other syndromes; worse in elderly and immunocompromised; case fatality rate ~10% in all patients with neurologic disease, but higher in elderly

TABLE 4 GLOBAL ZOOSES^a (continued)

Disease	Causative Organism	Animals Involved
VIRAL DISEASES (continued)		
Western equine encephalomyelitis (see p 1291)	Western equine encephalomyelitis virus (family <i>Togaviridae</i> , genus <i>Alphavirus</i>)	Birds are reservoir hosts, may also cycle in jackrabbits, rodents; equids, other mammals are incidental hosts; virus also found in reptiles, amphibians
Yellow fever	Yellow fever virus (family <i>Flaviviridae</i> , genus <i>Flavivirus</i>); only jungle cycle is zoonotic (people are reservoir for urban cycle)	Nonhuman primates
PRION DISEASE		
Variant Creutzfeldt-Jakob disease	Bovine spongiform encephalopathy prion	Cattle are most important host; also infects other ruminants, cats and other felids, lemurs

^a Many proven zoonoses, including some relatively rare arthropodborne viral infections and helminth infections, have been omitted, as well as those diseases caused by fish and reptile toxins.

^b Enterotoxigenic, enteroinvasive, enteropathogenic, and enteroaggressive strains are not considered zoonotic.

TABLE 4 GLOBAL ZOO NOSES^a (continued)

Known Distribution	Probable Means of Spread to People	Clinical Manifestations in People
VIRAL DISEASES (continued)		
Americas	Mosquito bites (<i>Aedes</i> , <i>Culex</i> , and <i>Ochlerotatus</i> spp); <i>Culex tarsalis</i> important in maintenance cycle in birds	Nonspecific febrile illness may be followed by encephalitis in infants and children, uncommonly in adults; case fatality rate 3%–4%
South America, Africa	Mosquito bites (<i>Haemagogus</i> spp and <i>Sabethes</i> spp in jungle cycles in South America, <i>Aedes</i> spp in jungle cycles in Africa)	Nonspecific, mild to severe febrile illness followed by liver and renal failure in some; hemorrhages (eg, epistaxis, hematemesis, melena, uterine hemorrhage) and often jaundice in severe cases; cases with hemorrhages often fatal
PRION DISEASE		
Most cases in the UK but also in many other countries	Ingestion of bovine products, especially those contaminated with CNS tissues	Neurodegenerative disorder similar to sporadic Creutzfeldt-Jakob disease but often in younger patients and progresses more rapidly; always fatal

PHARMACOLOGY INTRODUCTION

Once a diagnosis has been made and medical treatment is deemed necessary, safe and effective pharmacologic agents that exert the appropriate actions should be selected. A dosing regimen should be individualized for each patient. In addition to the route, which often is based on drug availability or convenience, a number of factors should be considered when designing a dosing regimen. These include host considerations that may alter the response to or disposition of the drugs. Adjustment in route, dose, or interval may be indicated based on host and drug factors. For antimicrobial drugs, microbial factors, including resistance, also should be considered. Finally, particularly for food animals, public health, environmental implications, and regulatory constraints must be considered.

EXTRA-LABEL DRUG USE, COMPOUNDED DRUGS, AND GENERIC DRUGS

A **new animal drug (NAD)** is “any drug intended for use in animals other than man...not generally recognized as safe and effective for the use under the conditions prescribed, recommended, or suggested in the labeling of the drug.” A drug’s label includes the label on the product itself as well as any accompanying material in or on the package, including the package insert.

To use an NAD in a legal manner, veterinarians must adhere to the specifications noted on the label. Otherwise, the drug is being used in an **extra-label** manner. Extra-label drug use, whether actual or

intended, occurs when the drug is used in a manner not in accordance with approved label directions. This includes but is not limited to a different dosage, interval, route, indication, or species.

In 1994, Congress passed the Animal Medicinal Drug Use Clarification Act (AMDUCA), which legalized extra-label drug use by veterinarians as long as specific criteria or restrictions are met. Most restrictions are largely applicable to extra-label drug use in food animals. For both food and nonfood animals, a valid **veterinary-client-patient relationship** must exist. For food animals, in the absence of a drug labeled for the intended use, extra-label drug use might involve drugs approved for use in other food animals, approved for use in nonfood animals, or approved for use in people. Restrictions regarding extra-label drug use of nonfood animal and human drugs are progressively restrictive. Extra-label drug use in food animals is permitted only by or under the supervision of a veterinarian, is allowed only for therapeutic purposes (ie, the animal's health is suffering or threatened), is not allowed when the drug is administered in feed, is not permitted if it results in violative food residues or any residues that may present a risk to public health, and is not allowed if specifically prohibited by the FDA.

Drugs specifically prohibited in food animals by the FDA as of May 2015 include chloramphenicol, clenbuterol, diethylstilbestrol, dimetridazole, ipronidazole, other nitroimidazoles, furazolidone, nitrofurazone, sulfonamide drugs in lactating dairy cattle (except for those specifically approved), fluoroquinolones, aglycopeptides (eg, vancomycin), phenylbutazone in female dairy cattle ≥ 20 mo old, cephalosporins (except cephalirin) in cattle, swine, chickens, or turkeys for disease prevention, and amantadine or neuraminidase inhibitor classes of drugs used to treat influenza A in poultry and ducks.

Use of a **compounded preparation** also constitutes extra-label drug use. However, a major distinction is that a compounded preparation undergoes no regulatory assessment or approval. Conditions under which compounding is legal also are specified in the AMDUCA. Compounding includes any manipulation of the drug beyond that stipulated on the label. Guidelines regarding the compounding of pharmaceuticals under the direction of a veterinarian are delineated in Compliance Policy Guideline 7125.40. Among the greatest concerns of the FDA regarding

compounded products is compounding intended to circumvent the drug approval process, resulting in mass marketing of products that have had little or no quality control to ensure purity, potency, and stability. The FDA considers a compounded product to be an adulterated, ie, unapproved, new animal drug and thus a violation. Conditions under which compounding is not subject to regulatory actions include a legitimate practice (pharmacy or veterinary; includes licensure), operation within the conformity of state law, for pharmacists in response to a prescription, and for veterinarians operating within a valid veterinary-client-patient relationship. Compounding of human drugs and, very occasionally, bulk drugs into appropriate dosage forms may be acceptable in certain circumstances. A legitimate medical need must be identified (eg, health or life of the animal is threatened or suffering may occur). Additionally, there must be no marketed, approved animal or human drug, regardless of whether it is used as labeled or in an extra label fashion, that may be substituted for the compounded agent. Occasionally, other rare circumstances may be considered. In 2013, Congress passed the Drug Quality and Security Act that, among other things, increases regulation of compounding in human medicine. However, this Act does not cover compounding of animal products, and Congress is examining further actions to more effectively regulate such compounding.

Pharmacists often can dispense an equivalent, less expensive, nonproprietary (generic) drug without prescriber approval. An exception occurs if a state has a mandatory substitution law or if the brand name product is dispensed along with a "dispensed as written" order. **Generic products** must not only contain the same active ingredient as the proprietary drug but also meet bioequivalence standards. Generics may be pharmaceutically equivalent but may not be therapeutically equivalent. Substitutions of generic drugs for proprietary drugs are recommended only for those drugs shown to be therapeutically equivalent. Those human drugs tested by the FDA and found to be therapeutically equivalent are listed in *Approved Drug Products with Therapeutic Equivalence Evaluations*, otherwise known as the "Orange Book." However, status of a generic drug is relevant only for the approved species and, as such, therapeutic equivalence of a human generic drug does not apply to extra label use of that drug in an animal.

Although AMDUCA legalizes extra-label drug use in the USA, selected states or other countries may have additional or complementary regulatory or legal restrictions. In all instances, it is important to read carefully the label instructions for use of specific drugs.

DISPOSITION AND FATE OF DRUGS

The goal of drug therapy is to achieve a pharmacologic response. The magnitude of the pharmacodynamic response to a drug generally reflects the number of receptors with which the drug interacts (drug-receptor theory). Because tissue drug concentrations generally parallel tissue concentrations, the ideal dose will result in plasma drug concentrations in a "therapeutic range." This population statistic is defined by a maximum drug concentration, above which the risk of adverse events (eg, toxicity) increases, and a minimum drug concentration, below which therapeutic failure may result. Plasma drug concentrations generally fluctuate during a dosing interval, because they are impacted by four drug movements acting simultaneously on the drug: **absorption** from the site of nonintravenous administration into the plasma, **distribution** into tissues and then back into plasma, where the drug can then be eliminated from the body either by **metabolism** or **excretion** of parent drug and/or metabolites. Many factors influence each of these four drug movements (ADME) and thus the time course of plasma drug concentrations after a dose is administered by any route. Understanding these factors, in turn, is important to individualizing drug therapy for the patient, because dosing regimens are modified to adjust for physiologic (eg, species, breed, gender, age), pharmacologic (eg, drug-drug or drug-diet interactions), and pathologic (eg, renal, hepatic, or cardiac disease) influences on drug disposition. Pharmacokinetics is the science that mathematically describes the time course of plasma drug concentrations after administration of a dose, ie, the result of ADME on plasma drug concentrations.

Passage of Drugs Across Cellular Membranes

Each of the drug movements generally relies on the drug passing through cell membranes (transcellular). Membrane barriers may be composed of several layers of cells (eg, skin, vagina, cornea, placenta) or a single layer of cells (eg, enterocytes, renal tubular epithelial cells), or they may consist only of a boundary less than one

cell in thickness (eg, hepatic sinusoids). Multilayered tissues each may present different types of barriers, eg, skin is protected by the dense stratum corneum, which is absent in mucous membranes. Not all drugs must pass through cell membranes; paracellular movement between cells increasingly is an important movement for some drugs, eg, in the GI tract.

Drugs and other molecules cross cellular membranes by several processes. Methods by which drugs move include bulk flow (eg, movement with blood, glomerular filtration), passive diffusion, carrier-mediated transport (ie, active or facilitated transport), and pinocytosis. Of these, passive diffusion is most important for movement of drug molecules and other xenobiotics (foreign chemicals), as well as many endogenous compounds.

The rate at which a drug passively diffuses through membranes is influenced by several factors, the most important of which is the concentration gradient of diffusible (eg, dissolved) drug across the membrane. However, other host and drug factors influence the rate and extent of passive diffusion. Host factors that increase diffusion include permeability and surface area of the membrane; thickness of the membrane negatively impacts diffusion. Drug characteristics that influence diffusion include molecular weight, lipophilicity, and degree of ionization. Most drugs are "small molecules" (<900 daltons), but diffusibility is more likely to occur for drugs <500 daltons. Drugs must be sufficiently lipid soluble (lipophilic) to pass through some level of cell membrane lipid bilayer to reach most drug receptors. The lipid-to-water partition coefficient describes the distribution (ratio) of a drug (concentration) in a lipid compared with water media. The distribution coefficient also takes into account ionization.

Many drugs are weak organic acids or bases. At physiologic pH, they tend to be partially ionized (dissociated) and partially nonionized (undissociated); the ratio of the respective forms depends on the dissociation constant (pK_a) of the drug, ie, the pH at which the drug is present in equal concentration in ionized and nonionized forms, and the pH of the solution in which the drug is dissolved. Only nonionized fraction diffuses through lipid membranes. Distribution across any membrane of a drug with any given pK_a reflects the degree of ionization and thus environmental pH on each side of the membrane. The Henderson Hasselbach equation predicts the ratio of ionized vs nonionized drug. In general, weak acids are

nonionized in acidic compared with alkaline environments, and weak bases are nonionized in alkaline compared with acidic environments. The more similar the environmental pH is to that of the pK_a of a weak acid or base, the more nonionized is the drug and the more likely it will diffuse. As long as the ratio of nonionized to ionized drug is ≥ 0.01 , the drug is considered diffusible.

Not all drugs must pass through cell membranes to reach their receptor. Aqueous pores in lipoproteinaceous biologic membranes offer a means of xenobiotic movement through the membrane for predominantly aqueous soluble drugs. Lipid-insoluble (water-soluble) compounds pass easily through these pores and to a lesser degree directly through the membrane. A hydrostatic or osmotic pressure difference across a membrane facilitates movement by promoting water flow through the aqueous pores. Bulk fluid movement carries or "drags" solute molecules through the pores as long as the solute molecules are smaller than the aqueous channels.

Several specialized transfer processes account for the passage of certain organic ions and other large lipid-insoluble substances across biologic membranes. Active transport, facilitated diffusion, and exchange diffusion are three distinct types of carrier-mediated systems used to move specific substances across cellular membranes. The highly selective carrier-mediated systems are principally used for transporting nutrients and natural substrates across biologic membranes. Among the mechanisms of active transport are transport proteins that move compounds, including drugs, into or out of cells. Transport proteins are located at portals of entry (eg, enterocytes of the GI tract or sinusoidal hepatic cells) or "sanctuary" tissues (eg, brain, CSF, placenta, prostate, eyes, or testicles), where they attempt to ensure that xenobiotics do not enter the protected tissue. As such, transport proteins are able to influence each drug movement (absorption, distribution, metabolism, and excretion). The most well known of the transport proteins is the ATP-binding cassette superfamily of efflux transporters, which includes P-glycoprotein, the multidrug resistance protein. Substrates for P-glycoprotein include both xenobiotics and dietary components. Additional transport proteins carry cations, anions, or organic compounds. Competition for transport increases oral absorption or

distribution of one of the competing molecules.

Pinocytosis is an important transport process in mammalian cells, particularly intestinal epithelial cells and renal tubular cells. Drugs that exist in solution as molecular aggregates have large molecular masses themselves or that are bound to macromolecules may be transferred across membranes by pinocytosis.

Drug Absorption

Absorption from the GI Tract: Many factors influence orally administered drugs. Before absorption, orally administered drugs must disintegrate and then dissolve; dissolution often is the rate-limiting factor in oral drug absorption. Drugs may be formulated by manufacturers to result in extended (occurring throughout the GI tract) or delayed absorption. Often, release kinetics of these drugs limit extrapolation of dosing regimens from one species to another. Once an orally administered drug has dissolved, multiple factors influence its absorption. Drug characteristics include molecular size, lipophilicity, and drug pK_a . Drug pK_a is particularly important in the GI tract, because environmental pH is markedly variable among the different regions or compartments. Host factors (in addition to environmental pH) determining oral absorption include epithelial permeability, GI motility, surface area (being greatest in the small intestine, which is the major site of drug absorption), transport and metabolizing proteins, and GI blood (which maintains the concentration gradient) and lymphatic flow. Epithelial permeability is influenced by disease. Additionally, in those species in which colostrum absorption is important, epithelial permeability is much greater. GI motility is important because it influences mixing of luminal contents, which is necessary for dissolved drug to come into contact with absorptive surfaces. Gastric motility determines gastric emptying, which in turn influences the rate of drug absorption. Changes in GI blood flow have minimal impact on drug absorption, because although GI blood flow maintains the concentration gradient necessary for passive diffusion, it is rarely the rate-limiting factor. Both efflux transport proteins (eg, P-glycoprotein) and drug-metabolizing enzymes located in the GI epithelium can markedly decrease drug absorption, contributing to a "first-pass effect." These proteins are subject to clinically relevant drug interactions and are likely to differ

among physiologic influences (eg, species, gender, age). A drug entering the portal circulation will be exposed to hepatocytes before reaching systemic circulation. If a large proportion of the drug (>75%) is removed or extracted as it passes through the liver, the oral bioavailability of the drug will be markedly reduced, also resulting in a "first-pass effect." For such drugs, the oral dose is proportionately higher than the parenteral dose. Food can markedly alter oral absorption of drugs by either diluting it, or more importantly, binding to it so that it is not absorbed.

Absorption from Topical

Administration: Drugs may be absorbed through the skin after topical application; however, the stratum corneum presents an effective barrier to transdermal movement of most drugs into circulation. As such, many drugs are absorbed after paracellular rather than transcellular movement. Intact skin allows the passage of small lipophilic substances but efficiently retards the diffusion of water-soluble molecules in most cases. Lipid-insoluble drugs generally penetrate the skin slowly compared with their rates of absorption through other body membranes. Absorption of drugs through the skin may be enhanced by heat, moisture, or disruption of the stratum corneum. Occlusive dressings increase heat and moisture; transdermal patches also disrupt the stratum corneum. Smaller molecules are more conducive to transdermal drug delivery. Different transdermal systems have been developed with the intent of systemic drug delivery. Certain solvents (eg, dimethyl sulfoxide [DMSO]) may facilitate the penetration of drugs through the skin. Damaged, inflamed, or hyperemic skin allows many drugs to penetrate the dermal barrier much more readily. For example, drugs administered transdermally as pluronic lecithin or other gels presumably penetrate the stratum corneum because it is disrupted, becoming more permeable. The same principles that govern the absorption of drugs through the skin also apply to the application of topical preparations on epithelial surfaces. In contrast to skin, mucosal epithelium has no stratum corneum, facilitating drug absorption. An advantage of the buccal mucosa is that a drug avoids first-pass metabolism.

Absorption from Tracheobronchial Surfaces and Alveoli:

Because volatile and gaseous anesthetics have relatively high lipid-to-water partition coefficients

and generally are rather small molecules, they diffuse practically instantaneously into the blood in the alveolar capillaries. In contrast, for drugs administered as aerosols, particles containing drugs can be deposited on the mucosal surface of the bronchi or bronchioles, or even in the alveoli, with the site influenced by particle size and breathing rate and depth. Whether or not the drug is absorbed from these sites depends on the characteristics previously described.

Absorption from Injection Delivery

Sites: After nonintravenous injection, diffusible drug molecules traverse the capillary wall by a combination of diffusion and filtration. Diffusion is the predominant mode of transfer for lipid-soluble molecules, small lipid-insoluble molecules, and ions. Because most capillaries are fenestrated, all drugs, whether lipid-soluble or not, cross the capillary wall at rates that are extremely rapid compared with their rates across other body membranes. In fact, the movement of most drug molecules in various tissues is limited only by the rate of blood flow rather than by the capillary wall. However, endothelial cells of sanctuaries, such as the blood-brain or CSF barrier, retina, and testicles, have tight intercellular junctions, thus restricting movement of drugs.

Aqueous solutions of drugs are usually absorbed from an IM injection site within 10–30 min, provided blood flow is unimpaired. Faster or slower absorption is possible, depending on the concentration and lipid solubility of the drug, vascularity (including number of vessels and state of vasoconstriction), the volume of injection, the osmolality of the solution, and other pharmaceutical factors. Substances with molecular weights >20,000 daltons are principally taken up into the lymphatics.

Absorption of drugs from subcutaneous tissues is influenced by the same factors that determine the rate of absorption from IM sites. Some drugs are absorbed as rapidly from subcutaneous tissues as from muscle, although absorption from injection sites in subcutaneous fat is always significantly delayed.

Increasing blood supply to the injection site by heating, massage, or exercise hastens the rate of dissemination and absorption.

The rate of absorption of an injected drug may be prolonged in a number of ways, including immobilization of the site, local cooling, a tourniquet, incorporation of a vasoconstrictor, an oil base, and implant

pellets and insoluble "depot" preparations. Among these depot preparations are drugs that are converted to less soluble esters, which must be released by esterases (eg, procaine and benzathine esters of penicillin or acetate esters of steroids) or less soluble complexes (eg, protamine zinc insulin), or that are administered as insoluble microcrystalline suspensions (eg, methylprednisolone acetate).

Bioavailability

Bioavailability refers to the extent to which a drug is absorbed into the body and thus is available to act on its intended target site. A drug is considered 100% bioavailable ($F=1$) when given intravenously (although pulmonary metabolism may make this not entirely true). Bioavailability of a particular route or formulation is the ratio of the area under the plasma drug concentration versus time curve (AUC) of the drug when the drug is given via that route or as that preparation to the AUC when the drug is given intravenously at the same dosage (in mg/kg):

$$F = \text{AUC}_{\text{non-IV}} / \text{AUC}_{\text{IV}}$$

The equation must be adjusted for dosage when appropriate:

$$F = (\text{AUC}_{\text{non-IV}} \times (\text{dose}_{\text{IV}})) / (\text{AUC}_{\text{IV}} \times (\text{dose}_{\text{non-IV}}))$$

Two products are considered bioequivalent if they result in the same rate and extent of absorption. Rate of absorption is reflected as the maximum plasma drug concentration (C_{max}) and the time (T_{max}) that C_{max} occurs. Thus, two drugs are bioequivalent if their AUC, C_{max} , and T_{max} do not significantly differ. Two different preparations or routes of administration may be equally bioavailable but not bioequivalent. Generic drugs must be demonstrated to be bioequivalent.

Once a drug reaches the systemic circulation, all other drug movements (distribution, metabolism, and excretion) will be the same regardless of the route or preparation. However, in some instances, absorption may be so slow (eg, delayed or extended-release formulation, absorption impacted by food) that it limits the rate at which the drug is eliminated (metabolized and/or excreted) from the body.

Drug Distribution

After absorption into the bloodstream, drugs are disseminated to all parts of the body. Occasionally, the drug molecule may

be so large (>65,000 daltons) or so highly bound to plasma proteins that it remains in the intravascular space after IV administration. Compounds that permeate freely through cell membranes become distributed, in time, throughout the body water to both extracellular and intracellular fluids, with the extent depending on drug chemistry. Substances that pass readily through and between capillary endothelial cells, but do not penetrate other cell membranes, are distributed into the extracellular fluid space. Drugs may also undergo redistribution in the body after initial high levels are achieved in tissues that have a rich vascular supply, eg, the brain. As the plasma concentration falls, the drug readily diffuses back into the circulation to be quickly redistributed to other tissues with high blood-flow rates, such as the muscles; over time, the drug also becomes deposited in lipid-rich tissues with poor blood supplies, such as the fat depots. Most drugs are not distributed equally throughout the body but tend to accumulate in certain specific tissues or fluids. The general principles that govern the passage and distribution of drugs across cellular membranes (see p 2492) are applicable to drug distribution. Basic drugs tend to accumulate in tissues and fluids with pH values lower than the pK_a of the drug; conversely, acidic drugs concentrate in regions of higher pH, provided the free drug is sufficiently lipid soluble to penetrate the membranes that separate the compartments. Even small differences in pH across boundary membranes, such as those that exist between plasma (pH 7.4) and other tissues such as CSF (pH 7.3), milk (pH 6.5–6.8), renal tubular fluid (pH 5–8), and inflamed tissue (pH 6–7) can lead to unequal distribution of drugs, referred to as "ion-trapping." Only freely diffusible and unbound drug molecules are generally able to pass from one compartment to another. However, some drugs are transported by carrier-mediated systems across certain cellular membranes, which leads to higher concentrations on one side than the other. Examples of such nonspecific transport mechanisms are found in renal tubular epithelial cells, hepatocytes, and the choroid plexus. Among the transport proteins, genetic differences in P-glycoprotein profoundly impact drug movement, particularly at portals of xenobiotic entry or sanctuaries.

Passive diffusion of drugs from capillaries to tissues may be limited by binding to plasma proteins. The most important is albumin, although the globulins and,

especially, α -1 acid glycoprotein (for bases) may also play a significant role. In general, protein binding is considered clinically relevant if $\geq 80\%$. For such drugs, factors influencing binding can impact drug disposition. These include plasma pH, concentration of plasma proteins, concentration of the drug, or the presence of a competing agent with a greater affinity for the limited number of binding sites. For example, a potentially toxic compound (such as most NSAIDs) may be 98% bound, but if for any reason it becomes only 96% bound, then the concentration of the free active drug that becomes available in the plasma is doubled, with potentially harmful consequences. The concentration of a drug administered in overdose may exceed the binding capacity of the plasma protein and lead to an excess of free drug, which can diffuse into various target tissues and produce exaggerated effects. Other reasons the fraction of unbound drug might increase include hypoalbuminemia and competition with other highly protein-bound drugs. The degree of protein binding of a drug cannot be extrapolated among the species, but in most species, NSAIDs, antifungal imidazoles, and doxycycline are examples of highly protein-bound drugs. More rapid clearance of the now unbound drug may mitigate the impact of higher drug concentrations.

Dissociation of a drug from plasma proteins also influences elimination from the body in that those drugs more tightly bound tend to have much longer elimination half-lives, because they are released gradually from the plasma protein reservoir (eg, cefovecin or long-acting sulfonamides).

Most unbound drugs distribute easily from capillaries to extracellular fluid. However, only the more lipid-soluble drugs can distribute to all tissues because of the presence of physiologic barriers presented by "sanctuaries" (eg, blood-brain, placental, and mammary barriers). For the CNS, drugs may gain access through either the capillary circulation (blood-brain barrier) or the CSF (also a blood barrier). Drugs penetrate into the cortex more rapidly than into white matter, probably because of the greater delivery rate of drug via the bloodstream to the tissue.

The pharmacologic factors and consequences of the diverse rates of entry of different drugs into the CNS are clinically relevant in that water-soluble, ionized drugs are less likely to enter the CNS, whereas drugs with low ionization, low plasma-protein binding, and a fairly high lipid-water partition coefficient penetrate more rapidly.

Inflammation, presented by for example meningoencephalitis, can substantially alter the permeability of the blood-brain barrier. In general, direct injection into the CSF is undesirable because of the risk of unexpected effects.

In pregnant animals, the degree of placentation may determine the extent of a placental barrier. Nutrients such as glucose, amino acids, minerals, and even some vitamins are actively transported across the placenta. The passage of drugs across the placenta is largely by lipid diffusion, and the factors discussed above play a role. The distribution of drugs within the fetus follows essentially the same pattern as in the adult, with some differences with respect to the volumes of drug distribution, plasma-protein binding, blood circulation, and greater permeability of interceding membranous barriers. Drugs that are potentially teratogenic should be avoided, particularly in early gestation.

The mammary gland epithelium, like other biologic membranes, acts as a lipid barrier, and many drugs readily diffuse from the plasma into milk. The pH of normal milk varies, being 6.5–6.8 in goats and cows. As such, weak bases tend to accumulate in milk. Drugs delivered by intramammary infusion can diffuse into plasma to a greater or lesser degree by the same processes noted earlier.

Once a drug is distributed into tissues, binding to macromolecules such as protein components of cells or fluids, dissolution in adipose tissue, formation of nondiffusible complexes in tissues such as bone, incorporation into specific storage granules, or binding to selective sites in tissues all impede movement of drugs back into plasma and account for differences in the cellular and organ distribution of particular drugs.

Drug Metabolism

Drugs that are lipid soluble will be passively reabsorbed as urine concentrates in the kidney unless they are converted by enzymatic processes to water-soluble drugs. This is accomplished by drug metabolism. Metabolism and subsequent excretion of drugs together comprise drug "elimination" from the body. Most drug metabolism occurs in the smooth endoplasmic reticulum of the liver. Metabolism generally consists of two phases: Phase I induces a chemical change (most frequently oxidation, but also reduction) that renders the drug more conducive to phase II. Phase II is a conjugative or synthetic addition of a

large, polar molecule that renders the drug water soluble and amenable to renal excretion.

Four possible sequelae follow phase I metabolism: 1) inactivation (eg, most NSAIDs); 2) activation from a "pro-drug" to the active form of the drug (eg, enalapril to enalaprilat); 3) modification of activity, ie, formation of active metabolites that may be characterized by activity greater than (eg, tramadol), less than (eg, diazepam), or equal to that of the parent compound; and 4) formation of toxic metabolites, which is generally due to direct cell damage (eg, acetaminophen). In some instances the toxic metabolite acts as an antigen, causing immune-mediated toxicity (eg, sulfonamides). Because phase II drug metabolism almost exclusively inactivates drugs (the notable exception being some acetylated and methylated drugs), it often protects the organ of metabolism from drug-induced toxicity. This is particularly true with the addition of glutathione, which scavenges oxygen radicals; in the face of drug toxicity, *N*-acetylcysteine will increase intracellular glutathione. Multiple isoforms of phase II drug-metabolizing enzymes exist. Glucuronide (the addition of which is catalyzed by glucuronide transferase) is the most common phase II reaction; cats are deficient in some, but not all, glucuronyl transferases. Other important phase II enzymes include sulfation (deficient in swine), acetylation (deficient in dogs), and methylation. Amino acid conjugations are particularly important in avian species.

Phase I drug metabolism is largely, but not exclusively, accomplished by heme-containing enzymes referred to as cytochrome P450 (CYP450). More than 20 superfamilies have been identified, with some being specific for some drug or drug classes but others characterized by broad substrate specificity. Among the major superfamilies are CYP3A, which in people has been demonstrated to be responsible for the larger proportion of drug metabolism. Others important to drug metabolism are CYP2C and CYP2D. CYP enzymes are responsible for synthesis (eg, adrenal steroids, fatty acids) and metabolism of many endogenous compounds.

Drug metabolism has largely been considered to be negligible in early life, with neonates being less able to eliminate lipid-soluble drugs than adults; dosing intervals should be prolonged in such instances. However, evidence is emerging that some pediatric animals may have increased rather than decreased metabolic capacity for some drugs compared with

adults. In those instances in which metabolic capacity has been demonstrated to be less, postnatal development in the liver appears to be biphasic, consisting of a rapid and nearly linear increase in activity during the first 3–4 wk, followed by slower development up to the tenth week postpartum. In older animals, decreases in hepatic mass, hepatic blood flow, and drug-metabolizing enzyme activity should lead to longer dosing intervals, and for drugs characterized by first-pass metabolism, to lower oral doses.

Many disease states impair the normal activity of the hepatic drug-metabolizing enzyme systems, which in turn decreases clearance and thus prolongs the half-lives of many drugs. Hepatotoxicity, acute hepatitis, or other extensive liver lesions invariably depress enzyme activity. Evidence of decreased plasma albumin as a result of hepatic disease generally indicates that hepatic drug metabolism will likewise be decreased. Hypothyroidism tends to decrease, and hyperthyroidism increase drug-metabolizing enzyme activity.

Pharmacogenomics refers to the study of the genetic basis for differential response to drugs. Differences in the duration of action of drugs in various species frequently can be attributed to differences in their rates of biotransformation. Species variations in drug metabolism are common. CYP450 3A4 is responsible for the broadest substrate activity in people, but this may not be true in animals and certainly may vary among species.

Differences in content and activity of CYP enzymes among ages, genders, and species are likely to play a role in differences to response to drugs. Polymorphisms among the breeds can result in "poor" versus "efficient" metabolizers, with the former predisposed to drug toxicity because of decreased metabolism. Such variants for certain enzymes have been described in people as being responsible for potentially lethal differences in drug metabolism.

Several other factors impact the rate and extent of drug metabolism. Drug interactions may reflect induction (eg, phenobarbital, rifampin, griseofulvin) or inhibition (eg, chloramphenicol, cimetidine, imidazole antifungals) of CYP enzymes, with the impact varying among isoenzymes and the sequelae of drug metabolism. Nutritional state and disease (especially hepatic disease) can also impact drug metabolism. The liver is not the only site of CYP450 activity, with sanctuaries and portals of entry being examples of sites where CYP activity can alter several aspects of ADME.

In addition to differences in CYP450 enzymes, differential handling of enantiomers is increasingly recognized among species. Enantiomers are mirror images of drug molecules that result when groups of atoms rotate around a center or "chiral" carbon. Generally, such compounds are sold as racemic mixtures (50:50 of each isomer); however, the body frequently handles each stereoisomer differentially, with differences also being seen among species. Many cardiac drugs and NSAIDs exist as racemic mixtures of enantiomers. This must be remembered when either dosages or withdrawal times are extrapolated from one species to another. However, some drugs are sold only as one isomer or the other, with the name often reflecting as such (eg, levetiracetam, dexmedetomidine, esomeprazole). Species differences have been better documented for phase II metabolism. Among the more important phase II reactions and the species in which the reactions are deficient are glucuronidation (cats), glutathione transferase (important for scavenging potentially toxic metabolites), sulfation (swine), and acetylation (dogs).

Drug Excretion

The body can clear itself of drugs either by metabolism or excretion. Excretion irreversibly removes drugs or metabolites from the body. The kidneys are the principal organ of excretion, but the liver, GI tract, and lungs also may play important roles. Milk, saliva, and sweat are usually of less importance, although the presence of an active drug in milk may affect nursing young and contributes to milk discard times.

Renal excretion of foreign compounds is accomplished either by glomerular filtration, passive diffusion into and out (eg, resorption) of the tubular lumen, and carrier-mediated secretion (eg, active transport or facilitated diffusion).

Among the more important factors determining renal excretion is renal blood flow, which in turn is influenced by cardiac output. Glomerular filtration in particular, but also carrier-mediated transport, is influenced by changes in cardiac output. Drugs that impact renal blood flow (eg, angiotensin-converting enzyme inhibitors) can also impact renal clearance.

Only unbound molecules <66,000 daltons are readily filtered through the glomerular membranes into the tubular lumen. Most active tubular secretion of drugs into tubules (renal excretion) occurs in the proximal convoluted tubule. Binding to

plasma proteins usually does not hinder tubular excretion of drugs. Transport proteins exist for weak acids (anions), bases (cations), or organic compounds. Most (passive) reabsorption of nonionized, lipid-soluble drugs occurs as urine is concentrated in the distal and collecting tubules. Acidification or alkalinization of the urine may alter the rate of excretion of some drugs because of ion trapping in the tubular fluid.

Concurrent administration of either acidic or basic drugs that are substrates for carrier-mediated secretion processes prolongs the elimination of the drug that has the lesser affinity for the carrier sites, thus increasing its duration of action.

Among the more important factors impacting renal excretion is renal or cardiac disease. Decreased renal blood flow will result in a proportional decrease in renal excretion. However, renal disease may also be accompanied by changes in the metabolic capacity of the kidneys and production of toxins that will compete with drug for protein-binding sites. Changes in acid-base balance may also influence urine pH.

Drugs and their metabolites may also be excreted either passively or actively by hepatocytes into the bile canaliculi and, ultimately, into the duodenum in the bile. Generally, biliary excretion occurs for drugs with molecular weights that exceed 600 daltons. Biliary excretion is a relatively slow process. Further, many drugs excreted in bile as glucuronide conjugates may become unconjugated by intestinal microflora. Released drug can be reabsorbed into the systemic circulation, resulting in "enterohepatic circulation." Such recirculation often accounts for prolonged half-lives of drugs that are primarily excreted in bile. Impairment of the excretory functions of the hepatocytes or obstruction of bile flow due to any cause interferes with the biliary excretion of drugs. Dose or interval should then be adjusted accordingly.

The other routes of excretion are of lesser clinical importance. Many drugs are excreted in the feces either because of limited oral absorption or diffusion directly into the GI tract. The rumenoreticulum can act as a drug reservoir because of ion trapping or can remove a drug because of microbial metabolism. The tracheobronchial tree also may be a potential avenue of excretion, as is alveolar elimination of inhalant anesthetics. The main factors governing elimination by this route are the same as those determining the uptake of inhalant anesthetics—the concentrations in

plasma and alveolar air and the blood/gas partition coefficient. The mammary and salivary glands excrete drugs by nonionic passive diffusion. The salivary route of excretion is important in ruminants because they secrete such voluminous amounts of alkaline saliva, although such drugs are likely to enter the GI tract.

PHARMACOKINETICS

Predicting how a drug behaves in the body can be accomplished through mathematical modeling of the time course of the drug in the body, or pharmacokinetics. Simplistically, pharmacokinetics describe what the body does to the drug, whereas pharmacodynamics describe what the drug does to the body. Pharmacokinetics are determined by following changes in plasma drug concentrations after a dose of the drug is administered at least via the desired route and ideally also after IV administration (100% bioavailability). The time course of plasma drug concentrations is mathematically “modeled” such that physiologic events impacting the changes in drug concentration might be determined. Most pharmacokinetic studies are conducted in healthy animals, yet dosing regimens should be individualized to adjust for physiologic (age, gender, species, and breed), pharmacologic (drug interactions), or pathologic (eg, renal or hepatic disease) differences or for animals receiving multiple drugs.

The pharmacodynamic response to a drug generally reflects the number of receptors with which the drug interacts (drug-receptor theory). In most instances, tissue drug concentrations parallel plasma drug concentrations.

After intravenous administration, the most relevant pharmacokinetic parameters that describe a drug and provide a basis for the dosing regimen are the apparent volume of distribution and the plasma clearance, both of which determine the elimination rate constant and elimination half-life. Additional parameters include the distribution rate constant and half-life and, if the drug is also given orally, the absorption rate constant and half-life.

After a drug is administered by rapid IV (eg, bolus) injection, the drug will be immediately distributed to the “central” vascular compartment, which includes highly perfused organs. Also immediately, plasma drug concentrations decline for two reasons: distribution of drug from plasma into tissues and back, and elimination from the body because of irreversible removal (ie, metabolism or excretion). As such, the

decline in plasma drug concentrations initially is rapid, but once distribution reaches a “pseudo” equilibrium such that the amount of drug moving into tissues equals that moving back into plasma, plasma drug concentration will decline only because of elimination from the body (metabolism and excretion). Each drug movement is “first order,” meaning a constant fraction or percentage (rather than amount) moves per unit time. As such, the time course of the drug in plasma must be plotted semilogarithmically ($y = \log$ plasma drug concentration, $x = \text{time}$). The result will be a decline in plasma drug concentrations that can be “fitted” by two lines: the first line, representing distribution and elimination, which declines very rapidly (steep slope), followed by a second “terminal” line, with a flatter slope because it represents elimination only. If the terminal line is drawn back to the y-axis, the Y intercept represents the plasma drug concentration after distribution has reached pseudoequilibrium (“B”). The slope of this terminal line is the elimination “rate constant,” k_{el} , and from it is derived the elimination half-life, $t_{1/2}$. The line that describes distribution also is characterized by a Y intercept (the drug concentration in the “central” compartment, or “A”) and a “distribution” rate constant (often referred to as α or k_d); it is from this rate constant that a distribution half-life can be determined. Once the curve is mathematically described by slopes and Y intercepts, given any time (t) point after the drug is administered, the amount of drug in the body or the plasma drug concentration (C_p) can then be predicted (C_p) = $Ae^{-\alpha t} + Be^{-k_{el}t}$ in which e is the natural log. From this data, clinically relevant parameters that influence the dosing regimen are then determined.

Apparent Volume of Distribution

If both the dose (mg/kg) and the drug concentration in plasma (the Y intercept of the terminal component of the plasma drug concentration [PDC] versus time curve, or “B”) are known, then an “apparent” volume of distribution can be calculated from $V_d = \text{dose/PDC}$. This theoretical volume describes the volume to which the drug must be distributed if the concentration in plasma represents the concentration throughout the body (ie, distribution has reached equilibrium). The term “apparent” underscores the fact that where the drug is distributed cannot be determined from V_d ; only that it goes *somewhere*. The pharmacokinetic measure used to indicate the

pattern of distribution of a drug in plasma and in the different tissues, as well as the size of the compartment into which a drug would seem to have distributed in relation to its concentration in plasma, is known as the apparent volume of distribution (V_d). It is usually reported as liters per kilogram (L/kg) and is determined by measuring peak plasma drug concentrations after distribution has reached equilibrium for a drug administered IV. That concentration is compared with the IV dose that was given: $V_d = \text{dose/PDC}$. For example, if 12 mg/kg of phenobarbital is given, and the resulting PDC after distribution has occurred is 20 mg/L, then the apparent volume to which phenobarbital is distributed (V_d) = (12 mg/kg/20 mg/L) or 0.6 L/kg.

The V_d is useful for three reasons. First, and perhaps most importantly, it can be used to calculate a dose if the target PDC is known: $\text{dose} = V_d \times \text{target PDC}$. For example, if the V_d of phenobarbital is 0.6 L/kg, and the target concentration of phenobarbital in a drug-naïve animal is 10 mg/L, the IV dose would be 10 mg/L $\times$ 0.6 L/kg or 6 mg/kg. Second, if the PDC at any time after the dose is known, the V_d can be used to calculate how much drug is left in the body. Finally, the V_d can be used to predict the relative ability of the drug to distribute to different body compartments: if the drug is limited to the extracellular compartment (interstitial fluid, plasma), as is typical of water-soluble drugs, this represents 20%–30% of the body weight, and the V_d of such a drug should be <0.3 L/kg. Lipid-soluble drugs are generally able to penetrate cell membranes and thus are distributed to both extracellular and intracellular fluid, which represents ~60% of the body weight. Such drugs are generally characterized by a $V_d > 0.6$ L/kg. Some drugs are limited to the plasma compartment and do not distribute well. An example would be a drug very tightly bound to plasma proteins; for such drugs, the V_d approximates the size of the blood compartment, or >0.1 L/kg. However, as the drug is freed from the protein, it will leave the plasma compartment and distribute into tissues. Many drugs are characterized by a V_d that exceeds the body weight of the animal (ie, >1 L/kg). For example, the mean digoxin V_d in dogs is 13 L/kg. This points out that the basis to determine V_d is PDC: if the drug leaves the plasma, regardless of where it goes, the V_d will increase. For digoxin, the drug binds to cardiac tissue; however, this is known only because follow-up studies demonstrated as such.

The V_d of a drug is usually constant over a wide dose range for a given species.

However, a number of clinically significant factors can influence the V_d , including age (larger in neonates and pediatrics, smaller in geriatrics); functional status of the kidneys (decreased with dehydration), liver (increased with edema), and heart; fluid accumulations; concentration of plasma proteins (influencing unbound drug only); acid-base status (particularly if ion trapping causes the drug to accumulate in tissues); inflammatory processes or necrosis; and any other causes for alteration in the degree of plasma-protein binding.

Drug Clearance

As soon as a drug reaches the systemic circulation, it immediately begins to be cleared from plasma. Clearance is the volume of blood from which a drug is irreversibly eliminated, or cleared. Plasma is most commonly sampled; however, plasma clearance represents the sum clearances by all organs. If the drug is cleared by only a single organ, then plasma clearance is the clearance of that organ. Clearance is a volume and, as such, its units are volume/mass/time (eg, mL/kg/min). An alternative definition of clearance is the volume of plasma that would contain the amount of drug excreted per unit time; this definition demonstrates the link between volume of distribution (V_d) and clearance: if the elimination rate constant is known, it describes the fraction of the V_d cleared and, together, they can be used to calculate clearance (CL) from the PDC vs time curve: $CL = V_d \times k_{el}/\text{time (min)}$. As such, like V_d , CL directly influences k_{el} , ie, rate at which drug is eliminated from the body: as CL increases, k_{el} becomes more steep. Clearance is independent of the V_d of a drug and thus the concentration of drug in the blood; no matter how much drug is in the blood, the same volume will be cleared per unit time.

The two major organs responsible for clearance are the liver and kidneys. Once a drug is metabolized, it is irreversibly eliminated from the body. Its metabolites, however, must be excreted (usually by the kidneys). Hepatic clearance is defined as the volume of plasma totally cleared per unit time as blood passes through the liver. The rate of hepatic clearance depends on drug delivery to the liver, ie, blood flow (Q) and the extraction (E) ratio of the drug, or fraction of the drug removed as it passes through the liver. Extraction, in turn, is determined by the intrinsic clearance (metabolic capacity) of the liver. Drugs cleared by the liver fall into two major categories.

"Flow-limited" drugs are extracted so rapidly that Q becomes the limiting factor of hepatic clearance. Binding to plasma proteins will not influence clearance of such drugs. In contrast, the rate-limiting step of "capacity-limited" drugs is intrinsic clearance, ie, the metabolic capacity of the liver. For such drugs, binding to serum proteins will decrease the rate of clearance. As such, highly protein-bound drugs are referred to as "capacity limited, binding sensitive" as opposed to drugs not highly protein bound and thus "capacity limited, binding insensitive."

Hepatic disease differentially impacts flow- and capacity-limited drugs. Hepatic clearance of flow-limited drugs will markedly decrease with changes in hepatic flow such as might occur with portosystemic shunting. When administered orally, such drugs are normally characterized by a high first-pass metabolism and reduced oral bioavailability. With portosystemic shunting, oral bioavailability can markedly increase and, as such, oral doses must be decreased in proportion to the shunted blood. Changes in hepatic mass and function will impact capacity-limited drugs. In general, if liver disease has negatively impacted serum albumin and BUN, the intrinsic metabolic capacity of the liver is also likely to be negatively impacted. However, if protein-binding decreases for a highly protein-bound drug such that more of the drug is unbound, hepatic clearance may not be as negatively impacted.

Renal clearance is defined as the volume of plasma totally cleared of a drug per unit time (eg, l/min) during passage through the kidneys. The renal clearance of drugs depends primarily on renal blood flow but also is impacted by urine pH, extent of plasma-protein binding, urine concentrating ability, and concomitant use of certain drugs. Serum creatinine or serum creatinine clearance can be used to assess changes in renal clearance as renal function declines. Either the dose or interval can be proportionately modified. For drugs with a short half-life, intervals are more appropriately prolonged (compared with decreasing dose) as serum creatinine increases; for drugs that accumulate because of a long half-life, the dose or interval might be proportionately decreased or prolonged, respectively.

Elimination Rate Constant: Among the most commonly cited pharmacokinetic parameters is the elimination half-life. It is derived from the elimination rate constant, k_{el} , which is the slope of the terminal, or

elimination, component of the PDC vs time curve. A "hybrid" parameter, k_{el} , is impacted by both CL and V_d . CL determines the decline in PDC; thus, the greater the volume of drug cleared, the steeper the slope, or k_{el} . The impact of V_d on half-life reflects its effect on PDC: a larger V_d means less drug is in the volume of blood cleared by the liver or kidneys. As such, the rate of elimination declines as V_d increases, resulting in an inverse relationship. The elimination half-life of a drug is the time that lapses as PDC declines by 50%. It is calculated from the slope of the line k_{el} : $t_{1/2} = 0.693/k_{el}$. The relationship between k_{el} and half-life reflects the fact that half-life becomes run of the slope ($t_2 - t_1$) as C_1 declines by 50% (ie, $C_1/C_2 = 2$). The natural log of 2 = 0.693. Because $t_{1/2}$ is the inverse of k_{el} , then $t_{1/2}$ is directly proportional to V_d (larger V_d results in a longer half-life) and inversely proportional to CL. Note that CL and V_d can be profoundly altered, yet $t_{1/2}$ may not change. For example, in an animal dehydrated because of renal dysfunction, CL may be decreased by 50%, doubling $t_{1/2}$. However, if the animal is markedly dehydrated, then V_d will decrease because of contraction of extracellular fluid volume. Because more drug is in each mL of blood cleared by the kidney, the same amount of drug may be eliminated, and as such k_{el} or $t_{1/2}$ may not change.

The elimination half-life determines the time to steady-state (see below) and the time for a drug to be eliminated from the body once drug administration is discontinued. Once a drug is discontinued, 50% of the drug is eliminated in one half-life, 75% in the second (half of 50%), 87.5% in the third, and so on. For practical purposes, most drug is eliminated by 3–5 half-lives. The $t_{1/2}$ along with tolerances determines withdrawal or milk discard times in food animals. The relationship between dosing interval and elimination half-life also determines whether a drug will fluctuate or accumulate during a dosing interval.

Single-dose Concentration Curves After Extravascular Administration:

When a drug is administered by an extravascular route, plasma drug concentrations rise until a peak or maximum drug concentration (C_{max}) is reached. Once the drug enters circulation, it is subjected immediately and simultaneously to distribution, metabolism, and excretion. The plasma drug concentration vs time curve after extravascular administration has an additional Y intercept and slope, with the slope reflecting the rate constant of absorption, k_a . The absorption half-life is the

time that elapses as 50% of the drug is absorbed into the system. Absorption generally is sufficiently slow that drug distribution is generally "masked" by the absorption phase. As such, as plasma drug concentrations decline after $C_{\max}$ is reached, the slope generally reflects k_a .

The term "bioavailability" is used to express the rate and extent of absorption of a drug (*see above*).

Steady State Plasma Concentration (Repeated Administration or Constant IV Infusion): In some cases, the desired therapeutic effect of a drug is produced with a single dose. However, to achieve a satisfactory response, it is frequently necessary to maintain drug concentrations in the therapeutic range for a longer time. Rather than administering large doses, which could result in potentially toxic plasma drug concentrations, multiple dosing occurs at regular, safer intervals. For drugs with a very short half-life, the drug may be administered through a catheter as a constant-rate infusion, which is essentially continuous IV delivery. The rate of administration depends on the amount of fluctuation in drug concentration that can occur during a dosing interval, which in turn is determined by the relationship between $t_{1/2}$ and the dosing interval, T .

If a drug is administered at an interval substantively longer than its half-life, most of the drug will be eliminated during each dosing interval. As such, little drug remains with the subsequent dose, and plasma drug concentrations will fluctuate ($C_{\max}$ to $C_{\min}$) during the dosing interval. For example, if a drug with a 4-hr half-life is administered every 12 hr, 87.5% of the drug will be eliminated during each dosing interval. With each dose, there is a risk of drug concentrations becoming subtherapeutic; increasing the dose will result in a small increase in $C_{\min}$ but may substantially increase $C_{\max}$, thus increasing the risk of toxicity. A more appropriate response would be to decrease the dosing interval. However, this may be necessary only if drug efficacy depends on the presence of the drug. For example, this degree of fluctuation may be acceptable for a concentration-dependent antimicrobial. However, if the drug is an anticonvulsant, the risk of seizures increases just before the next dose. If the drug is time-dependent, drug concentrations may drop below the minimum inhibitory concentration of the infecting microbe. In contrast to drugs with a short half-life, drugs with a long half-life compared with the dosing interval will accumulate with each dose, because much

of the drug remains in the body when the next dose is given. Such drugs will begin to accumulate with the first dose and will continue to do so until a "steady state" equilibrium is reached such that the amount of drug eliminated during each dosing interval is equivalent to the amount of drug administered during that same interval. The accumulation ratio describes the magnitude of increase of either $C_{\max}$ or $C_{\min}$ at steady state compared with the first dose. The longer the half-life compared with the dosing interval, the greater the accumulation ratio. The time to steady state, regardless of the drug or dose is 3–5 drug elimination half-lives. However, administration must occur with the same preparation at the same dosing regimen. In such cases, 50% of the plateau or steady-state concentration will be reached in one $t_{1/2}$, 75% at two $t_{1/2}$, 87.6% at three $t_{1/2}$, and 93.6% at four $t_{1/2}$. As with drug elimination, for practical purposes, steady state is achieved by 3–5 half-lives. Response to the drug, whether efficacy or toxicity, cannot be assessed until steady state is reached. Because the amount of drug in the body is large compared with each dose, manipulating plasma drug concentrations for such drugs is difficult, because changes require dosing for 3–5 half-lives at the new dose.

If the time to reach steady state, and thus time to therapeutic effect, is unacceptable, steady-state plasma drug concentrations may be achieved more rapidly by administration of a loading dose or doses ($\text{dose} = V_d \times \text{target concentration}$; if the drug is given orally, $\text{dose} = (V_d/F) \times \text{target concentration}$). However, the drug is not at steady state but only at steady state concentrations. If the maintenance dose does not maintain what the loading dose achieved, then as steady state at the maintenance dose is reached, plasma drug concentrations may increase to toxicity or decline to a subtherapeutic concentration. Drugs with very short half-lives are often administered by constant-rate infusions in animals in critical condition; in such cases, the interval is infinitely short compared with the half-life, and the drug will accumulate until steady state is reached. The rate of infusion (mcg/kg/min) is equal to the CL (mL/min/kg) $\times$ target concentration (mcg/mL); a loading dose should be given if the time to steady state is unacceptably long.

DRUG ACTION AND PHARMACODYNAMICS

Pharmacodynamics is the study of the biochemical and physiologic effects of drugs and their mechanisms of action on the

body or on microorganisms and other parasites within or on the body. It considers both drug action, which refers to the initial consequence of a drug-receptor interaction, and drug effect, which refers to the subsequent effects. The drug action of digoxin, for example, is inhibition of membrane $\text{Na}^+/\text{K}^+ \text{--} \text{ATPase}$; the drug effect is augmentation of cardiac contractility. In this example, the clinical response might comprise improved exercise tolerance.

Not all drugs exert their pharmacologic actions via receptor-mediated mechanisms. The action of some drugs—including inhalation anesthetic agents, osmotic diuretics, purgatives, antiseptics, antacids, chelating agents, and urinary acidifying and alkalinizing agents—is attributed to their chemical action or physicochemical properties. Certain cancer and antiviral chemotherapeutic agents, which are analogues of pyrimidine and purine bases, elicit their effects when they are incorporated into nucleic acids and serve as substrates for DNA or RNA synthesis. The effect of most drugs, however, results from their interactions with receptors. These interactions and the resulting conformational changes in the receptor initiate biochemical and physiologic changes that characterize the drug's response.

Drug Concentration and Effect

Drug therapy is intended to result in a particular pharmacologic response of desired intensity and duration while avoiding adverse drug reactions. The relationship between the administered dose and the clinical response has been investigated for some drugs using a pharmacokinetic/pharmacodynamic (PK/PD) modeling approach, which is generally based on the plasma concentration-response relationship. For other drugs, a simpler relationship between the concentration and effect in an idealized *in vitro* system is modeled mathematically to conceptualize receptor occupancy and drug response. The model assumes that the drug interacts reversibly with its receptor and produces an effect proportional to the number of receptors occupied, up to a maximal effect when all receptors are occupied. The reaction scheme for the model is:

in which k_2 and k_1 are rate constants.

The relationship between effect and the concentration of free drug for the model is

given by the Hill equation, which can be written as:

$$E = \frac{E_{\max} \times C}{EC_{50} + C}$$

in which E is the effect observed at concentration C , $E_{\max}$ is the maximal response that can be produced by the drug (efficacy), EC_{50} is the concentration of drug that produces 50% of maximal effect (potency), and the Hill coefficient n is the slope of the $\log_{10}$ concentration-effect relationship (sensitivity).

The above equation describes a rectangular hyperbola when response (y -axis) is plotted against concentration (x -axis). However, dose- or concentration-response data is generally plotted as drug effect (y -axis) against $\log_{10}$ dose or concentration (x -axis). The transformation yields a sigmoidal curve that allows the potency of different drugs to be readily compared. In addition, the effect of drugs used at therapeutic concentrations commonly falls on the portion of the sigmoidal curve that is approximately linear, i.e., between 20% and 80% of maximal effect. This makes for easier interpretation of the plotted data.

Agonists and Antagonists

An **agonist** is a drug that binds to receptors and thereby alters (stabilizes) the proportion of receptors in the active conformation, resulting in a biologic response. A full agonist results in a maximal response by occupying all or a fraction of receptors. A partial agonist results in less than a maximal response even when the drug occupies all of the receptors.

There are four types of drug antagonism. **Chemical antagonism** involves chemical interaction between a drug and either a chemical or another drug leading to a reduced or nil response. **Physiologic antagonism** occurs when two drugs acting on different receptors and pathways exert opposing actions on the same physiologic system. **Pharmacokinetic antagonism** is the result of one drug suppressing the effect of a second drug by reducing its absorption, altering its distribution, or increasing its rate of elimination. **Pharmacologic antagonism** occurs when the antagonist inhibits the effect of a full or partial agonist by acting on the same pathway but not necessarily on the same receptor.

Pharmacologic antagonists comprise three subcategories. A **reversible competitive antagonist** results in inhibition that can be overcome by

increasing the concentration of agonist. The presence of a reversible competitive antagonist causes a parallel rightward shift of the log concentration-effect curve of the agonist without altering $E_{\max}$ or EC_{50} . An **irreversible competitive antagonist** also involves competition between agonist and antagonist for the same receptors, but stronger binding forces prevent the effect of the antagonist being fully reversed, even at high agonist concentrations. The presence of an irreversible competitive antagonist causes a rightward shift of the log concentration-effect curve of the agonist that generally displays decreased slope and reduced maximum effect. A **noncompetitive antagonist** inhibits agonist activity by blocking one of the sequential reactions between receptor activation and the pharmacologic response. Noncompetitive antagonism is generally reversible but can be irreversible. Noncompetitive antagonists and irreversible competitive antagonists cause similar perturbations in the log concentration-effect curve of agonists. Isolated tissue experiments are used to distinguish the two subcategories, because noncompetitive antagonists are generally reversible.

Agonists, but not antagonists, elicit an effect even when they bind to the same site on the same receptor. An explanation is provided by both structural and functional studies, which indicate that receptors exist in at least two conformations, active and inactive, and these are in equilibrium. Because agonists have a higher affinity for the receptor's active conformation, agonists drive the equilibrium to the active state, thereby activating the receptor. Conversely, antagonists have a higher affinity for the receptor's inactive conformation and push the equilibrium to the inactive state, producing no effect.

The concept of **spare receptors** explains a maximum response being achieved when only a fraction of the total number of receptors is occupied. For example, an action potential and maximal twitch of muscle fibers is elicited when 0.13% of the total number of receptors at a skeletal neuromuscular junction is simultaneously activated. From a functional perspective, spare receptors are significant, because they increase both the sensitivity and speed of a tissue's responsiveness to a ligand.

Structure-Activity Relationships

Structure-activity relationships are exploited in drug design, because small changes in chemical structure can produce

profound changes in potency. For example, the substitution of a proton by a methyl group accounts for codeine being ~1,000 times less potent than morphine in its action on opioid receptors.

Signal Transduction and Drug Action

Most receptors are proteins. The best characterized of these are regulatory proteins, enzymes, transport proteins, and structural proteins. Nucleic acids are also important drug receptors, particularly for cancer chemotherapeutic agents.

The receptors for several neurotransmitters modulate the opening and closing of ion channels through ligand gating or voltage gating. The nicotinic acetylcholine receptor is an example of a ligand-gated receptor; it allows Na^+ to flow down its concentration gradient into cells, resulting in depolarization. Most clinically useful neuromuscular blocking drugs compete with acetylcholine for the receptor but do not initiate ion-channel opening. Other ligand-gated ion channels include the CNS receptors for the excitatory amino acids (glutamate and aspartate), the inhibitory amino acids (γ -aminobutyric acid [GABA] and glycine), and certain serotonin (5-HT₃) receptors. The sodium channel receptor is an example of a voltage-gated receptor; these are present in the membranes of excitable nerve, cardiac, and skeletal muscle cells. In the resting state, the Na^+/K^+ -ATPase pump in these cells maintains an intracellular Na^+ concentration much lower than that in the extracellular environment. Membrane depolarization causes channel opening and a transient influx of Na^+ ions, followed by inactivation and return to the resting state. The action of local anesthetics is due to their direct interaction with voltage-gated Na^+ channels.

Many transmembrane receptors are linked to guanosine triphosphate binding proteins, which activate second messenger systems. Two important second messenger systems are cyclic adenosine monophosphate (cAMP) and the phosphoinositides. In cAMP second messenger systems, binding of the ligand to the receptor increases or decreases adenyl cyclase activity, which in turn regulates the formation of cAMP from adenosine triphosphate. The activation of protein kinase A by cAMP results in the phosphorylation of proteins and a physiologic effect. From a therapeutic standpoint, drug binding to β -adrenergic, histamine H_2 , or dopamine D_1 receptors activates adenyl cyclase, whereas binding to muscarinic M_2 , α_2 -adrenergic, dopamine

D₂, opiate μ and δ , adenosine A₁, or GABA type B receptors inhibits adenyl cyclase. In phosphoinositide second messenger systems, membrane phosphatidylinositol 4,5-bisphosphate is hydrolyzed to 1,4,5-trisphosphate (IP₃) and 1,2-diacylglycerol (DAG) by activation of phospholipase C. Both IP₃ and DAG activate kinases, and in the case of IP₃, this involves the mobilization of calcium from intracellular stores. The action of numerous drugs is due to their interaction with receptors that rely on these second messengers, which include α_1 -adrenergic, muscarinic M₁ or M₂, serotonin 5-HT₂, and thyrotropin-releasing hormone receptors.

Protein tyrosine kinase receptors are generally transmembrane enzymes that phosphorylate proteins exclusively on tyrosine residues, rather than on serine or threonine residues. They include endocrine hormone receptors for insulin and receptors for several growth hormones.

Intracellular receptors mediate the action of hormones such as glucocorticoids, estrogen, and thyroid hormone and related drugs. The hormones, which regulate gene expression in the nucleus, are lipophilic and freely diffuse through the cell membrane to reach the receptor. Glucocorticoid receptors reside predominantly in the cytoplasm in an inactive form until they bind to the glucocorticoid steroid ligand. This results in receptor activation and translocation to the nucleus, where the receptor interacts with specific DNA sequences. Unlike glucocorticoid receptors, the receptors for estrogen and thyroid hormone reside in the nucleus.

Intracellular receptors are also important in mediating the action of antimicrobial drugs, including the penicillins, sulfonamides, trimethoprim, aminoglycosides, phenicols, macrolides, and fluoroquinolones. The mechanisms of action include inhibition of bacterial protein synthesis, inhibition of cell wall synthesis, inhibition of enzymatic activity, alteration of cell membrane permeability, and blockade of specific biochemical pathways.

Receptor-mediated mechanisms of action of several classes of anthelmintics are well understood. For example, the benzimidazoles and pro-benzimidazoles bind to nematode tubulin, preventing its polymerization during microtubular assembly and thus disrupting cell division. Depletion of ATP as the result of salicylanilides uncoupling oxidative phosphorylation and the inhibition of enzymes in the glycolytic pathway by benzene sulfonamides are other examples. Several classes of anthelmintics

interfere with neurotransmission in parasites. A case in point is macrocyclic lactones, which potentiate inhibitory neurotransmission via GABA and glutamate-gated chlorine channels (*see* ANTHELMINTICS, p 2647).

Drug Dose and Clinical Response

To make rational therapeutic decisions, it is necessary to understand the fundamental concepts linking drug doses to concentrations to clinical responses. The concentration-response relationships for drugs may be graded or quantal. A **graded concentration-response curve** can be constructed for responses measured on a continuous scale, eg, heart rate. Graded concentration-response curves relate the intensity of response to the size of the dose and, hence, are useful to characterize the actions of drugs. A **quantal concentration-response curve** can be constructed for drugs that elicit an all-or-none response, eg, presence or absence of convulsions. For most drugs, the doses required to produce a specified quantal effect in a population are log normally distributed, so that the frequency distribution of responses plotted against log dose is a gaussian normal distribution curve. The percentage of the population requiring a particular dose to exhibit the effect can be determined from this curve. When these data are plotted as a cumulative frequency distribution, a sigmoidal dose-response curve is generated.

The **equilibrium dissociation constant of the receptor-drug complex, K_D** , is the ratio of rate constants for the reverse (k_2) and forward (k_1) reaction between the drug and receptor and the drug-receptor complex (*see* p 2503). K_D is also the drug concentration at which receptor occupancy is half of maximum. Drugs with a high K_D (low affinity) dissociate rapidly from receptors; conversely, drugs with a low K_D (high affinity) dissociate slowly from receptors. These effects impact the rate at which biologic responses end.

Potency refers to the concentration (EC_{50}) or dose (ED_{50}) of a drug required to produce 50% of the drug's maximal effect as depicted by a graded dose-response curve. EC_{50} equals K_D when there is a linear relationship between occupancy and response. Often, signal amplification occurs between receptor occupancy and response, which results in the EC_{50} for response being much less (ie, positioned to the left on the x-axis of the log dose-response curve) than K_D for receptor occupancy. Potency depends on both the affinity of a drug for its

receptor and the efficiency with which drug-receptor interaction is coupled to response. The dose of drug required to produce an effect is inversely related to potency. In general, low potency is important only if it results in a need to administer the drug in large doses that are impractical. Quantal dose-response curves provide information on the potency of drugs that is different from the information derived from graded dose-response curves. In a quantal dose-response relationship, the ED_{50} is the dose at which 50% of individuals exhibit the specified quantal effect.

The **median inhibitory concentration**, or IC_{50} , is the concentration of an antagonist that reduces a specified response to 50% of the maximal possible effect.

Efficacy (also referred to as intrinsic activity) of a drug is the ability of the drug to elicit a response when it binds to the receptor. As discussed above, conformational changes in receptors as a result of drug occupancy initiate biochemical and physiologic events that characterize the drug's response. In some tissues, agonists demonstrating high efficacy can result in a maximal effect, even when only a small fraction of the receptors is occupied (the concept of spare receptors is discussed above).

Selectivity refers to a drug's ability to preferentially produce a particular effect and is related to the structural specificity of drug binding to receptors. For example, cyclooxygenase-2 (COX-2) preferential NSAIDs demonstrate partial specificity for COX-2, the inducible enzyme formed at sites of inflammation. By comparison, COX-2 selective NSAIDs are without significant effect on COX-1, the constitutive enzyme that performs a range of physiologic functions. For certain drugs, selectivity is species dependent. For example, $S(+)$ -carprofen is COX-2 selective in dogs and cats, nonselective of COX-1 and COX-2 in horses, and COX-2 preferential in calves.

Specificity of drug action relates to the number of different mechanisms involved. Examples of specific drugs include atropine (a muscarinic receptor antagonist), salbutamol (a β_2 -adrenoceptor agonist), and cimetidine (an H_2 -receptor antagonist). By contrast, nonspecific drugs result in drug effects through several mechanisms of action. For example, phenothiazine causes blockade of D_2 -dopamine receptors, α -adrenergic receptors, and muscarinic receptors.

The **affinity** of a drug for a receptor describes how avidly the drug binds to the receptor (ie, the K_D). The chemical forces in

drug-receptor interactions include electrostatic forces, van der Waal forces, and the forces associated with hydrogen bonds and hydrophobic bonds. Variation in the strength of these forces, and therefore the thermal energy in the system, determines the degree of association and dissociation of the drug and the receptor. Covalent binding of drug to receptor (exemplified by fluoroquinolones acting on bacteria) leads to formation of an irreversible link.

The **therapeutic index** of a drug is the ratio of the dose that results in an undesired effect to the dose that results in a desired effect. The therapeutic index of a drug is usually defined as the ratio of LD_{50} to ED_{50} (median lethal and median effective doses, respectively, in 50% of individuals), which indicates how selective the drug is in eliciting its desired effect. Values of LD_{50} and ED_{50} for this purpose are derived from quantal dose-response curves generated in animal studies.

The information obtained from dose- and concentration-response curves is critically important when choosing between drugs and when determining the dose to administer. A drug is chosen largely on the basis of its clinical effectiveness for a particular therapeutic indication. In this context, the drug concentration at the receptor (determined by the pharmacokinetic properties of the drug) and the efficacy of the drug-receptor complex are the primary determinants of a drug's clinical effectiveness. The administered dose of a drug, by comparison, depends to a greater extent on potency than on maximal efficacy.

The maximal efficacy of the drug-receptor complex to result in a graded effect is E_{max} or I_{max} on a graded dose-response curve. E_{max} or I_{max} is derived from a quantitative dose-response relationship for a single animal and varies among individuals. The extrapolation of this value of E_{max} to a clinical case is only an estimate, but it facilitates a comparison of the maximal efficacy of drugs that result in a specified effect by identical receptors. A drug's potency (ie, EC_{50} , ED_{50} , or IC_{50}) obtained from either graded or quantal dose-response curves is used to determine the dose that should be administered. The slope of the graded dose-response curve (n in the Hill equation, p 2507) provides information concerning the dose range over which a drug elicits its effect. Other information concerning the selectivity of drug action and the therapeutic index is also obtained from the graded dose-response curve. When quantal effects are being considered,

information concerning pharmacologic potency, selectivity of drug action, the margin of safety, and the potential variability of responsiveness among individuals is obtained from quantal dose-response curves.

Pharmacodynamics of Antimicrobial Drugs

The approach used to investigate the pharmacodynamics of antimicrobial drugs (and parasiticides) differs from that of other veterinary drugs on account of the need to address target pathogens that have structure, biochemistry, and capacity for replication which are markedly dissimilar to those of their mammalian host. The individual drugs within each group of antimicrobial drugs differ in potency and in antimicrobial spectrum of activity. The minimum inhibitory concentration (MIC), which is the lowest concentration of drug that completely inhibits bacterial growth, is determined *in vitro* as a measure of susceptibility of bacterial species and strains to a given drug. Importantly, the MIC₉₀ provides a measure of potency, EC₅₀.

● Other surrogate markers of bacteriologic effect exist and include the minimum bactericidal concentration (MBC), which is the concentration of antimicrobial drug that produces a 3-log-unit or 99.9% reduction in bacterial count, postantibiotic effect, sub-MIC postantibiotic effect, and time-kill data. More recently, the application of PK/PD principles to antimicrobial drug action has led to PK/PD integration and PK/PD modeling. **PK/PD integration** brings together data from PK and PD studies. The surrogate PK/PD index that best correlates with efficacy for a given drug is selected based on the drug's killing mechanism, namely concentration dependent, time dependent, or codependent (ie, both time and concentration determine outcome). The PK/PD index selected for aminoglycosides, which act by concentration-dependent killing mechanisms, is $C_{\text{max}}/\text{MIC}$ ratio (C_{max} is the maximum plasma concentration after administration of a drug by a nonvascular route); for β -lactams, which act by time-dependent killing mechanisms, it is $T > \text{MIC}$ (T is the time for which plasma concentration exceeds MIC, expressed as a percentage of the dosage interval); and for fluoroquinolones, which act by concentration-dependent killing mechanisms, AUC/MIC ratio (AUC is the area under the plasma drug concentration-time curve) is selected. The objective of **PK/PD modeling** is to define the three key pharmacodynamic

properties that define any drug, namely E_{max} or I_{max} (efficacy); EC_{50} (or EC_{90} or EC_{90}) (potency); and slope (n) in the Hill equation, which indicates sensitivity and selectivity. PK/PD modeling permits breakpoint values to achieve a bacteriostatic or bactericidal effect, or bacterial eradication to be computed, which are used to optimize efficacy and minimize resistance.

Time-effect Relationships: The ability of drugs to reach the receptor is determined by pharmacokinetic parameters that characterize the absorption, distribution, and clearance of a drug. There may not be a simple temporal correlation between plasma concentration of a drug and its therapeutic effect. Plotting plasma concentrations (x-axis) versus therapeutic effect (y-axis) in chronologic order displays the data as a loop for some drugs. This phenomenon is referred to as hysteresis in the concentration-effect relationship. The effect of most drugs lag behind the plasma concentration. This results in a counter-clockwise hysteresis loop. For example, the NSAID robenicoxib has prolonged local effects after blood concentrations have decreased below effective levels. A clockwise hysteresis loop is observed for cocaine and pseudoephedrine when tachyphylaxis develops (see below). The temporal correlation between plasma concentration and therapeutic effect also varies for the different classes of antagonists. For instance, the extent and duration of action of a competitive antagonist depends on its concentration in plasma, which depends (in part) on its rate of elimination. This requires that the dose be adjusted accordingly to maintain plasma concentrations in the therapeutic range. By contrast, the duration of action of an irreversible antagonist is relatively independent of its rate of elimination and, therefore, plasma concentration, and more dependent on the rate of turnover of receptor molecules.

Down-regulation and Up-regulation of Receptors:

The density of most receptors is not constant with time, which has important therapeutic implications. Down-regulation of receptors may occur as a result of continual stimulation by an agonist and manifests as the development of tachyphylaxis, which demonstrates a clockwise hysteresis loop in the concentration-effect relationship. Conversely, additional receptors can be synthesized in response to chronic receptor antagonism—a phenomenon known as up-regulation.

Because more receptors are now available, a hyperreactive response occurs when the cell is exposed to an agonist.

ROUTES OF ADMINISTRATION AND DOSAGE FORMS

A diverse range of dosage forms and delivery systems has been developed to provide for the care and welfare of animals. The development of dosage forms draws on the discipline of biopharmaceutics, which integrates an understanding of formulations, dissolution, stability, and controlled release (pharmaceutics); absorption, distribution, metabolism, and excretion (pharmacokinetics, PK); concentration-effect relationships and drug-receptor interactions (pharmacodynamics, PD); and treatment of the disease state (therapeutics). Formulation of a dosage form typically involves combining an active ingredient and one or more excipients; the resultant dosage form determines the route of administration and the clinical efficacy and safety of the drug. Optimization of drug doses is also critical to achieving clinical efficacy and safety. Increasingly, a PK/PD model that describes the drug response is the basis of dose optimization. The PK and PD phases are linked by the premise that free drug in the systemic circulation is in equilibrium with the receptors. The PD phase generally involves interaction of the drug with a receptor, which triggers post-receptor events and eventually leads to a drug effect (see p 2503).

Drug delivery strategies for veterinary formulations are complicated by the diversity of species and breeds treated, the wide range in body sizes, different husbandry practices, seasonal variations, cost constraints associated with the value of the animal being treated, the persistence of residues in food and fiber (see p 2518), and the level of convenience, among other factors. Innovative solutions have been developed to meet many of these challenges (eg, the convenient dosing option offered by topical spot-on formulations to treat external and internal parasites on dogs and cats, the microencapsulation of NSAIDs as a way to mask taste when these agents are added to the rations of horses). The anatomy of the GI tract of ruminants presents unique opportunities for controlled-release drug delivery systems, and many such systems are on the market. For example, controlled-release boluses have been developed to deliver antimicrobials, anthelmintics, production enhancers, nutritional supplements, and other drugs.

Oral Route of Administration and Dosage Forms

The oral route of administration is frequently used in both companion and food animals. In dogs and cats, tablets, capsules, solutions, and suspensions are administered orally; pastes are also applied to the forelimbs of cats from which they are licked and ingested. In horses, solutions and suspensions are administered by nasogastric tubes, pastes are applied to the tongue, and granules are added to rations for ingestion. The oral route of administration is the most widely used in cattle, pigs, and poultry. Formulations range from premixes and drinking water additives to licks, pastes, drenches, tablets, capsules, and boluses. Oral dosage forms are usually intended for systemic effects resulting from drug absorption from the GI tract; however, some oral suspensions, eg, kaolin, are intended to produce local effects, and these are not absorbed. Disadvantages of the oral route of administration include the relatively slow onset of action, the possibilities of irregular absorption, the destruction of acid-labile drugs in the stomach, and the unsuitability of this route for many high-molecular-weight drugs. Oral dosage forms require careful pharmaceutical formulation.

Oral dosage forms comprise liquids (solutions, suspensions, emulsions, elixirs, and syrups), semisolids (pastes), and solids (tablets, capsules, powders, granules, premixes, and medicated blocks). These dosage forms together with examples of modified-release delivery systems for ruminants are discussed below.

A **solution** is a mixture of two or more components that form a single phase that is homogeneous down to the molecular level. Solutions offer several advantages over other dosage forms. Compared with solid dosage forms, solutions are absorbed faster and generally cause less irritation of the GI mucosa. Moreover, phase separation on storage is not a concern with solutions, as it may be for suspensions and emulsions. The disadvantages of solutions include susceptibility to microbial contamination and the hydrolysis in aqueous solution of susceptible active ingredients. In addition, the taste of some drugs is more unpleasant when in solution. A range of additives is used in the formulation of oral solutions, including buffers, flavors, antioxidants, and preservatives. Oral solutions provide a convenient means of drug administration to neonates and young animals.

A **suspension** is a coarse dispersion of insoluble drug particles, generally with a

diameter $>1\text{ }\mu\text{m}$, in a liquid (usually aqueous) medium. Suspensions are useful to administer insoluble or poorly soluble drugs or when the presence of a finely divided form of the material in the GI tract is required. An example of the latter is the treatment of "frothy bloat" with dimethyl polysiloxanes, which relies on a dispersion of finely divided silica in the forestomach of ruminants. The taste of most drugs is less noticeable in suspension than in solution, because the drug is less soluble in suspension. Particle size is an important determinant of the dissolution rate and bioavailability of drugs in suspension. In addition to the excipients described above for solutions, suspensions include surfactants and thickening agents. Surfactants wet the solid particles, thereby ensuring the particles disperse readily throughout the liquid. Thickening agents reduce the rate at which particles settle to the bottom of the container. Some settling is acceptable, provided the sediment can be readily dispersed when the container is shaken. Redispersion of the suspension may not be achievable if the sediment has packed closely to form a hard mass, a process known as "caking."

An **emulsion** is a system consisting of two immiscible liquid phases, one of which is dispersed throughout the other in the form of fine droplets; droplet diameter generally ranges from $0.1\text{--}100\text{ }\mu\text{m}$. The two phases of an emulsion are known as the dispersed phase and the continuous phase. Emulsions are inherently unstable and are stabilized through the use of an emulsifying agent, which prevents coalescence of the dispersed droplets. Creaming, as occurs with milk, also occurs with pharmaceutical emulsions. However, it is not a serious problem because a uniform dispersion returns upon shaking. Creaming is, nonetheless, undesirable because it is associated with an increased likelihood of the droplets coalescing and the emulsion "breaking." Other additives include buffers, antioxidants, and preservatives. Emulsions for oral administration are usually oil (the active ingredient) in water, and they facilitate the administration of oily substances such as castor oil or liquid paraffin in a more palatable form.

An **elixir** is a sweetened, usually hydroalcoholic solution of a bitter or nauseous drug intended for oral administration. The hydroalcoholic character of elixirs allows, within limits, both water-soluble and alcohol-soluble medicinal substances to be maintained in solution. The proportion of alcohol in elixirs varies widely, a character-

istic used to advantage to solubilize medicinal agents. If the active ingredient is sensitive to moisture, it may be formulated as a flavored powder or granulation and reconstituted in water immediately before oral administration. Nonmedicated elixirs are used as the vehicles for pharmaceutical formulations.

A **syrup** is a concentrated aqueous solution of sugar or a sugar substitute with or without flavoring agents and a water-soluble drug. Sucrose is the most frequently used sugar, and syrups usually contain 60%–80%. Syrups may also contain cosolvents, solubilizing agents, thickeners, or stabilizers. Nonmedicated syrups are used as vehicles for water-soluble drugs.

A **paste** is a two-component semisolid in which drug is dispersed as a powder in an aqueous or fatty base. The particle size of the active ingredient in pastes can be as large as $100\text{ }\mu\text{m}$. The vehicle containing the drug may be water; a polyhydroxy liquid such as glycerin, propylene glycol, or polyethylene glycol; a vegetable oil; or a mineral oil. Other formulation excipients include thickening agents, cosolvents, adsorbents, humectants, and preservatives. The thickening agent may be a naturally occurring material such as acacia or tragacanth, or a synthetic or chemically modified derivative such as xanthum gum or hydroxypropylmethyl cellulose. The degree of cohesiveness, plasticity, and syringeability of pastes is attributed to the thickening agent. It may be necessary to include a cosolvent to increase the solubility of the drug. Syneresis of pastes is a form of instability in which the solid and liquid components of the formulation separate over time; it is prevented by including an adsorbent such as microcrystalline cellulose. A humectant (eg, glycerin or propylene glycol) is used to prevent the paste that collects at the nozzle of the dispenser from forming a hard crust. Microbial growth in the formulation is inhibited using a preservative. It is critical that pastes have a pleasant taste or are tasteless and are able to be used throughout a wide temperature range. Pastes are a popular dosage form to treat cats and horses and can be easily and safely administered by owners.

A **tablet** consists of one or more active ingredients and numerous excipients and may be a conventional tablet that is swallowed whole, a chewable tablet, or a modified-release tablet (these are commonly referred to as modified-release boluses when the unit size is large). Conventional and chewable tablets are

used to administer drugs to dogs and cats, whereas modified-release boluses are administered to cattle, sheep, and goats. The physical and chemical stability of tablets is generally better than that of liquid dosage forms. The main disadvantages of tablets are a relatively slow onset of action because of the need to pass into the intestine and then undergo disintegration and dissolution before absorption across the gut wall, the low bioavailability of poorly water-soluble drugs or poorly absorbed drugs, and the local irritation of the GI mucosa that some drugs may cause.

A **capsule** is an oral dosage form usually made from gelatin and filled with an active ingredient and excipients. Two common capsule types are available: hard gelatin capsules for solid-fill formulations, and soft gelatin capsules for liquid-fill or semisolid-fill formulations. Soft gelatin capsules are suitable to formulate poorly water-soluble drugs because they afford good drug release and absorption by the GI tract. Gelatin capsules are frequently more expensive than tablets but have some advantages. For example, particle size is rarely altered during capsule manufacture, and capsules mask the taste and odor of the active ingredient and protect photolabile ingredients.

A **powder** is a formulation in which a drug powder is mixed with other powdered excipients to produce a final product for oral administration. Powders have better chemical stability than liquids and dissolve faster than tablets or capsules because disintegration is not an issue. This translates into faster absorption for those drugs characterized by dissolution rate-limited absorption. Unpleasant tastes can be more pronounced with powders than with other dosage forms and can be a particular concern with in-feed powders, leading to variable ingestion of the desired dose. Moreover, sick animals often eat less and are therefore not amenable to treatment with in-feed powder formulations. Drug powders are principally used prophylactically in feed or formulated as a soluble powder for addition to drinking water or milk replacer. Powders have also been formulated with emulsifying agents to facilitate their administration as liquid drenches.

A **granule** is a dosage form consisting of powder particles that have been aggregated to form a larger mass, usually 2–4 mm in diameter. Granulation overcomes segregation of the different particle sizes during storage and/or dose administration, the latter being a potential source of inaccurate

dosing. Granules and powders generally behave similarly; however, granules must deaggregate before dissolution and absorption.

A **premix** is a solid dosage form in which an active ingredient, such as a coccidiostat, production enhancer, or nutritional supplement, is formulated with excipients. Premix products are mixed homogeneously with feed at rates (when expressed on an active ingredient basis) that range from a few milligrams to ~200 g/ton of feed. They are administered to poultry, pigs, and ruminants. The density, particle size, and geometry of the premix particles should match as closely as possible those of the feed in which the premix will be incorporated to facilitate uniform mixing. Issues such as instability, electrostatic charge, and hygroscopicity must also be addressed. The excipients present in premix formulations include carriers, liquid binders, diluents, anticaking agents, and antidust agents. Carriers, such as wheat middlings, soybean mill run, and rice hulls, bind active ingredients to their surfaces and are important in attaining uniform mixing of the active ingredient. A liquid binding agent, such as a vegetable oil, should be included in the formulation whenever a carrier is used. Diluents increase the bulk of premix formulations, but unlike carriers, they do not bind the active ingredients. Examples of diluents include ground limestone, dicalcium phosphate, dextrose, and kaolin. Caking in a premix formulation may be caused by hygroscopic ingredients and is addressed by adding small amounts of anticaking agents such as calcium silicate, silicon dioxide, and hydrophobic starch. The dust associated with powdered premix formulations can have serious implications for both operator safety and economic losses and is reduced by including a vegetable oil or light mineral oil in the formulation. An alternative approach to overcoming dust is to granulate the premix formulation.

A **medicated block** is a compressed feed material that contains an active ingredient, such as a drug, anthelmintic, surfactant (for bloat prevention), or a nutritional supplement, and is commonly packaged in a cardboard box to feed to livestock. Ruminants typically have free access to the medicated block over several days, and variable consumption may be problematic. This concern is addressed by ensuring the active ingredient is nontoxic, stable, palatable, and preferably of low solubility. In addition, excipients in the formulation modulate consumption by altering the

palatability and/or the hardness of the medicated block. For example, molasses increases palatability, and sodium chloride decreases it. Additionally, the incorporation of a binder such as lignin sulfonate in blocks manufactured by compression, or magnesium oxide in blocks manufactured by chemical reaction, increases hardness. The hygroscopic nature of molasses in a formulation may also impact the hardness of medicated blocks and is addressed by using appropriate packaging.

Oral Modified-release Delivery Systems for Ruminants

Several modified-release delivery systems have been developed that take advantage of the unique anatomy of the ruminant forestomach. Prominent among these systems are intraruminal boluses, which contain a range of active ingredients including parasiticides, nutritional supplements, antibloat agents, and production enhancers. They are administered using a balling gun. Most of the commercially available intraruminal boluses are continuous-release devices that rely on erosion, diffusion from a reservoir, dissolution of a dispersed matrix, or an osmotic "driver" to release the active ingredient. The pay-out period for intraruminal boluses is commonly >100 days. Regurgitation during rumination is prevented by the bolus having a density of $\sim 3 \text{ g/cm}^3$ or a variable geometry.

Other types of oral modified-release delivery systems are also available for ruminants. For example, sustained-release boluses that deliver sulfonamides throughout a period of ~ 72 hr are available to treat cattle. In addition, sustained-release boluses containing methoprene or diflubenzuron are approved for the control of manure-breeding flies in cattle.

The intraruminal devices to supplement ruminants with selenium, cobalt, or copper include soluble glass boluses and intraruminal pellets. Boluses of soluble glass containing selenium, cobalt, and copper are available for cattle and sheep. Because glass is susceptible to sudden changes in temperature, glass boluses should be at least $15^\circ\text{--}20^\circ\text{C}$ at the time of administration to avoid fracturing, which in turn may lead to regurgitation. Glass boluses are designed to dissolve in ruminal fluids, thereby releasing the incorporated elements. The composition of the glass determines the solubility of the bolus, with an increase in the ratio of monovalent to divalent cations resulting in an increase in solubility. The

glass boluses are retained in the rumen for up to 9 mo.

Intraruminal pellets containing selenium or cobalt are available for sheep. Selenium or cobalt is released throughout a period of ~ 3 yr from the pellet matrix, which consists of compressed iron grit. When selenium or cobalt intraruminal pellets are administered alone, a "grinder" is usually coadministered to prevent the formation of calcium phosphate coatings on the surface of the pellets.

Copper capsules, which contain oxidized copper wire particles encapsulated in gelatin, are available for adult sheep and goats. After oral administration, the gelatin capsule dissolves in the rumen and releases the particles of copper oxide. The particles progress to the abomasum, where some are trapped in the mucosal folds and release copper.

Parenteral Route of Administration and Dosage Forms

A drug given parenterally is one given by a route other than the mouth (topical dosage forms are considered separately). The three main parenteral routes of drug administration are IV, IM, and SC, and in all cases administration is usually via a hollow needle. Injectable preparations are usually sterile solutions or suspensions of drug in water or other suitable physiologically acceptable vehicles. Volumes delivered can range from milliliter to liter quantities. The time of onset of action for IV administration is seconds, and for IM and SC injections is minutes. Depot injectable preparations achieve prolonged release and maintain therapeutic concentrations of drug throughout 2–5 days. The bioavailability of a drug, particularly from prolonged-release formulations, can be influenced by the location of the IM injection site. SC implants and pellets also achieve prolonged release of drug. A number of recombinant proteins and peptides are orally inactive and must be given by the parenteral route. Specialized dosage forms, usually for parenteral administration, are required for vaccines. In food animals, intramammary infusions and intravaginal devices are administered by the parenteral route.

Parenteral dosage forms and delivery systems include injectables (ie, solutions, suspensions, emulsions, and dry powders for reconstitution), intramammary infusions, intravaginal delivery systems, and implants. These dosage forms and delivery systems as well as the special considerations relating to intra-articular injections,

recombinant proteins and peptides, and vaccines are discussed below.

A **solution** for injection is a mixture of two or more components that form a single phase that is homogeneous down to the molecular level. "Water for injection" is the most widely used solvent for parenteral formulations. However, a nonaqueous solvent or a mixed aqueous/nonaqueous solvent system may be necessary to stabilize drugs that are readily hydrolyzed by water or to improve solubility. A range of excipients may be included in parenteral solutions, including antioxidants, antimicrobial agents, buffers, chelating agents, inert gases, and substances to adjust tonicity. Antioxidants maintain product stability by being preferentially oxidized over the shelf life of the product. Antimicrobial preservatives inhibit the growth of any microbes accidentally introduced when doses are being withdrawn from multiple-dose bottles, and they act as adjuncts in aseptic processing of products. Buffers are necessary to maintain both solubility of the active ingredient and stability of the product. Chelating agents are added to complex and thereby inactivate metals, including copper, iron, and zinc, which generally catalyze oxidative degradation of drugs. Inert gases are used to displace the air in solutions and enhance product integrity of oxygen-sensitive drugs. Isotonicity of the formulation is achieved by including a tonicity-adjusting agent. Failing to adjust the tonicity of the solution can result in the hemolysis or crenation of erythrocytes when hypotonic or hypertonic solutions, respectively, are given IV in quantities >100 mL. Injectable formulations must be sterile and free of pyrogens. Pyrogenic substances are primarily lipid polysaccharides derived from microorganisms, with those produced by gram-negative bacilli generally being most potent. Injectable solutions are very commonly used, and aqueous solutions given IM result in immediate drug absorption, provided precipitation at the injection site does not occur.

A **suspension** for injection consists of insoluble solid particles dispersed in a liquid medium, with the solid particles accounting for 0.5%–30% of the suspension. The vehicle may be aqueous, oil, or both. Caking of injectable suspensions is minimized through the production of flocculated systems, comprising clusters of particles (flocs) held together in a loose, open structure. Excipients in injectable suspensions include antimicrobial preservatives, surfactants, dispersing or

suspending agents, and buffers. Surfactants wet the suspended powders and provide acceptable syringeability while suspending agents modify the viscosity of the formulation. The ease of injection and the availability of the drug in depot therapy are affected by the viscosity of the suspension and the particle size of the suspended drug. These systems afford enhanced stability to active ingredients that are prone to hydrolysis in aqueous solutions. Injectable suspensions are commonly used. Compared with that of injectable solutions, the rate of drug absorption of injectable suspensions is prolonged, because additional time is required for disintegration and dissolution of the suspended drug particles. The slower release of drug from an oily suspension compared with that of an aqueous suspension is attributed to the additional time taken by drug particles suspended in an oil depot to reach the oil/water boundary and become wetted before dissolving in tissue fluids.

An **emulsion** for injection is a heterogeneous dispersion of one immiscible liquid in another; it relies on an emulsifying agent for stability. Parenteral emulsions are rare, because it is seldom necessary to achieve an emulsion for drug administration. Untoward physiologic effects after IV administration may occur, including emboli in blood vessels if the droplets are >1 μm in diameter. Formulation options for injectable emulsions are also severely restricted, because suitable stabilizers and emulsifiers are very limited. Examples of parenteral emulsions include oil-in-water, sustained-release depot preparations (given IM), and water-in-oil emulsions of allergenic extracts (given SC).

A **dry powder** for parenteral administration is reconstituted as a solution or as a suspension immediately before injection. The principal advantage of this dosage form is that it overcomes the problem of instability in solution. Proteins and other materials that are extremely heat sensitive cannot be dried in pharmaceutical driers. Rather, freeze-drying, or lyophilization, is used to produce a porous powder that reconstitutes readily.

Intramammary infusion products to treat mastitis are available for lactating and nonlactating (dry) cows. Lactating cow intramammary infusions should demonstrate fast and even distribution of the drug and a low degree of binding to udder tissue. These properties result in lower concentrations of drug residues in the milk. In contrast, it is desirable for nonlactating cow formulations to demonstrate prolonged

drug release and a high degree of binding to mammary secretions and udder tissues. Particle size is particularly important, because it affects both the rate of release of the active ingredient and irritancy to the udder tissue. Drug particle size in nonlactating intramammary formulations is usually smaller than in those for lactating cows, which is critical to reduce irritancy during prolonged retention in the udder. Thickening agents are added to modify the rate of release of the suspended particles from oil formulations, and antioxidants are commonly incorporated to prevent rancidity. Mastitis infusion products are often terminally sterilized by irradiation.

Intravaginal delivery systems include controlled internal drug-release (CIDR) devices, progesterone-releasing intravaginal devices (PRIDs), and vaginal sponges. These systems are used for estrus synchronization in sheep, goats, and cattle. Silicone is used in the manufacture of the T-shaped CIDR device and the coil-shaped PRID, whereas intravaginal sponges are made from polyurethane. The active ingredients in these systems are synthetic or natural hormones such as progesterone, methylacetoxypregesterone, fluorogestone acetate, or estradiol benzoate. An applicator consisting of a speculum and a separate plunger is used to insert sponges into the vaginal cavities of sheep and goats, and PRIDs into the vaginal cavities of cattle. A different type of applicator is used to insert CIDR devices into the vaginal cavities of sheep, goats, and cattle. Retention in the vagina depends on either the wings (CIDR device) or the entire device (sponges and PRIDs) expanding. With all three devices, gentle pressure is exerted on the vaginal wall. Retention of the device is >95%.

Most implants used in veterinary medicine are compressed tablets or dispersed matrix systems in which the drug is uniformly dispersed within a nondegradable polymer. Drug release from dispersed matrix systems involves dissolution of the drug into the polymer, followed by diffusion of the drug through the polymer and partitioning from the surface of the polymer into the surrounding aqueous environment. Implants are available to increase weight gain and feed conversion efficiency in food animals. These implants are typically prepared in a manner similar to tablets. One controlled-release implant consists of a cylindrical core of silicone, surrounded by an outer layer of estradiol-loaded silicone. A range of implants is available to enhance reproductive performance in breeding animals. These include ear implants

containing norgestomet dispersed in polyethylene methacrylate or silicone, a biocompatible tablet implant containing deslorelin (a GnRH agonist) for use in mares that does not require removal, and a sustained-release pellet of melatonin, which is implanted in the ear of ewes to enhance breeding performance. Testosterone pellets are available to implant in the ears of wethers at doses of 70–100 mg every 3 mo for the prevention of ulcerative posthitis.

Special Dosage Form Considerations with Intra-articular Injections:

The dosage forms used in intra-articular administration are sterile aqueous solutions. In horses, the two most common reasons for intra-articular injections are to anesthetize or “block” a joint during a lameness examination and to treat noninfectious inflammatory joint diseases such as synovitis and capsulitis. Drugs, including glucocorticoids, pentosan polysulfate sodium, and hyaluronic acid, are administered intra-articularly in inflammatory joint disease. The intra-articular administration of glucocorticoids avoids the adverse effects associated with large systemic doses. In dogs, hyaluronate sodium is administered by intra-articular injection for adjunctive treatment of synovitis.

Special Dosage Form Considerations with Recombinant Proteins and Peptides:

Recombinant proteins and peptides are used in some countries to increase feed conversion efficiency and milk production in cattle (bovine growth hormone), increase feed conversion efficiency and produce leaner carcasses in pigs (porcine growth hormone), for the chemical shearing of sheep (epidermal growth factor), to reduce the incidence of skeletal weaknesses leading to leg injuries in horses (equine growth hormone), and for other uses. Recombinant proteins and peptides have been formulated as solutions, lyophilized powders, implants, and microparticles. The chemical and physical instability of recombinant proteins and peptides is a special consideration during formulation development. The major causes of chemical instability are proteolysis, deamidation, oxidation, and racemization. Causes of physical instability are aggregation, precipitation, denaturation, and adsorption to surfaces. A range of strategies has been reported to stabilize formulations containing recombinant proteins and peptides, including the choice of carrier vehicle (eg, oleaginous vehicles), the use

of lyophilization excipients, the use of stabilizers such as sugars and detergents, chemical modification of the proteins and peptides, and the use of site-directed mutagenesis to synthesize more stable proteins.

Special Dosage Form Considerations with Live Vaccines, Inactivated and Subunit Vaccines, and DNA Vaccines:

The organisms in live vaccines are subjected to freeze drying and, less commonly, to deep freezing at or below -70°C . To maintain the viability of organisms under these conditions, formulations include complex mixtures of proteins, peptides or amino acids, sugars, and mineral salts. The viability of organisms is additionally protected using stabilizers such as lactose or other saccharides, skim milk, and serum.

Formulations used for inactivated and subunit vaccines consist of antigen(s), adjuvants, stabilizers, and preservatives (in the case of multiple-dose products). Inactivating agents such as phenol, thiomersal, and formaldehyde are used to kill the virus or bacteria without destroying the critical integrity of the antigens necessary to induce a protective immune response. Adjuvants enhance the immunogenicity of antigens by stimulating the immune system and prolonging antigen release. In this respect, aluminum hydroxide, aluminum phosphate, and oil emulsions are generally preferred to confer antibody-mediated immunity, whereas saponin, quil A, and immunity-stimulating complexes are preferred to confer cell-mediated immunity.

Plasmid DNA vectors have been used to express antigens *in vivo* to generate immune responses. Two delivery systems for DNA vaccines have been reported. In one system, the segment of DNA is coated with gold and administered to the patient using a "gene gun." The other delivery system uses a viral vector or plasmid to carry the DNA segment into the patient.

Topical Route of Administration and Dosage Forms

The topical route of administration is used for local treatment of skin, control of external and internal parasites, and transdermal delivery of therapeutic agents. Drugs applied to the skin for local effect include antiseptics, antifungals, anti-inflammatory agents, and skin emollients. The rate of drug release from ointments, creams, and pastes is principally determined by the semisolid base used. In dogs and cats, an

extensive range of topical formulations is used in the control of fleas, lice, mites, and ticks. These include insecticidal and acaricidal soaps, foams, shampoos, sprays, and rinses. Also available are topical delivery systems such as spot-on formulations and flea and tick collars and medallions. In food animals, a diverse range of topical dosage forms and delivery systems are used to control external parasites. For example, most pour-on formulations, plunge and shower dip concentrates, and jetting fluids are suspension concentrates or emulsifiable concentrates. In addition, many pour-on formulations display endectocidal activity in cattle. The efficacious systemic concentrations attained with these preparations result from the animal's licking behavior and, to a lesser extent, percutaneous absorption of the active ingredient. Numerous methods are used to apply parasitocides to farm animals (see below). A special consideration relating to the use of topical dosage forms is the potential for residues in wool and mohair to occur. The topical route of administration is also used to deliver therapeutic agents systemically. Transdermal patches, for instance, are used to deliver analgesics to the systemic circulation.

The topical dosage forms available to treat animals include solids (dusting powders), semisolids (creams, ointments, pastes, and gels), and liquids (solutions, suspension concentrates, suspoemulsions, emulsifiable concentrates, paints, and tinctures). These dosage forms as well as the specialized topical dosage forms and delivery systems for transdermal drug delivery and parasite control are discussed below.

A **dusting powder** is a finely divided insoluble powder containing ingredients such as talc, zinc oxide, or starch. Coarse powders often have a gritty feel, whereas powders containing particles that are $<20\text{ }\mu\text{m}$ in all dimensions have a smooth feel. Some dusting powders absorb moisture, which discourages bacterial growth. Others are used for their lubricant properties. The use of dusting powders is indicated on skin folds and contraindicated on wet surfaces, because caking is likely to result.

A **cream** is a semisolid emulsion formulated for application to the skin or mucous membranes. Droplet diameter in topical emulsions generally ranges from $0.1\text{--}100\text{ }\mu\text{m}$. Cream emulsions are most commonly oil-in-water but may be water-in-oil. The former readily rub into the skin (hence the term "vanishing" cream) and are removed by licking and washing.

By comparison, water-in-oil emulsions are emollient and cleansing. Water-in-oil emulsions are also less greasy and spread more readily than ointments, and they soothe inflamed skin as a consequence of the water in the formulation evaporating.

An **ointment** is a greasy, semisolid preparation that contains dissolved or dispersed drug. A range of ointment bases is used, including hydrocarbons, vegetable oils, silicones, absorption bases consisting of a mixture of hydrocarbons and lanolin, emulsifying bases consisting of a mixture of hydrocarbons and an emulsifying agent, and water-soluble bases. Ointment bases influence topical drug bioavailability via two mechanisms. First, their occlusive properties are responsible for hydrating the stratum corneum, which enhances the flux of drug across the skin. Second, they affect drug dissolution within the ointment and drug partitioning from the ointment into the skin. Ointments are effective emollients because of their occlusive nature. They are indicated for chronic, dry lesions and contraindicated in exudative lesions.

A **paste** for topical use is a stiff preparation containing a high proportion of finely powdered solids such as starch, zinc oxide, calcium carbonate, and talc. Pastes are less greasy than ointments, because much of the fluid hydrocarbon fraction is absorbed onto the solid particles; they are also less occlusive than ointments. Pastes are indicated for ulcerated lesions.

A **gel** is a nongreasy, semisolid, aqueous solution. The semisolid properties are due to a polymer imparting a continuous structure to the hydrophilic liquid. The polymers used include natural gums such as tragacanth, pectin, and agar; semisynthetic materials such as methylcellulose, hydroxymethylcellulose, and carboxymethylcellulose; and synthetic polymers such as carbopol. Medicaments are generally well released from gels, which are easily washed off on account of their water miscibility.

A **solution** for topical use is a mixture of two or more components that form a single phase down to the molecular level. Topical solutions include eye drops, ear drops, and lotions. Eye drops are sterile liquids that contain a range of drugs, including local anesthetics, antibiotics, anti-inflammatory agents, and drugs acting on the autonomic nervous system of the eye. They are instilled onto the eyeball or within the conjunctival sac. Ear drops are solutions of drugs such as antibiotics, insecticides, or anti-inflammatory agents. The vehicle may be water, glycerol, propylene glycol, or alcohol/water

mixtures. They are applied to the external auditory canal.

A **lotion** is usually an aqueous solution (or suspension) for application to inflamed, ulcerated skin. Lotions cool the skin by evaporation of solvents, leaving a film of dry powder. Lotions are suitable for use on hairy areas and for lesions with minor exudation and ulceration.

A **suspension concentrate** for topical use is a mixture of insoluble, solid active ingredients, which are typically at high concentrations, in water or oil. Suspension concentrate formulations are generally water-based; the water-insoluble active ingredients and inert ingredients are of very small particle size (0.1–5 μm). Other formulation additives include suspending agents, surfactants, and other excipients to ensure the production of a shelf-stable, pourable product. Surfactants wet, disperse, and stabilize the solid particles in the continuous phase, prevent flocculation, and prevent changes in particle size. Thickening agents are included to increase the viscosity of the formulation, thereby overcoming sedimentation of the suspended particles and affording good long-term stability. Suspension concentrates are used topically as pour-ons, plunge and shower dip concentrates, and jetting fluids.

A **suspoemulsion** combines the elements of an emulsion and a suspension, allowing active ingredients with widely varying physical properties to be formulated in a single product. Typically, a suspoemulsion contains one or more solvent-soluble active ingredients in an emulsion phase, combined with one or more low solubility active ingredients in a continuous aqueous suspension phase.

After dilution, an **emulsifiable concentrate** for topical use produces a two-phase system involving two immiscible liquids, a dispersed phase, consisting of fine oil droplets ranging in size from 0.5 μm to several hundred microns, and a continuous phase. Addition of an emulsifiable concentrate formulation to water results in the formation of an emulsion, which relies on surface-active agents concentrating at the oil/water interface. Active ingredients that are soluble in water-immiscible organic solvents are frequently formulated as emulsifiable concentrates. The flocculation of oil droplets in emulsifiable concentrate formulations leads to a layer of cream that can be readily dispersed by mild agitation, whereas the coalescence of droplets leads to the inversion or "breaking" of the emulsion. Water with a high content of Ca^{2+} and/or Mg^{2+} reacts with anionic surfactants

in the emulsifiable concentrate formulation; this affects both spontaneity of emulsification and stability. Zinc sulfate, used as a dip additive to minimize the spread of dermatophilosis in sheep, also adversely affects emulsions.

A **flank paint** comprises an antifoaming agent such as a detergent or mineral oil and is used to prevent pasture bloating in cattle. A flank paint is applied to the flanks of animals, from where it is licked off and ingested. Bloat, or ruminal tympany, refers to excessive accumulation of gas in the rumen. Frothy bloat commonly develops in cattle on pasture, particularly those grazing lush, leguminous pastures. Frothing of rumen ingesta occurs when the viscosity of the fluid is increased. Froth obstructs the cardia of the stomach, preventing the eructation of excessive gas produced in the rumen. Antifoaming agents reduce the stability of the froth by lowering the viscosity of the fluid ingesta.

A **tincture** for topical application uses a vehicle containing 15%–80% alcohol, requiring the preparation to be tightly stoppered and not exposed to high temperatures. In addition to alcohol, tinctures may contain cosolvents, stabilizers, and solubilizers. Iodine tincture is a topical anti-infective that contains 44%–50% alcohol. The reddish brown color of iodine tincture produces skin staining that delineates treated skin. Friar's balsam is compound benzoin tincture and is used to protect and toughen ulcerated or fissured skin.

Specialized Topical Dosage Forms and Delivery Systems for Transdermal Drug Delivery: A **transdermal delivery gel** consists of a vehicle, most commonly pluronic lecithin organogel (PLO gel), which delivers drug via the transdermal route to the bloodstream. The micellar composition of PLO gel enhances skin penetration of the pharmaceutical agent present in the formulation. PLO gel is generally well tolerated and is nontoxic if ingested. However, not all drugs are suitable for transdermal application, and there are relatively few studies of the bioavailability of drugs from compounded transdermal gels. Transdermal gels are used to deliver drugs to treat several diseases in dogs and cats, including undesirable behavior, cardiac disease, and hyperthyroidism. The dose is applied to the inner surface of the pinnae, thereby offering ease of administration, especially in cats.

A **transdermal delivery patch** typically consists of a drug incorporated into a reservoir, a protective backing layer, a

rate-limiting release membrane, and an adhesive layer to secure the patch to the skin. The physicochemical properties of a drug suitable for transdermal delivery ideally include low molecular weight (<500 daltons), high potency, water solubility (to facilitate movement of the drug out of the reservoir and to allow passage through the epidermal and dermal layers of the skin), and lipid solubility (to permit penetration of the stratum corneum of the skin). Fentanyl, a synthetic opioid agonist, is delivered by transdermal patch in dogs, cats, and horses.

Specialized Topical Dosage Forms, Delivery Systems, and Application Methods for Parasite Control: The control of internal and external parasites of companion and food-producing animals has led to development of specialized dosage forms, delivery systems, and application methods unique to veterinary medicine.

A **spot-on formulation** is a solution of active ingredient(s) that typically contains a cosolvent and a spreading agent. The active ingredients in spot-on products for flea, GI parasite, or heartworm control in dogs and cats include fipronil, imidacloprid, selamectin, pyriproxyfen, ivermectin, and moxidectin. Spot-on formulations are also available to control lice in cattle. The physicochemical properties of the active ingredient(s) are important determinants of topical or transdermal behavior. Topical activity against ectoparasites depends to some extent on the active ingredient spreading, mixing with the sebum coating the skin and hair, and forming depots in the pilosebaceous units. The mechanism of percutaneous drug absorption varies between species and is not completely understood. However, low molecular weight and a high lipid/water partition coefficient tend to favor passage of the drug through the skin.

Backliner products for sheep consist of pour-on and spray-on formulations for the control of lice and sheep blowflies. Sheep lousicides include synthetic pyrethroids, organophosphates, and insect growth regulators. These products are formulated for pour-on application within 24 hr after shearing (ie, off-shears) or spray-on application (in short-wool sheep with wool growth <6 wk, and in long-wool sheep with wool growth >6 wk). Their efficacy against lice depends on topical activity and not on percutaneous absorption of the active ingredient into the bloodstream. Translocation of the pesticide from the application site to remote sites at concentrations lethal

to lice is critical to the efficacy of these products and, in the case of pour-on applications, is facilitated by the increased secretion of wool grease that occurs at shearing.

The active ingredients in sheep blowfly products include insect growth regulators, synthetic pyrethroids, and organophosphates. After their topical application, sheep blowfly larvicides form follicular depots and subsequently translocate as a coating on new wool growing out of the follicles.

Hand-jetting of long-wool sheep (wool growth >6 wk) is done to control lice, keds, mites, and sheep blowflies. The pesticides used include rotenone, synthetic pyrethroids, organophosphates, insect growth regulators, and macrocyclic lactones. Hand-jetting involves the use of a handpiece (or wand) to "rake" a pesticide solution into the wool along the dorsal midline and sometimes into the breech, crutch, and poll. The solution is applied under pressure and penetrates to the skin.

Some **pour-on products** on the market are formulated to deliver an active ingredient percutaneously. The macrocyclic lactones ivermectin, moxidectin, doramectin, and eprinomectin are formulated as pour-on preparations for application to cattle. These formulations are usually solutions or emulsifiable concentrates for dilution with water before use. The principal route of percutaneous absorption for most drugs in people is the intercellular pathway, making the intercellular lipid matrix the primary barrier to absorption. However, this may not be the case in species in which the emulsifying properties of skin secretions and the large numbers of follicles and glands per unit surface area must be considered (eg, cattle and sheep). Ionized solutes, for example, are reported to cross the skin of animals via shunt pathways (sweat ducts, follicles). Pour-on products are formulated to spread without run-off when applied to the skin and to be resistant to rain. The formulation also facilitates the partitioning of the drug out of the vehicle and into the skin and transport of the drug across the skin. The control of these processes is critical, because some drug is required to remain at the skin if the drug is to be active against external parasites that are not blood sucking. In addition, too rapid passage of drug through the skin may result in unacceptable chemical residues in tissues or milk.

The **plunge dipping** of sheep and cattle for external parasites requires a dipping vat, which may be a portable unit or a permanent in-ground structure shielded from

direct sunlight by roofing. A draining pen located at the exit of the vat allows dip wash that drains off treated animals to return to the vat. Dip chemicals are usually formulated as aqueous solutions, emulsifiable concentrates, or suspension concentrates, all of which are diluted with water before use. The high costs associated with plunge dipping relate principally to the costs of chemicals for charging large vats, labor, and the disposal of the hazardous wastes. Plunge dips must be managed properly and the pesticide maintained at the concentration recommended by the manufacturer. Dipping of sheep and cattle is associated with "stripping" of the active ingredient from the dip wash (eg, pesticide loss from the dip wash occurring at a greater rate than water loss) and is categorized as mechanical or chemical. In the case of sheep, mechanical stripping results from the fleece acting as a sieve toward the active ingredient, with the degree of filtration being primarily determined by particle size. Chemical stripping is due to the preferential absorption of pesticide by the fleece. To counteract stripping, a complex dip management regimen that involves reinforcement and "topping-up" is used. Reinforcement refers to the addition of undiluted chemical product to the dip without the addition of water, whereas topping-up refers to the addition of water and undiluted chemical product to the dip vat to return the volume to the starting level. Proper dip management also minimizes contamination of the dip with organic matter. This requires that the race leading to the vat is constructed of concrete or slats to remove dirt from the animals' feet and that animals be held in a yard overnight before dipping, during which time they are offered water but no feed.

Hand spraying generally results in uneven coverage of animals and is considered an inefficient method of application. By comparison, recirculating and nonrecirculating **spray races** facilitate whole body spraying and wet cattle to the skin. The situation with sheep is different—the very short contact time in a spray race limits the uptake of insecticide, which means the fleece seldom becomes saturated. Because of this, spray races should be used as an adjunct to shower or plunge dipping of sheep.

Shower dips are less labor intensive than plunge dips and are cheaper to operate. A typical shower dip consists of a sump containing the dip wash, a pump, and a showering pen constructed with a concrete floor and fitted with rotating and fixed

nozzles. There are two types of shower dips: a conventional shower dip in which the sump volume is periodically maintained by adding fresh dip wash, and a constant replenishment shower dip in which a small-volume sump is continually filled from a large-volume supply tank to maintain dip levels. Proper dip management requires attention to the factors described above for plunge dipping. In addition, all equipment must be functioning properly for the fleece to become saturated. Sheep should not be dipped (by either the plunge or shower method) until shearing wounds have healed to avoid clostridial infections or caseous lymphadenitis caused by *Corynebacterium pseudotuberculosis*. Moreover, the correct use of bacteriostats is recommended to prevent post-dipping lameness caused by *Erysipelothrix insidiosus*.

Insecticidal collars are plasticized polymer resins impregnated with an active ingredient. Collars for the control of ticks and fleas on dogs and cats release the active ingredient as a vapor, a dust, or a liquid, depending on the physicochemical properties of the chemical. Volatile liquid insecticides such as dichlorvos or naled are used in vapor-release collars. The insecticide distributes through the collar matrix as a vapor before being released. Powdered insecticides such as phosmet, stirofos, carbaryl, and propoxur are used in dust-release collars. Translocation of the active ingredient within the collar matrix leads to deposits forming at the surface; distribution of the insecticide to the animal depends on the animal's physical activity. Nonvolatile liquid insecticides such as chlorfenvinphos or diazinon are used in liquid-release collars. The active ingredient distributes as a liquid in the collar matrix and to the surface, where it is released. The animal's activity plus the dissolution of lipophilic insecticides in skin secretions are important factors in translocation of the insecticide from the collar to the animal.

Two types of insecticide-releasing **ear tags** to control flies on cattle are available. One is constructed from a polymer that provides structural support and acts as a release rate-controlling matrix. The other is a membrane-based ear tag that consists of an insecticidal reservoir with a relatively impermeable backing on one side and a rate-controlling membrane on the other. Both types rely on the animal's ear head movements and grooming to transfer insecticide from the surface of the ear tag to the animal's skin or to other animals.

Back rubbers typically consist of burlap supported across lanes, gateways, or areas

where cattle congregate. Back rubbers are charged by soaking thoroughly in oil-containing pesticide, typically a synthetic pyrethroid, an organophosphate, or a combination of the two. The oil retards evaporation of the insecticide and enhances adherence to the animal's coat.

Dust bags facilitate the self-treatment of cattle to control flies and lice. They are constructed of an inner porous bag containing the active ingredient, which is commonly a synthetic pyrethroid or an organophosphate, and an outer weather-proof skirt. Dust bags are hung in lanes or gateways so that passing cattle brush against them and receive a topical application of pesticide.

Inhaled Dosage Forms and Delivery Systems

Inhalational anesthetics are critical in management of anesthesia. Currently, enflurane, halothane, isoflurane, methoxyflurane, and nitrous oxide are the most commonly used inhaled anesthetic agents. These agents are usually delivered to animals in a carrier gas that includes oxygen, using an anesthetic machine fitted with one or more vaporizers and a patient breathing circuit.

Inhalational therapy of airway disease is used to deliver high concentrations of drugs to the lungs while avoiding or minimizing systemic adverse effects. To be delivered into the airways, a drug must be presented as an aerosol, either as solid particles or liquid droplets in air. Particle or droplet size largely determines the extent to which the drug penetrates the alveoli. Particles too small or too large for optimal delivery into alveolar sacs are either exhaled or deposited on larger bronchial airways. Compared with delivery by the oral or parenteral routes, the onset of pharmacologic action of inhaled agents is faster and the doses administered smaller, thereby reducing the potential incidence of adverse systemic effects. The delivery systems used for inhalational therapy of airway disease in animals are nebulizers and metered-dose inhalers. In the poultry industry, inhalation of aerosolized vaccines is a common way to immunize flocks of birds.

CHEMICAL RESIDUES IN FOOD AND FIBER

Veterinary drugs and pesticides are used routinely in animal production to manage diseases and control parasites, and crop protection chemicals are used in production

of animal feeds. It is possible, therefore, for foodstuffs of animal origin to be adulterated with residues of veterinary drugs and pesticides, and for animal fibers to be contaminated with residues of ectoparasiticides. Veterinarians must consider the implications of both possibilities when providing for the health and welfare of animals. First, animals and animal products destined for human consumption must not contain residues of drugs or pesticides that exceed legally permitted concentrations. Second, pesticide residues in fiber have potential implications for public health, occupational health and safety, and environmental safety.

Chemical Residues in Foodstuffs of Animal Origin

Chemical residues can be found in animal tissues, milk, honey, or eggs after administration of veterinary drugs and medicated premixes, application of pesticides to animals, or consumption of stockfeeds previously treated with agricultural chemicals.

Residues Resulting from Veterinary Drugs, Medicated Feeds, or Application of Pesticides: Extensive regulatory and monitoring systems have been established to ensure that chemical residues in food do not constitute an unacceptable health risk. The premarket approval process undertaken by regulatory authorities for new veterinary drugs and medicated feeds evaluates the quality, safety, and efficacy of these products. For veterinary medicines intended for administration to food-producing animals, an additional consideration is the safety of edible tissues and products (milk, honey, eggs) derived from treated animals. Regulatory authorities establish maximum residue limits (MRLs) or tolerances and set withdrawal times that ensure residues of the active constituent will not exceed the MRL when the label instructions for the product are followed.

Residue programs consist of two principal activities: monitoring and surveillance. Residue-monitoring programs randomly sample food commodities from animals. Samples are assayed for residues of specific veterinary drugs, pesticides, and environmental contaminants, and the residues are assessed for compliance with the applicable MRL or environmental standard. The number of samples taken for monitoring purposes typically provides a 95% probability of detecting at least one violation when 1% of the animal population

contains residues above the MRL. Surveillance programs, by comparison, take samples from animals suspected of having violative residues on the basis of clinical signs or herd history. Food from animals identified with violative residues of veterinary drugs or pesticides do not enter the food chain.

Residue monitoring is also a trade requirement, either mandatory or as an expectation, of importing countries allowing market access to food products derived from animals. Compliance with the national standards of importing countries becomes more difficult when the health standards, regulatory policies, and MRL-setting approaches of the exporting country and importing country differ. The situation is further exacerbated when patterns of use differ across countries or when the minor status of a disease or pest in a country does not warrant product registration, in which case MRLs are unlikely to be established.

Regulatory authorities undertake premarket approval assessments of applications in support of new veterinary drugs and medicated feeds. These assessments consider scientific data submitted by the sponsor. In the case of veterinary medicines proposed for use in food-producing animals, the data must demonstrate the safety of any residues remaining in the edible tissues or products from treated animals. These data describe the compound's toxicology, metabolism, pharmacokinetics, residue depletion, and dietary exposure. The key parameters derived in the safety and residue evaluations are defined below.

The **acceptable daily intake (ADI)** is the amount of a veterinary drug, expressed on a body weight basis, that can be ingested daily over a lifetime without an appreciable risk to human health. The ADI is established based on a review of animal studies on toxicologic, pharmacologic, or microbiologic effects as appropriate. Conservative safety factors are built into the ADI.

The **safe concentration** is the maximal allowable concentration of total residues of toxicologic concern in edible tissue. The safe concentration is calculated from the ADI and considers the weight of an average person and the amount of meat, milk, honey, or eggs consumed daily by a high-consuming individual.

An **MRL**, or **tolerance**, is the maximal concentration of residue resulting from the use of a veterinary drug (expressed in mg/kg or mcg/kg on a fresh-weight basis) that is legally permitted as acceptable in or on a

food. It is based on the type and amount of residue considered to be without any toxicologic hazard for human health as expressed by the ADI. Other relevant public health risks and aspects relating to food technology, good practice in the use of veterinary drugs, and analytical methodologies are also considered when establishing the MRL.

The **marker residue** is the parent drug, its metabolites, or any combination of these, with a known relationship to the concentration of the total residue in the last tissue to deplete to the safe concentration. When the marker residue in the target tissue has depleted to the MRL, the total residue will have depleted to the safe concentration in all edible tissues.

The **target tissue** is the edible tissue with residues that deplete to a concentration below the MRL at a slower rate than that in other edible tissues. It is considered suitable for monitoring compliance with the MRL of each edible tissue from a treated animal. The target tissue is frequently liver or kidney for the purpose of domestic monitoring, and muscle or fat for monitoring meat or carcasses in international trade.

The **withdrawal time** is the period of time between the last administration of a drug and the detection of residues of that drug to levels below the MRL in food from a treated animal. Compliance with the preslaughter withdrawal time ensures the total residues deplete to below the safe concentration, and the marker residue depletes to below the MRL. Failure to observe the correct withdrawal time is the most common cause of violative residues of veterinary drugs in food.

Regulatory authorities determine withdrawal times based on residue depletion data that has been generated using healthy animals representative of those typically treated with the specific product. The drug formulation used in these trials is identical to the market formulation, which is administered at the maximal label rate. The withdrawal time is usually determined statistically, taking into account variability among animals in drug disposition.

Unlike an MRL, which applies to a veterinary drug regardless of the dosage form, route of administration, or dosage regimen, the withdrawal time stated in the product labeling applies only to that particular formulation when administered by the recommended route and in accordance with the dosage regimen. Altering any of these factors modifies the pharmacokinetic behavior of the drug in

the animal and invalidates the stated withdrawal time. In addition, a range of physiologic and pathologic factors may modify the drug's disposition in the animal and prolong drug elimination.

In the USA, some veterinary or human drugs can be used extra-label (off-label) in food-producing animals under the Animal Medicinal Drug Use Clarification Act, provided certain conditions are met (more information can be obtained on the FDA website, www.fda.gov). Veterinarians must be mindful, however, that the extra-label use of a small number of veterinary drugs is prohibited by the FDA. Extra-label use refers to use in a species not included in the product labeling or at a dosage rate higher than that stated in the product labeling. For drugs used in this manner, data are inadequate to demonstrate the safety of food products derived from the treated animal. An understanding of pharmacokinetic principles allows extended withdrawal times to be estimated both when veterinary drugs are used in an extra-label manner and in situations that may lead to changes in the kinetic behavior of a drug in an individual animal. The pharmacokinetic principles involved as well as two relevant practical examples that demonstrate such occurrences are discussed below.

The elimination **half-life** is the time required for the concentration of a drug to be reduced by 50%. Therefore, 99.9% of an administered dose is eliminated over 10 half-lives. In food-producing animals, the residues of drugs with longer terminal elimination half-lives take longer to deplete to below the MRL. The pharmacokinetic behavior of the drug determines whether the elimination half-life in tissues will exceed the elimination half-life in plasma. In food-producing animals, the terminal elimination half-life for the slow elimination phase, or γ phase, of the residue concentration versus time profile determines the withdrawal time. Half-life is determined by both clearance (Cl) and volume of distribution (Vd) as shown by the relationship:

$$t_{1/2} = 0.693 \times \frac{V_d}{Cl}$$

Clearance is the blood volume cleared of drug per unit time and refers to the irreversible elimination of a drug from the body. The principal organs of elimination are the liver and kidneys; organ clearance is related to blood flow and the efficiency of drug removal. To determine hepatic clearance, for example:

$$Cl_H = Q_H \times E_H$$

in which Q = blood flow and E = the extraction ratio. Factors that affect hepatic clearance include hepatic function, hepatic microsomal enzyme activity, and hepatic blood flow.

Volume of distribution relates the amount of drug in the body to the concentration of drug in plasma. For a drug administered IV, the relationship is:

$$V_d = \frac{\text{amount of drug in body (dose)}}{\text{concentration (C}_{\max})}$$

V_d is a characteristic property of the drug rather than the biologic system. A drug confined to the vascular compartment has a minimal value of V_d equal to plasma volume. Factors influencing V_d include the size of the drug molecule, lipid solubility, drug pK_a , and tissue blood flow. Certain disease states effect changes in the V_d of a drug, particularly changes in drug binding.

If it is necessary to administer a drug to a healthy animal at twice the recommended rate, the elimination half-life of the drug is unchanged. Assuming the pharmacokinetic behavior of the drug demonstrates first-order kinetics, which is generally the case, doubling the administered dose will increase the depletion time by one half-life. Thus, the withdrawal time should be extended by one half-life to arrive at the same concentration as observed for the recommended rate. However, if a drug is administered to an unhealthy animal with impaired drug excretion in which clearance is reduced by 50%, it can be seen from the relationship for half-life shown above that reducing clearance by 50% will double the half-life. Accordingly, the withdrawal time should be doubled to arrive at the same concentration as seen in an animal with a fully functional excretory system.

The predicted result should always be verified using a rapid-screening test. The detection of residues is likely to signal that the withdrawal time should be extended and the rapid-screening test repeated.

Residues Resulting from Consumption of Stockfeeds Treated with Agricultural Chemicals: The use of agricultural chemicals can result in residues in crops and pastures that are subsequently consumed by animals. During drought conditions, the feeding of potentially contaminated crop byproducts, such as stubbles and fodder, and processed fractions, including grape marc, citrus pulp, fruit pomace, and cannery wastes, is likely to become more prevalent. In all cases, chemical residues may result in the edible

tissues, milk, honey, or eggs derived from these animals.

For approved uses of crop protection chemicals that are likely to result in dietary exposure of food-producing animals, regulatory authorities establish animal commodity MRLs. The approach adopted for establishing these MRLs is fundamentally different from the one that applies to veterinary drugs. Animal transfer studies, which allow determination of the relationship between the level of chemical in the animal diet and the concentration of residue found in edible tissues, milk, honey, and eggs, are pivotal in determining MRLs. MRLs for animal tissues, milk, honey, and eggs are established at concentrations that cover the highest residues expected to be found from the estimated livestock dietary exposure. Human dietary exposure assessments are also performed to verify that food complying with MRLs is safe for consumption. In animal production systems, compliance with animal commodity MRLs relies on adherence to a stipulated period to allow residues in the crop to deplete before it is fed to animals, a stipulated period to allow residues in the animal to deplete before slaughter, or a combination of both.

Chemical Residues in Animal Fibers

From an economic standpoint, the major animal fibers are wool and mohair. Although this discussion primarily focuses on pesticide residues in wool, many of the concepts apply equally to mohair.

Flies, lice, keds, and mites adversely affect wool production and have animal welfare implications for the sheep industry. Ectoparasiticides have been the mainstay to manage infestations of these parasites in sheep flocks for many years. Two important manifestations of chemical application to sheep are the emergence of resistant strains of parasites and the contamination of wool with pesticide residues. These two factors are linked, because the application of pesticides to resistant strains of flies or lice increases the likelihood of treatment failure and the need to re-treat later in the wool-growing season. Higher residues in both the wool on treated sheep and in harvested fleeces are possible consequences. Nonetheless, late-season applications are justified in some situations on animal health and welfare or economic grounds. In view of community health and safety expectations and changing environmental standards, wool producers are seeking ways to manage external parasites

on sheep that rely less on chemicals. Integrated pest management (IPM) approaches may involve various husbandry options, such as shearing and crutching to combat flystrike; genetic improvements, such as selecting against animals susceptible to fleece rot and flystrike; biologic and environmental controls, such as the use of fly traps; and the selective use of chemicals.

Pesticide residues in wool are influenced by many factors, including the chemical and formulation used, the method of application, the rate and timing of the chemical application, and the length of wool at the time of application. (See *also* ROUTES OF ADMINISTRATION AND DOSAGE FORMS, p 2508.) The product types and chemical groups commonly used in the management of flies and lice on sheep include off-shears backline or spray-on products containing insect growth regulators (IGRs), organophosphate pesticides (OPs), and synthetic pyrethroid pesticides; short-wool plunge or shower dips that use IGRs, magnesium fluorosilicate, OPs, and spinosad; long-wool backline or spray-on products containing IGRs; and long-wool jetting products containing IGRs, macrocyclic lactones, OPs, or spinosad. Wool producers must ensure that pesticides are applied in accordance with the label directions. With some chemicals, application to sheep with >6 wk wool growth results in unacceptably high residues remaining in wool to the next shearing. Repeat applications of pesticides may also result in higher wool residues at the next shearing, and backline products commonly leave higher residues at the site of application.

Although the use of sheep ectoparasitides can result in significant chemical residues on treated wool, any risk to public health is successfully mitigated by the following steps. First, scouring removes residual pesticide from processed wool destined for the manufacture of woollen garments. Second, in the case of lanolin used in pharmaceuticals and cosmetics and as nipple emollients by nursing mothers, any residual pesticide associated with the wax component is removed during refining of the lanolin. Additional assurance regarding the quality of low-pesticide grades of lanolin is provided by compliance with the applicable regulatory standards.

With respect to occupational health and safety, residual pesticide in wool wax poses a hazard to shearers and other wool handlers during wool harvesting. For instance, nervous disorders and dermal irritation have allegedly occurred in shearers after shearing sheep treated with certain OPs and synthetic pyrethroid

pesticides, respectively. In addition, long-wool backline applications of synthetic pyrethroid pesticides can result in residue concentrations at the tips of backline staples high enough to cause dermal erythema in shearers and wool handlers. In Australia, such occupational health risks are managed by prescribing a sheep rehandling period in the product labeling. The sheep rehandling period is the time that must elapse between the application of the ectoparasiticide and safely handling the treated animal. If sheep must be handled during the rehandling period, personal protective equipment should be used.

Chemical residues on treated wool may pose a risk to the environment when effluent is discharged during processing (eg, into rivers). This concern has led to the enactment of legislation to protect the environment. For some pesticides, environmental quality standards at concentrations that will not harm the most sensitive organisms in aquatic ecosystems have been established. In the EU, textile products are subject to eco-label requirements. In Australia, environmental risks posed by residues of ectoparasiticides on treated wool are mitigated by assigning a wool-harvesting interval (also referred to as a wool withholding period). The wool-harvesting interval is the time that must elapse before treated sheep may be shorn, ensuring that harvested wool meets the prescribed environmental residue limits.

The depletion of pesticide residues in wool has been mathematically modeled to predict the likely consequences of treatments at different times during the wool-growing season and to determine how late a pesticide may be applied to sheep without resulting in excessive residues at shearing. Modeling is a useful tool to determine wool-harvesting intervals and to help wool producers choose a pesticide and method of application. Test kits to quantify pesticide residues in wool are also available.

NANOTECHNOLOGY

Nanotechnology is a new enabling technology with the potential to revolutionize animal health. A nanomaterial has been defined as a material engineered to be <100 nm in one or more dimensions. A nanometer is one one-billionth of a meter; to put the nanoscale into perspective, a human hair is ~80,000 nm in diameter. Chemicals at the nanoscale display physical and chemical behaviors that can differ markedly from those of the bulk chemical (eg, in optical properties, conductivity, or electromagne-

tism). These behaviors are attributed to a combination of the small size, chemical composition, physicochemical properties, and surface structures of nanomaterials. Of major importance to the development of nanotechnologies for animal health will be a thoughtful, thorough, and balanced assessment of the benefits and risks involved. Risks can originate from any novel hazards of nanomaterials, the distribution profiles of nanomaterials in animals, the exposure of people to nanomaterials, and the toxicity and fate of nanomaterials in the environment. Additional challenges relate to the detection and analysis of nanomaterials.

This discussion focuses on the application of nanotechnology in the delivery of veterinary drugs and vaccines, a field predicted to expand. Many of the benefits of nanotechnology in drug delivery are the result of improved apparent solubility or stability or both; an increased concentration of drug at the site of action (increased efficacy); a decreased concentration of drug at locations in the body remote from the site of action (reduced systemic toxicity); and modified pharmacokinetics, including controlled release.

There are numerous “drivers” of nanotechnology-based drug delivery. Pharmaceutical considerations are one such driver (*see* drug nanocrystals, below); another is the need for veterinary nanomedicines that overcome problems refractory to conventional therapy. One objective of “smart” drug delivery is to target specific sites. This strategy allows the use of smaller quantities of drug than would otherwise be possible. The passive targeting of intravenously administered drug, for example, depends on the enhanced permeability and retention (EPR) effect, a phenomenon whereby nanoparticles extravasate at sites of increased vascular permeability, such as tumors, infections, and areas of inflammation, and then accumulate at these sites. Surface modification of nanoparticles is used to prolong the circulation time and enhance the EPR effect. For example, coating nanoparticles with the hydrophilic substance polyethylene glycol lessens opsonization through a steric effect, thereby reducing the subsequent uptake of nanoparticles by the reticuloendothelial system. Conversely, uncoated nanoparticles are rapidly phagocytosed, a process used to advantage to treat intracellular parasites and infections located in phagocytic cells. In a separate process known as active drug targeting, nanoparticles with targeting moieties (eg, antibodies, ligands) attached to their surfaces are able to bind to specific

tissues or cell types. Similarly, magnetic nanoparticles under the influence of an alternating magnetic field transport drugs to their sites of action. Individualized and targeted drug therapy across animal species is an extension of the “smart” drug delivery concept. With this approach, miniature sensing and delivery devices, some with embedded PK/PD algorithms or using nanodelivery platforms that provide local feedback on delivery mechanisms, are envisioned. Also envisioned are nanoscale devices with the capability to detect and treat an infection, nutrient deficiency, or other health problem before symptoms are evident. In the case of antibiotics, the envisioned system would use less drug, thereby relieving concerns surrounding the potential development of antibiotic-resistant strains of bacteria and thus increasing food safety for consumers. Exciting advancements in the field of vaccine delivery are also being made (*see* vaccine delivery and vaccine adjuvants, below).

The ratio of surface area to volume of a **drug nanocrystal** is orders of magnitude greater than that of its microscale or macroscale drug counterpart. Poorly water soluble drugs with a bioavailability that is dissolution-rate limited demonstrate markedly improved bioavailability when administered in a nanoform. Another advantage is that drug nanocrystals demonstrate reduced variability in bioavailability for the fed and fasted states. Nanosized drug crystals are produced either by top-down technology, in which micronized particles are subjected to milling or grinding, or by bottom-up technology involving nanoprecipitation.

Drugs and proteins conjugated to polymers such as polyethylene glycol degrade more slowly than do drugs or proteins alone. As a consequence, conjugates remain in the circulation longer than the parent drug or protein. A prolonged circulation time allows for less frequent administration and results in increased extravasation of drug due to the EPR effect and, consequently, a higher drug concentration at the site of action.

Dendrimers are highly branched polymers consisting of an initiator core; interior layers composed of repeating units; and terminal moieties that can be functionalized to modify solubility, miscibility, and reactivity of the resulting macromolecule. From a drug-carrying perspective, dendrimers are relatively new. High loadings of drug can be incorporated into the dendrimer core or attached to the terminal moieties on the dendrimer surface.

Dendrimers are particularly attractive for ocular, pulmonary, and oral drug delivery.

Polyplexes are complexes of polymers and DNA with promising benefits for gene therapy.

Polymeric micelles comprise an internal zone known as the "core" and an external zone known as the "shell" formed by amphiphilic block copolymers such as poly(propylene oxide), poly(L-amino acids), and poly(esters). The advantages of polymeric micelles for drug delivery include solubilization of poorly soluble molecules and sustained drug release due to drug encapsulation protecting the drug from degradation and metabolism. Polymeric micelles can also enhance the delivery of drugs to desired biologic sites, thereby improving therapeutic efficacy and attenuating unwanted adverse effects.

Liposomes are self-assembled vesicles that possess a central aqueous cavity surrounded by a lipid membrane formed by a concentric bilayer(s) (also known as a lamella[e]). When liposomes come in contact with biologic cells, they tend to unravel and merge with the membrane of the cell, releasing their payload of drugs or other agents. Liposomes can be designed to achieve various functions, including the protection of the active ingredient from degradation in the GI tract, the transport of drugs to sites of action, and prolongation of the residence time of the active ingredient *in vivo*.

Solid lipid nanoparticles are synthesized from solid lipids. These nanoparticles demonstrate excellent physical stability and protect the incorporated drug from chemical degradation; however, low drug loading capacity is a disadvantage. Studies suggest it will be possible to develop a range of dosage forms, allowing solid lipid nanoparticles to be delivered by most routes of administration.

Polymeric nanoparticles consist of two main forms: polymeric nanocapsules and polymeric nanospheres. Polymeric nanocapsules can be prepared from natural and synthetic materials such as chitosan and poly(lactide-co-glycolide), respectively. From a drug delivery perspective, polymeric nanocapsules demonstrate a high drug loading capacity and facilitate increased drug bioavailability and controlled drug release. Other applications of polymeric nanocapsules include the detection, diagnosis, and treatment of disease, and imaging. Polymeric nanospheres differ from polymeric nanocapsules, because drug is physically and uniformly dispersed in a dense polymeric matrix with the former.

Magnetic nanoparticles have two therapeutic applications: drug delivery and therapeutic hyperthermia. The former application involves drug-coated magnetic nanoparticles that are generally >50 nm in size. After IV administration, these nanoparticles are directed to the site of drug action using a magnetic field. Subsequent retention of the nanoparticles at the site of action is also achieved using a magnetic field, and this facilitates localized drug release. By comparison, magnetic nanoparticles for therapeutic hyperthermia are smaller in size (~5 nm). Hyperthermia via hysteresis energy loss results when an external alternating magnetic field is applied to the magnetic nanoparticles. A typical outcome of therapeutic hyperthermia is tumor cell necrosis.

An example of a nanotechnology-based device for **vaccine delivery** is the Nanopatch®, used in people to deliver vaccines dermally. The Nanopatch® is a silicon wafer the size of a postage stamp with thousands of projections (>20,000/cm²), each of which is ~100 µm long and with a tip diameter of ~1 µm. The tips of the projections are dry coated with vaccine at the nanoscale; hence, there is no requirement for refrigeration of the vaccine during storage and transport. When the device is applied to a patient's skin, the projections protrude into the wet cellular environment below the skin surface; on wetting, the vaccine is delivered in <2 min. Only one one-hundredth of the dose delivered conventionally by a needle and syringe is administered to achieve a comparable immunologic response, which is consistent with skin having more immune cells than muscle.

Nanotechnology-based vaccines may decrease unwanted inflammatory response. For example, studies have shown that the delivery of 50 nm ovalbumin adjuvant coupled to polystyrene nanobeads to sheep do not cause inflammatory reactions at the injection site. This outcome is thought to be attributed to the fact that adjuvants at the nanoscale mimic the size of viruses, which are well tolerated by cells.

Nanoclays have numerous applications, including the delivery of agrochemicals and the control of blue-green algae in waterways, and many potential applications in human and veterinary medicine. For example, nanobiohybrids are nanoclay hosts with various biologic materials such as DNA intercalated between the layers that have potential applications in gene therapy. The nanobiohybrid host system is comprised of magnesium-aluminum

layered double hydroxides wherein the positive charge of the sheets of magnesium and aluminum hydroxides is balanced by the negative charge of hydrated anions. Through ion exchange, the interlayer anions can be replaced with negatively charged biomolecules such as DNA. After delivery to a biologic system, nanobiohybrids are phagocytosed, and the biologic material released from the inorganic host either by dissolution of the inorganic host in the acidic environment of lysosomes or through reverse ion-exchange within the cellular fluids.

Gold nanomaterial is biocompatible, and when formulated as gold nanoparticles it is used in the diagnosis and treatment of diseases such as cancer. For therapeutic purposes, gold nanoparticles are coated with disease-specific surface moieties and a hydrophilic substance such as polyethylene glycol to prolong circulation time. Near infrared irradiation is used to visualize and destroy gold-targeted cancer cells by optical hyperthermia.

Carbon nanotubes are being investigated as nanovector systems. These nanomaterials have a high optical absorbance at infrared frequencies and may in the future be used in a similar manner to gold nanoshells. The possible longterm toxicity of carbon nanotubes due to bioaccumulation is currently under investigation.

Quantum dots are luminescent semiconductor crystals with unique

optical properties, including high-level fluorescence, long-term stability, simultaneous detection of multiple signals, and tunable emission spectra. In the future, they may be used as a multifunctional therapeutic for lymph node mapping, identification of molecular targets, photodynamic therapy, drug delivery, and surgical oncology. Quantum dots with cadmium selenium/zinc sulfide cores with sizes ranging from 13–24 nm emit different narrow wavelengths of detectable light. This capability would allow detection of heterogeneous tumors by coating quantum dots of different core sizes, and therefore emitting different wavelengths of light, with different cancer-specific antibodies to help understand optimal tumor therapy. The in vitro toxicity associated with the core of quantum dots (eg, cadmium selenium) can generally be overcome by coating the core with other metals such as zinc sulfide or adding a protective hydrophilic coating (eg, polyethylene glycol). Further research is necessary to evaluate the longterm stability of quantum dots in vivo, which is a major barrier to clinical translation.

Increased bioavailability as well as improvements in targeted and controlled delivery of existing drugs and their application through nanotechnology should improve ease of administration and safety and efficacy profiles for both animals and people.

SYSTEMIC PHARMACOTHERAPEUTICS OF THE CARDIOVASCULAR SYSTEM

See also PRINCIPLES OF THERAPY OF CARDIOVASCULAR DISEASE, p 74, MANAGEMENT OF HEART FAILURE, p 103, and FLUID THERAPY, p 1675.

See table 1 for a listing of commonly used cardiovascular drugs and dosages. *See also* p 2625.

DIURETICS

Diuretics are the cornerstone of therapy in management of animals with congestive heart failure (CHF) characterized by cardiogenic pulmonary edema, pleural effusion, ascites, or a combination of these signs. Three classes of diuretics are used to treat CHF in dogs and cats: loop diuretics, thiazide diuretics, and potassium-sparing

diuretics. They differ in their relative potency and mechanisms of action. The loop diuretics are the most potent and have a high ceiling, enabling them to be used in a dose-dependent way to treat mild to life-threatening CHF. Additionally, they can be administered orally or parenterally. Thiazide diuretics are mild to moderate in potency. They are typically used in conjunction with a loop diuretic (eg, furosemide) in animals with severe refractory CHF. Historically, the use of potassium-sparing diuretics (eg, spironolactone) has been reserved for those animals that have right heart failure or have become hypokalemic secondary to the use of other diuretics, or for those animals refractory to other agents.

TABLE 1 COMMONLY USED CARDIOVASCULAR DRUGS AND DOSAGES

Drug	Dosage
Amiodarone	Dog: 8–10 mg/kg, PO, every 12–24 hr for 7–10 days, then reduce to 4–6 mg/kg/day for longterm treatment
Amlodipine	Dog: 0.1–0.2 mg/kg, PO, bid; or 0.2–0.4 mg/kg/day, PO Cat: 0.625–1.25 mg/cat, PO, once to twice daily
Aspirin (antiplatelet dosage)	Dog: 5–10 mg/kg, PO, every 1–2 days Cat: 1–2 mg/kg/day, PO; or ¼ of an 81-mg tablet/cat, PO, every 3 days (or twice per week)
Atenolol	Dog: 0.2–1 mg/kg, PO, bid Cat: 1–2.5 mg/kg, PO, bid; or 6.25–12.5 mg/cat, bid
Benazepril	Dog: 0.25–0.5 mg/kg, PO, once to twice daily Cat: 0.25–0.5 mg/kg, PO, bid; or 0.5 mg/kg/day, PO
Clopidogrel	Dog: loading dose for rapid onset of action (90 min) 10 mg/kg, PO (once); 1–2 mg/kg/day, PO, longterm Cat: ¼ of a 75-mg tablet (18.75 mg)/day/cat, PO
Diltiazem	Dog: 0.5–2 mg/kg, PO, tid (standard formulation); 1–4 mg/kg, PO, bid (sustained release) Cat: 7.5 mg/cat, PO, tid (standard formulation); 3–6 mg/cat, PO, once to twice daily (sustained release)
Dobutamine	Dog: 2.5–15 mcg/kg/min, CRI ^a
Enalapril	Dog: 0.25–0.5 mg/kg, PO, bid Cat: 0.25–0.5 mg/kg, PO, bid; or 0.5 mg/kg/day, PO
Furosemide	Dog: 2–4 mg/kg, IV, IM, SC, every 1–6 hr; 0.25–1 mg/kg/hr, CRI; or 1–5 mg/kg, PO, bid-tid Cat: 0.5–2 mg/kg, IV, IM, SC, every 1–8 hr; 0.25–0.6 mg/kg/hr, CRI; or 1–2 mg/kg, PO, once to twice daily
Heparin	Dog: 100–200 U/kg, SC, tid-qid (unfractionated) Dog and cat: 100–200 IU/kg, SC, once to twice daily (low molecular weight)
Hydralazine	Dog: 0.5–3 mg/kg, PO, bid
Lidocaine	Dog: 2–4 mg/kg, IV; 25–75 mcg/kg/min, CRI
Mexiletine	Dog: 4–6 mg/kg, PO, tid
Nitroglycerin ointment 2% (1 in. = 15 mg)	Dog: 4–12 mg, topically, bid (maximum 15 mg/dog/dose) Cat: 2–4 mg/cat, topically, tid-qid for 1–2 days
Pimobendan	Dog, cat: 0.25–0.3 mg/kg, PO, bid
Procainamide	Dog: 4–6 mg/kg, PO, every 2–4 hr (regular formulation); 10–20 mg/kg, PO, tid (sustained release); 2–25 mg/kg, slow IV bolus to effect, or CRI at 25–40 mcg/kg/min
Quinidine sulfate	Dog: 5–10 mg/kg, IV, qid; or 6–20 mg/kg, PO, tid-qid
Quinidine gluconate	Dog: 6–20 mg/kg, IM, qid; or 6–20 mg/kg, PO, tid-qid

TABLE 1

COMMONLY USED CARDIOVASCULAR DRUGS AND DOSAGES (continued)

Drug	Dosage
Sildenafil	Dog: 1–3 mg/kg, PO, bid-tid
Sotalol	Dog, cat: 1–2.5 mg/kg, PO, bid
Spironolactone	Dog: 1–2 mg/kg, PO, bid; or 2 mg/kg/day, PO Cat: 1–2 mg/kg, PO, once to twice daily
Torsemide	Dog: 0.25–0.4 mg/kg, PO, once to twice daily

^a CRI = constant-rate infusion

All diuretics share a similar adverse effect profile, including electrolyte and acid-base disturbances, dehydration, and prerenal and renal azotemia. The relative risk of azotemia is increased when a diuretic is used concurrently with an angiotensin-converting enzyme (ACE) inhibitor and/or an NSAID or other potential renal toxin. Diuretics may also increase the risk of digoxin toxicity. In addition, diuretic resistance can develop with long-term treatment. The most common electrolyte and acid-base abnormalities include hypokalemia, hyponatremia, hypomagnesemia, and metabolic alkalosis. These effects are potentiated by the use of more than one diuretic (sequential nephron blockade), concurrent hypoxemia/anorexia, and the use of higher doses. Typically, potential adverse effects are more severe in cats than in dogs.

Numerous factors determine the response to diuretic therapy. These include the potency of the drug, the dosage administered, the duration of action of the drug, the route of administration, renal blood flow, glomerular filtration rate, and nephron function. The plasma concentration depends on the route of administration (IV administration will produce a higher concentration than PO administration) and the dose. The duration of effect will also determine the total diuretic effect produced in a certain period.

Animals with CHF may become refractory to furosemide because of decreased delivery of the drug to the nephron as a result of reduced renal blood flow or hormonal stimulus for sodium and water retention. Therefore, strategies to increase renal blood flow and/or plasma concentration may ameliorate diuretic resistance.

Furosemide

Furosemide is a loop diuretic and the most commonly used diuretic to treat CHF in

dogs and cats. Torsemide is another loop diuretic that is ~10 times as potent and has a longer duration of action than furosemide with a similar adverse effect profile. However, current clinical experience with torsemide is far less than that of furosemide; thus, furosemide remains the diuretic of choice in dogs and cats with CHF.

Preparations and Disposition:

Furosemide is available in oral (tablets, suspensions) and parenteral formulations. Compounded liquids (from tablets) may be better tolerated in cats than the commercially available, alcohol-based, 1% syrup.

All loop diuretics inhibit sodium, potassium, and chloride reabsorption in the thick portion of the ascending loop of Henle, leading to inhibition of sodium and commensurate water reabsorption in the nephron. Furosemide diuresis results in enhanced excretion of sodium, chloride, potassium, hydrogen, calcium, magnesium, and possibly phosphate. Chloride excretion is equal to or exceeds sodium excretion. Enhanced hydrogen ion excretion without a concomitant increase in bicarbonate excretion can result in metabolic alkalosis. Despite the increase in net acid excretion, urinary pH falls slightly after furosemide administration, while urine specific gravity is generally reduced to approximately 1.006–1.020.

In addition to its diuretic effects, furosemide acts as a mild systemic venodilator, decreasing systemic venous pressure before diuresis occurs, especially after IV administration. Furosemide decreases renal vascular resistance. Thus, it acutely increases renal blood flow (~50%) without changing glomerular filtration rate.

Furosemide is highly protein bound (86%–91%). The ratio of kidney to plasma concentration is 5:1. A small amount of furosemide (1%–14%) is metabolized to a

glucuronide derivative in dogs, but this metabolism does not occur in the liver. In dogs, ~45% of furosemide is excreted in the bile and 55% in the urine. After IV administration, furosemide has an elimination half-life of ~1 hr, and its onset of action is within 5 min; peak effects occur within 30 min, and duration of effect is 2–3 hr. Approximately 50% of the drug is cleared from the body within the first 30 min, 90% within the first 2 hr, and almost all is eliminated within 3 hr.

Furosemide is rapidly but incompletely absorbed after PO administration with a bioavailability of 40%–50%. The terminal half-life after administration PO is biexponential. The initial phase has a half-life of ~30 min, with the second phase half-life of ~7 hr. The initial disposition phase has the most effect on plasma concentration, with concentration decreasing from therapeutic to subtherapeutic within 4–6 hr of PO administration. After PO administration, onset of action occurs within 60 min, peak effects occur within 1–2 hr, and duration of effect is ~6 hr. In healthy dogs, a dose of furosemide given at 2.5 mg/kg, IM, results in maximal natriuresis (beyond that dose there is no further increase in sodium excretion). This occurs at a plasma concentration of ~0.8 mcg/mL. Because the diuretic effect of furosemide depends on its hematogenous delivery to the kidneys, animals with decreased renal blood flow (eg, those with heart failure) need a higher plasma concentration (higher dose) to produce the same effect observed in healthy dogs. This is achieved by administering higher oral doses or by administering the drug IV.

Cats are more sensitive to furosemide than dogs. Clinically, cats commonly require no more than 1–2 mg/kg, PO, once to twice daily for longterm treatment of pulmonary edema. However, higher dosages may be needed in cats with severe heart failure because of reduced renal blood flow.

Drug Interactions and Toxicity: Drug interactions and adverse effects/toxicities are typically those described for diuretics as a class. However, some special considerations for furosemide bear mentioning. Furosemide has the potential for ototoxicity. When administered as the sole agent, furosemide in dosages >20 mg/kg, IV, can result in loss of hearing in dogs. Dosages of 50–100 mg/kg result in profound loss of hearing. Furosemide can also potentiate the ototoxic and nephrotoxic effects of other drugs such as the aminoglycosides.

Clinical Use: For treatment of life-threatening cardiogenic pulmonary edema in dogs, parenteral dosages of 2–4 mg/kg, every 1–6 hr, IV, IM, or SC in dogs and 0.5–2 mg/kg, every 1–8 hr, IV, IM, or SC in cats are typically used. Dosing intervals depend on the response to therapy; initially, boluses can be given every 1–2 hr and decreased to every 4–8 hr in dogs, and given every 2 hr and decreased to every 6–8 hr in cats. Alternatively, a constant-rate infusion (CRI) of 0.25–1 mg/kg/hr in dogs or 0.25–0.6 mg/kg/hr in cats could be used. Bolus administration and CRI for treatment of life-threatening pulmonary edema is tapered over 12–24 hr as clinical signs resolve. Typical starting dosages for longterm management of CHF in dogs are 2 mg/kg, PO, bid, with a range of 1–5 mg/kg, PO, bid-tid, and in cats are 1 mg/kg/day, PO, with a range of 1–2 mg/kg, PO, once to twice daily to a maximum total daily dose of 4–6 mg/kg.

Furosemide should be stored at 15°–30°C and protected from light. Parenteral formulations having a yellow color have degraded and should not be used. Furosemide tablets that have been exposed to light may be discolored and should not be used. Furosemide injection can be mixed with 0.9% saline or Ringer's solution. A precipitate may form if the injection is mixed with strongly acidic solutions such as those containing ascorbic acid, tetracycline, adrenaline (epinephrine), or noradrenaline (norepinephrine). Furosemide injection should not be mixed with lidocaine, alkaloids, antihistamines, or morphine.

Thiazide Diuretics

The thiazides act primarily by reducing membrane permeability to sodium and chloride in the distal convoluted tubule. They promote potassium loss at this site and produce large increases in urine sodium concentration but only mild to moderate increases in urine volume. The thiazides are ineffective when renal blood flow is low, which may explain their lack of efficacy as a sole agent in animals with severe heart failure.

Preparations and Disposition: Hydrochlorothiazide is available in tablet form. In dogs, thiazides are well absorbed after oral administration. Hydrochlorothiazide has an onset of action within 2 hr, peaks at 4 hr, and lasts 12 hr.

Drug Interactions and Toxicity: Drug interactions include a decrease in efficacy of anticoagulants and insulin and an

increase in efficacy of digoxin, loop diuretics, vitamin D, and some anesthetics. Thiazide diuretics are also reported to prolong the half-life of quinidine.

The most common adverse effects of thiazide diuretics are electrolyte disturbances. Thiazide diuretics are potassium wasting, and when combined with loop diuretics, the likelihood of adverse effects such as azotemia and hypokalemia are increased. They may also increase calcium reabsorption and thus lead to hypercalcemia. Adverse effects, including renal failure, can be minimized when hydrochlorothiazide is added to chronic CHF treatment protocols that include high-dose furosemide by reducing the total daily dose of furosemide by approximately 25%–50% and starting at the lower end of the monotherapy dosage range for hydrochlorothiazide (2 mg/kg, PO, bid).

Clinical Use: Compared with that of furosemide, the relative potency of thiazide diuretics is low in dogs and cats when used as monotherapy; thus, they are rarely used as first-line diuretics in these species. Thiazides are primarily used in dogs that have developed furosemide resistance and are commonly referred to as rescue diuretics in dogs. The typical monotherapy dosage for hydrochlorothiazide in dogs is 2–4 mg/kg, PO, bid. When hydrochlorothiazide is added to furosemide, the initial dosage should be 2 mg/kg, PO, bid. The typical monotherapy dosage for hydrochlorothiazide in cats is 0.5–2 mg/kg, PO, once to twice daily.

Potassium-sparing Diuretics

This class of diuretics acts by inhibiting the action of aldosterone on distal tubular cells or by blocking sodium reabsorption in the latter regions of the distal tubule and collecting tubules, exerting a mild diuretic effect compared with that of furosemide. Spironolactone is structurally similar to aldosterone and binds competitively to aldosterone-binding sites in the distal tubule. Because of its aldosterone antagonism, spironolactone is also considered an inhibitor of the renin-angiotensin aldosterone system (RAAS) and thus a neuroendocrine modulator. Spironolactone is the most commonly used potassium-sparing diuretic in veterinary medicine.

Preparations and Disposition:

Spironolactone is available as a tablet for oral administration. It is highly protein-bound, metabolized by the liver, and excreted by the

kidneys. Peak diuresis occurs as late as 2–3 days after administration.

Drug Interactions and Toxicity: Potential toxicities include hyperkalemia, which may be exacerbated by concurrent therapy with an ACE inhibitor, especially if furosemide is not also administered. Facial excoriation has been reported in cats, but initial reports may overestimate the frequency.

Clinical Use: In dogs with CHF, particularly those with ascites secondary to right heart failure, an increased plasma aldosterone concentration may be present, and the effect of these diuretics may be enhanced. However, potassium-sparing diuretics are weak diuretics when used alone and thus should never be used as sole agents in animals with heart failure. When potassium-sparing diuretics are administered with other diuretics such as furosemide, potassium loss is decreased, which may be beneficial. Recent studies suggest that adding spironolactone to chronic CHF treatment in dogs may improve survival. The increasing use of spironolactone in veterinary medicine is related to these potential cardioprotective/antifibrotic effects and not its diuretic effect per se. The dosage of spironolactone for diuretic use is 2–4 mg/kg/day. Lower dosages (0.5–1 mg/kg, bid) may be considered for inhibition of the RAAS. Typical dosages for adjunctive treatment of CHF in dogs are 1–2 mg/kg, PO, bid, or 2 mg/kg/day, PO; similar dosages are used for a cardioprotective indication in dogs. Typical dosages for adjunctive treatment of CHF in cats are 1–2 mg/kg, PO, once to twice daily.

POSITIVE INOTROPES

Positive inotropes increase the strength of cardiac muscle contraction by increasing the quantity of intracellular calcium available for binding by muscle proteins, by increasing the sensitivity of contractile proteins to calcium, or a combination of both (eg, pimobendan). This, in turn, augments contractile protein interaction in the myocardial cell. Intracellular calcium can be increased by altering the $\text{Na}^+/\text{Ca}^{2+}$ exchange pump, by increasing production of cyclic adenosine monophosphate (cAMP) via stimulation of adenylate cyclase, or by decreasing degradation of cAMP via inhibition of phosphodiesterases.

Cardiac Glycosides

The probable mechanism of action for the modest inotropic effect of digoxin is

inhibition of the membrane-bound Na^+/K^+ -ATPase pump; when this occurs, Na^+ increases in the cell, the exchange of Na^+ for Ca^{2+} via the $\text{Na}^+/\text{Ca}^{2+}$ exchange pump is augmented, and there is a small increase in calcium influx. The increased intracellular calcium in turn leads to increased release of Ca^{2+} from the sarcoplasmic reticulum and increased contractility of the cardiac muscle. However, because these changes are modest, digoxin does not result in significant inotropy, and the availability of more potent oral positive inotropes has superseded its use for this indication.

Digoxin also has a combination of both proarrhythmic and antiarrhythmic properties. The alterations in the ratio of intracellular and extracellular electrolytes caused by digoxin can result in increased automaticity and cardiac arrhythmias. Negative chronotropic effects are due to decreased conduction velocity in the atrioventricular (AV) node via increased parasympathetic tone, as well as direct effects that help slow AV nodal conduction and prolong the AV nodal cell refractory period. Digoxin also has parasympathomimetic effects on the sinoatrial node and atria. In addition, it potentiates vagal (cholinergic) activity in the heart. The changes in conduction can lead to AV nodal blockade and reductions in heart rate (ventricular response rate) when digoxin is used to treat supraventricular arrhythmias, including atrial fibrillation. However, digoxin is rarely efficacious as a single agent for this indication. Digoxin has a narrow therapeutic window, and at toxic levels it can directly slow sinus nodal activity due to increased sensitivity to acetylcholine. Because the atria are sensitive to acetylcholine, atrial conduction is also enhanced in the diseased heart, which can then lead to atrial arrhythmias. Digoxin is believed to improve vascular baroreceptor responsiveness, thereby minimizing sympathetic activation in heart failure states. This is accomplished via decreasing plasma catecholamine concentrations, which affect both sympathetic nerve activity and plasma renin activity, thereby minimizing sympathetic activation. In this way, digoxin may be considered to be a neuromodulator. Lastly, digoxin also has been reported to have a mild diuretic effect via the Na^+/K^+ ATPase pumps present in the renal tubular epithelial cells.

Preparations and Disposition: The oral form of digoxin is the most widely used preparation. Other preparations are available but not used routinely in veterinary medicine.

Absorption of oral digoxin is variable; ~60% of the tablet formulation is absorbed. With little hepatic metabolism, almost all the absorbed drug reaches the vasculature. Absorption is slowed by food. Digoxin is distributed slowly and concentrated in cardiac tissues, and ~25% is bound to plasma proteins. It is primarily eliminated unchanged via the kidneys (15% is metabolized and excreted via the liver); its half-life (~23–39 hr in dogs, and extremely variable in cats) is strongly influenced by renal function. Steady state is reached after ~5 half-lives, and maintenance doses should theoretically achieve a therapeutic serum concentration within 2–4 days.

Drug Interactions and Toxicity:

A number of medications can increase plasma digoxin concentrations, including aspirin, quinidine, chloramphenicol, aminoglycosides (eg, neomycin), amiodarone, anticholinergics, diltiazem, esmolol, flecainide, tetracycline, and spironolactone. Furosemide, hydrochlorothiazide, amphotericin B, and glucocorticoids deplete body potassium and thus potentiate digitalis intoxication and proarrhythmic effects. Administration of β -adrenergic agonists (eg, dobutamine) also increases the risk of proarrhythmia. Longterm administration of phenobarbital may decrease digoxin concentrations by increasing clearance. Calcium channel blockers and β -blockers will potentiate action on the AV node conduction, increasing risk of AV block.

Toxic effects with digitalis glycosides are common and can be lethal. Cats are more sensitive to digoxin than dogs. Probably the most frequent cause of toxicity is inadvertent overdosing. The potential for toxicity is increased with hypokalemia and azotemia. The likelihood and severity of toxicity are related to the severity of cardiac disease. Other factors that would require dosage adjustment to prevent toxicity include renal failure (azotemia), hypothyroidism, decreased muscle mass (a significant amount of digoxin is bound to skeletal muscle), ascites, hypercalcemia, and myocardial failure leading to reduced renal blood flow. Signs of toxicity relate to the GI system (most common adverse effects) or CNS, or manifest as arrhythmias, with digitalis capable of inducing any type of cardiac arrhythmia. GI signs of toxicity include diarrhea, anorexia, and nausea and vomiting due to direct stimulation of the chemoreceptor trigger zone. Frequently, these are the earliest indications of toxicity. Neurologic effects include malaise and

drowsiness. Digoxin toxicity can be diagnosed (and avoided) by monitoring plasma drug concentrations. Treatment of intoxication includes discontinuing therapy with digitalis and potassium-depleting diuretics and administering phenytoin (blocks AV nodal effects of digitalis), lidocaine (for ventricular arrhythmias), and if indicated, potassium (preferably PO). Atropine may be useful to treat both clinically significant sinus bradycardia and second- or third-degree heart block induced by cholinergic augmentation. Arrhythmias, clinical signs, and electrolyte abnormalities should be treated as clinically indicated on a case-by-case basis.

Clinical Use: In general, the availability of other medications with similar activities and more favorable risk-benefit ratios with respect to toxicity have dramatically reduced the clinical use of digoxin in dogs. Digoxin is rarely if ever used in cats for any indication. Current typical clinical indications in dogs are for adjunctive (in combination with another antiarrhythmic) treatment of supraventricular arrhythmias such as atrial fibrillation or flutter, as part of management of chronic, advanced, or refractory CHF, or to treat vasovagal syncope.

Maintenance dosages are 0.003–0.011 mg/kg, PO, bid, for dogs, and 0.005–0.01 mg/kg, PO, every 24–48 hr for cats. In general, initial dosages should be at the lower end of the range and rounded down, and then titrated up, if needed, based on measurement of serum digoxin levels (target serum concentrations 0.8–1.2 ng/mL 8–12 hr after administration). Toxicity can occur even in animals that have levels in the therapeutic range. Levels should be monitored 3–5 days after initial treatment (8–12 hours after administration) and every 6 mo thereafter or sooner if signs of toxicity develop. Digoxin dosages should be calculated based on lean body weight and reduced in obese or cachectic animals and in the presence of ascites. Known electrolyte disorders should be corrected before digitalis glycosides are administered.

Phosphodiesterase Inhibitors

Phosphodiesterase (PDE) inhibitors, also known as inodilators, block the breakdown of cAMP and therefore increase intracellular cAMP concentrations. The result is an increase in myocardial contractility and peripheral vasodilation. Methylxanthine derivatives have been classified as PDE inhibitors, but this is controversial. Of the

methylxanthines, theophylline is the most cardiopotent. In addition to their cardiac effects, methylxanthines have significant CNS, renal, and smooth muscle effects, including on bronchial smooth muscle. The use of methylxanthines in cardiac disease is limited to conditions that would benefit from bronchodilation.

Pimobendan is a benzimidazole pyridazinone derivative and is a positive inotrope and balanced systemic arterial and venous dilator. In failing hearts, it exerts positive inotropic effects primarily through sensitization of the cardiac contractile apparatus to intracellular calcium. As a PDE 3 inhibitor, pimobendan can potentially increase intracellular calcium concentration and myocardial oxygen consumption. However, the cardiac PDE effects of pimobendan are reportedly minimal at pharmacologic doses in dogs with heart disease, which is a major advantage relative to other inotropic PDE inhibitors such as milrinone. PDE 3 inhibitors such as pimobendan result in balanced vasodilation (combination of venous and arterial dilation) leading to a reduction of both cardiac preload and afterload. In addition, pimobendan may have some direct endothelial-derived vasodilatory effects. The significance of alterations in proinflammatory cytokine concentrations such as tumor necrosis factor- β and interleukins 1 β and 6 on the progression of heart failure has been documented in many forms of heart disease. Maladaptive alterations in these cytokine concentrations are associated with increased morbidity and mortality, and pimobendan has demonstrated beneficial modulation of several such cytokines in various models of heart failure. Pimobendan reportedly may have some platelet inhibitory effect in dogs and cats, but the clinical significance of this is not yet clear. Lastly, PDE 3 inhibition in cardiomyocytes leads to more rapid relaxation; thus, pimobendan can also be considered to be a positive lusitrope.

In dogs, pimobendan is extensively metabolized, and both the parent drug and active metabolite are >90% bound to plasma protein. The steady state volume of distribution of pimobendan is 2.6 L/kg, and the terminal elimination half-lives of pimobendan and its active metabolite are 0.5 and 2 hr, respectively. Oral bioavailability is reduced by food until steady state is reached in a few days. Consequently, pimobendan should be administered on an empty stomach at least 1 hr before feeding for maximal effects when starting therapy. Hemodynamic effects after PO administra-

tion on an empty stomach peak in 1 hr and last 8–12 hr; therefore, pimobendan can provide rapid short-term support to dogs with acute or decompensated heart failure. IV preparations are available in some countries.

Pimobendan is approved for treatment of CHF due to dilated cardiomyopathy (DCM) and chronic degenerative mitral valvular disease (DMVD) in dogs. It has also been shown to prolong symptom-free survival in Doberman Pinschers with occult DCM. Pimobendan has an excellent safety profile, and clinical data suggest that it is safe when administered concomitantly with other medications commonly used in treatment of canine CHF. Reported adverse effects are minimal, but the main one is GI intolerance of the chewable tablet formulation. Pimobendan is contraindicated in dogs with known outflow tract obstruction (eg, subaortic stenosis). Pimobendan is not approved for use in cats. A number of retrospective studies in cats, using dosages similar to those used in dogs, suggest it is well tolerated, but there is no definitive proof of efficacy.

The mechanism of action of the bipyridine derivatives **amrinone** and **milrinone** is probably inhibition of PDE and increased levels of intracellular cAMP. Both amrinone and milrinone are available for IV administration and are suitable only for short-term management of CHF. However, with the wide availability and known efficacy of pimobendan, these medications have fallen out of favor for treatment of CHF.

β-Adrenergic Agonists

These drugs cause a positive inotropic effect by activating β-receptors with subsequent stimulation of adenylate cyclase and increased cAMP.

Dopamine is an endogenous catecholamine precursor with selective β₁ activity. However, it also stimulates release of norepinephrine. At low doses, it stimulates renal dopaminergic receptors, which causes increased renal blood flow and diuresis. It is rapidly metabolized by the body and has a half-life of <2 min. Dopamine is available as a solution, which is further diluted with saline or dextrose. It is administered IV, usually by CRI (1–15 mcg/kg/min). Cardiac arrhythmias may develop due to β-adrenergic activity. Indications include cardiogenic or endotoxic shock and oliguria. In cardiogenic shock, infusion of equal concentrations of dopamine and dobutamine may afford more advantages

than either drug alone. Both medications should be titrated up slowly while monitoring for arrhythmias, blood pressure, and clinical response to treatment.

Dopamine is contraindicated in the face of ventricular arrhythmias and when a pheochromocytoma is suspected. Care should be used in the setting of aortic stenosis. If the animal has recently taken a monoamine oxidase inhibitor, the rate of dopamine metabolism by the tissue will fall and the dosage should be reduced to one-tenth of usual.

Dobutamine is a synthetic drug similar to dopamine, but it does not cause release of norepinephrine and therefore has minimal effects other than β₁ activity. Dobutamine is a more effective positive inotrope than dopamine with less chronotropic effects, although it does not dilate the renal vascular bed. Its plasma half-life is ~2 min. Dobutamine is prepared as a solution to be diluted with 5% dextrose or normal saline. When compared with dopamine, dobutamine is the preferred β-adrenergic agonist for short-term therapy of refractory CHF when pimobendan alone is not successful or insufficient. Dobutamine causes an immediate increase in blood pressure due to increased cardiac output. It is given as a CRI at 2–15 mcg/kg/min; heart rate, blood pressure, and cardiac output should be monitored. In cats, dobutamine has a longer half-life and causes CNS stimulation, so lower infusion rates (0.5–10 mcg/kg/min) should be used. It is rarely indicated in cats.

Compared with other inotropic drugs, **epinephrine**, with its β₁ and β₂ effects, causes the greatest increase in the rate of energy usage and myocardial oxygen demand. This increase in oxygen need may be detrimental to the failing heart. Epinephrine also causes vasoconstriction and bronchodilation. Epinephrine is rapidly metabolized in the GI tract and is not effective after administration PO. Absorption is more rapid after IM versus SC administration. Epinephrine is available in several preparations and is effective after IV, pulmonary, and nasal administration. However, because of the decreased efficiency of cardiac work, epinephrine is not used as a positive inotropic agent but rather for emergency therapy of cardiac arrest and anaphylactic shock. Ventricular arrhythmias should be expected and are a contraindication to using epinephrine except in life-threatening situations.

Isoproterenol is a nonspecific β-agonist that, like epinephrine, increases myocardial oxygen demand. Tachycardia and the

potential for other arrhythmias excludes its use in a cardiac patient except for short-term therapy of bradyarrhythmias (eg, AV block). It is typically used as a CRI to effect based on the heart rate desired.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Angiotensin-converting enzyme (ACE) inhibitors are widely used to treat chronic CHF in dogs and cats. In the pathogenesis of CHF, the proteolytic enzyme renin is released by the kidneys and acts on angiotensinogen, which is produced by the liver and distributed in the blood, to produce angiotensin I. The formation of angiotensin II from angiotensin I occurs through the action of ACE. Angiotensin II causes retention of Na^+ and water, in part through stimulation of the synthesis and release of aldosterone by the adrenal cortex. Angiotensin II also causes vasoconstriction, thus increasing systemic vascular resistance. ACE also results in degradation of bradykinin and, thus, ACE inhibitors lead to increased levels of bradykinin that contribute to their vasodilatory effects. By inhibiting the formation of angiotensin II, ACE inhibitors prevent vasoconstriction and reduce retention of Na^+ and water in animals with CHF. ACE inhibitors are balanced vasodilators, reducing both preload and afterload. The effects during CHF include decreased vascular resistance and cardiac filling pressures and increased cardiac output and exercise tolerance. However, ACE inhibitors have only a mild effect on afterload reduction and should not be used as monotherapy in animals with severe systemic hypertension (>160 mmHg).

Preparations and Disposition: Enalapril and benazepril are widely used ACE inhibitors and are available in a variety of tablet sizes for oral administration. Compared with enalapril and benazepril, captopril has a greater propensity for GI adverse effects and a shorter half-life in dogs, necessitating more frequent dosing; thus, its use has fallen out of favor. A wide variety of other ACE inhibitors (eg, lisinopril, ramipril) are sometimes used in veterinary medicine. Choice in part is often related to drug availability, cost, and availability of canine and feline pharmacokinetic and pharmacodynamic data.

After absorption from the GI tract, enalapril is converted in the liver to the active metabolite enalaprilat. Oral

bioavailability is ~60%. Serum concentration of enalaprilat peaks in 3–4 hr. The half-life is ~11 hr, and effects last 12–14 hr, indicating the need for dosing intervals of every 12 hr if 24-hr suppression of ACE is desired. Excretion of enalapril and enalaprilat is primarily renal; therefore, the half-life of enalapril/enalaprilat is increased in animals with severe CHF (reduced renal perfusion) or renal failure, and dose reduction may be warranted.

Like enalapril, benazepril is a prodrug converted to its main active metabolite benazeprilat in the liver. Benazepril is well absorbed in dogs, and oral bioavailability increases by ~35% with repeated dosing. After administration of oral benazepril, benazeprilat concentration peaks in plasma within 1–3 hr and is rapidly distributed. Benazeprilat is excreted approximately equally in the bile and urine in dogs. The terminal half-life is ~3.5 hr. This combined excretion may allow better dosing control in animals with preexisting renal insufficiency; however, benazepril is no more renal protective than any other ACE inhibitor at equipotent doses. When benazepril is administered longterm, dosages from 0.25–1 mg/kg produce indistinguishable effects at the time of peak effect (2 hr after PO administration) and at trough effect (24 hr after PO administration); thus, dosing intervals may be as long as 24 hr, but benazepril is often dosed every 12 hr to ensure continuous ACE throughout the day.

Drug Interactions and Toxicity:

Hypotension may develop with concurrent use of ACE inhibitors and other vasodilators (eg, amlodipine) or diuretics. Concurrent use of potassium-sparing diuretics (eg, spironolactone) may cause hyperkalemia. Enalapril and benazepril appear safe when used concomitantly with furosemide, pimobendan, digoxin, antiarrhythmics, β -blockers, bronchodilators, and cough suppressants. However, it has been suggested that concurrent use of NSAIDs may increase risk of adverse effects.

ACE inhibitors have a good safety profile and have been used safely in combination with other cardiovascular drugs (including diuretics and pimobendan). However, azotemia may develop, and monitoring of BUN and creatinine (with possible dosage adjustments) is warranted. This possible complication is the result of the partial loss of renal autoregulation of blood flow mediated by angiotensin II. Other possible, albeit rare, adverse effects include GI disturbances (anorexia, vomiting, diarrhea), syncope due to hypotension, weakness, and

ataxia. Preexisting renal disease and dehydration increase the risk of adverse effects; thus, animals with these predisposing conditions should be monitored closely. Cough is a common adverse effect of this class of drugs in people but is not a recognized problem in dogs or cats.

Clinical Use: ACE inhibitors are indicated in treatment of CHF in dogs and cats stemming from a wide variety of diseases. However, there is no proof that ACE inhibitors may delay the onset of CHF in asymptomatic animals with cardiac disease. ACE inhibitors are also frequently used (typically in combination with other arterial dilators) to manage systemic hypertension in dogs and cats. Somewhat paradoxically, ACE inhibitors such as benazepril have been shown to be beneficial in treatment of some forms of renal disease. Enalapril is approved in the USA to treat CHF secondary to DCM and MMVD in dogs. Benazepril is approved in several countries other than the USA to treat CHF in dogs.

The recommended dosage of enalapril and benazepril for treatment of CHF in dogs is 0.25–0.5 mg/kg, PO, once to twice daily. However, based on the half-life, if continuous ACE inhibition is desired and well tolerated, then a 12-hr dosing interval is recommended. The recommended dosage for adjunctive treatment of CHF in cats is 0.25–0.5 mg/kg, PO, bid, or 0.5 mg/kg/day, PO. Similar doses are used when enalapril or benazepril is used to treat systemic hypertension. However, enalapril and benazepril have only modest arterial vasodilatory effects and should not be used as monotherapy in animals with severe systemic hypertension (systolic blood pressure >160–180 mmHg). In general, regardless of clinical indication, starting at the lower dose range and increasing to maximal dose with monitoring of renal function, serum potassium, and systemic blood pressure is recommended. Higher doses of benazepril, if tolerated, may be indicated to treat some forms of renal disease (eg, protein-losing glomerulopathy).

VASOACTIVE DRUGS

Vasodilator drugs can be categorized as afterload reducers or preload reducers. Afterload is reduced by dilation of arterioles (ie, resistance vessels), whereas preload is reduced by dilation of veins (ie, capacitance vessels). Arterial dilators are used in treatment of systemic hypertension in dogs and cats and as adjunctive treatment for CHF in dogs, particularly when CHF is secondary to degenerative mitral valve disease.

Arterial Dilators

Hydralazine is an arteriolar vasodilator, the mechanism of action of which is not clearly elucidated. It directly relaxes the vascular smooth muscle in systemic arterioles by inhibiting calcium fluxes into the cell or by increasing local prostacyclin concentrations. Hydralazine has no effect on systemic venous tone. It is bound to smooth muscle, which results in a biologic half-life longer than plasma half-life. Hydralazine is well absorbed after administration PO but (in people) is subject to first-pass metabolism. The incidence of toxicity caused by hydralazine may be significant and related to its potency as an arterial dilator leading to hypotension. The potency of hydralazine can be both beneficial and detrimental: it results in good to profound improvement in most animals in which it is indicated, but it can also result in systemic hypotension. The effective dosage range in dogs is 0.5–3 mg/kg, PO, bid. This dose must be titrated, starting with a low dose and titrating up to an effective clinical endpoint while monitoring for hypotension. Doses may need to be even lower when hydralazine is combined with other drugs that have arterial dilatory effects.

Calcium channel blockers as a class are considered vasodilators, but individual agents have different relative potencies and additional effects. Calcium channel blockers are also class IV antiarrhythmics, negative inotropes (an adverse property), and positive lusitropes (drugs that improve relaxation of cardiomyocytes).

Amlodipine primarily affects the calcium channels in the small arterioles, leading to arterial dilation. Amlodipine is the only calcium channel blocker used in veterinary medicine that has potent arterial dilatory effects with negligible effects on inotropy and conduction. The effects of amlodipine are similar to those of hydralazine, and it is used for similar indications in dogs and cats. Amlodipine appears to be better tolerated by the GI tract. The effective dosage range in dogs is 0.1–0.2 mg/kg, PO, bid, or 0.2–0.4 mg/kg/day, PO. The effective dosage range in cats is 0.625–1.25 mg/cat, PO, once to twice daily. This dose must be titrated, starting with a low dose and titrating up to an effective clinical endpoint while monitoring for hypotension. Doses may need to be even lower when amlodipine is combined with other drugs that have arterial dilatory effects. In resistant systemic hypertension, doses at the higher end of the range are needed. In

CHF in dogs, initial dosages should be at the lower end of the range and titrated to effect with appropriate monitoring. Gingival hyperplasia has been reported as an adverse effect of amlodipine in dogs and cats.

Arterial and Venous Dilators

(Mixed dilators)

Organic nitrates and nitrites relax both arterial and venous vascular smooth muscle through a complex series of events. At low concentrations, which are generally used clinically, venous dilation predominates, and net systemic vascular resistance is usually not affected. Pharmacologic effects occur rapidly. First-pass metabolism limits the use of these drugs to IV, sublingual, and topical (ointment) administration. Tolerance is a problem with sustained administration.

Nitroglycerin, an organic nitrate, relaxes vascular smooth muscle. However, the dosage of nitroglycerin used clinically results in predominantly venous dilation and preload reduction. Nitroglycerin is indicated for acute (emergency) adjunctive treatment of CHF in dogs and cats; however, efficacy for this indication in these species is anecdotal. It is available for IV and sublingual use and as an ointment. The 2% ointment preparation (1 in. = 15 mg) is the most commonly used; it is applied to the hairless portion of the animal's skin (abdomen or ear). The dosage in dogs is 4–12 mg, topically, bid (maximum of 15 mg/dog per dose) for 1–2 days, and in cats, 2–4 mg/cat, topically, every 6–8 hr for 1–2 days. The most prevalent adverse effect involves accidental exposure of veterinary personnel, which can be avoided by careful application and labeling of application sites.

Nitroprusside is one of the most potent vasodilators available. It is an organic nitrate and reduces preload (venous dilation) and afterload (arterial dilation) in a dose-dependent manner. Advantages of nitroprusside include potency, rapid onset of action, and short half-life. The main disadvantage is that it must be administered by CRI (1–10 mcg/kg/min, IV), with appropriate, typically invasive, blood pressure monitoring. Nitroprusside is indicated in dogs for emergency reduction of blood pressure in a hypertensive crisis and for immediate afterload reduction (severe, life-threatening CHF). Nitroprusside should only be used for 48–72 hr because of buildup of its toxic metabolite, cyanide.

Prazosin is an α_1 -adrenergic receptor blocker and thus considered to be a mixed vasodilator. It is effective when given PO, but tolerance develops rapidly. It also

undergoes significant first-pass metabolism. Prazosin is rarely used clinically in small animals to treat primary cardiac disease. The dosage in dogs and cats is 0.5–2 mg/kg per animal, PO, bid-tid, or 0.07 mg/kg, PO, bid-tid.

Phosphodiesterase 5 Inhibitor

Sildenafil is an orally active phosphodiesterase 5 inhibitor. Phosphodiesterase 5 (PDE 5) is found in a relatively high concentration in the lungs and the corpus cavernosum of the penis. In dogs, pulmonary hypertension is a clinically important disease with high morbidity and mortality rates; it is typically a sequela of another disease process and thus requires a balanced therapeutic approach that targets the underlying etiology as well as palliation of clinical signs. An important goal of therapy is to reduce pulmonary artery resistance. Conventional systemic arteriolar dilators have no preferential effect on pulmonary vasculature and thus have no benefit and may worsen clinical signs attributable to pulmonary hypertension. Inhibition of PDE 5 in the small arterioles of the lung leads to dilation that is more significant than dilation of the systemic arterioles. In people with pulmonary hypertension, PDE 5 inhibitors improve both exercise tolerance and quality of life. Sildenafil has been used in dogs for adjunctive treatment of clinical signs related to pulmonary hypertension secondary to a variety of etiologies; proof of efficacy remains predominantly anecdotal, although it does appear to be safe and well tolerated for this indication.

The typical starting dosage in dogs is 1 mg/kg PO, tid, or 1–2 mg/kg, PO, bid. The reported dosage range is 1–3 mg/kg, PO, bid-tid. Efficacy may be potentiated with coadministration of L-arginine at 250–500 mg/dog, PO, bid. Adverse effects of sildenafil appear to be rare in dogs, but anecdotal systemic hypotension is possible. There are no reported drug interactions, and published reports have documented use of sildenafil in dogs in combination with many other medications, including conventional heart failure medications (eg, diuretics, ACE inhibitors, pimobendan), with no recognized adverse effects.

ANTIARRHYTHMICS

Antiarrhythmics are typically classified according to their predominant electrophysiologic effect on myocardial cells.

However, the electrophysiologic effects of some agents span more than one class, and some have ancillary properties unrelated to their antiarrhythmic effects. However, this classification scheme typically does not aid in selection of an antiarrhythmic for a specific clinical indication (eg, ventricular vs supraventricular arrhythmias). Many antiarrhythmics have never been used with any frequency in veterinary medicine (and are not covered here). In addition, many of these agents (in particular the class I medications) have fallen out of favor for treatment of arrhythmias in people, and as a consequence their availability and costs are becoming problematic.

Class I Drugs

Class I agents comprise the group of agents generally known as “membrane-stabilizing drugs” such as quinidine, procainamide, and lidocaine. These agents work by selectively blocking a proportion of the fast sodium channels in cardiomyocytes, leading to depression of phase 0 of the action potential and subsequent reductions in conduction velocity. These agents are often subdivided into three subclasses (A, B, and C) based on their concurrent effects on repolarization; however, this has little clinical relevance.

Class IA Drugs: Class IA drugs used in veterinary medicine include quinidine and procainamide.

Quinidine is related to the antimalarial drug quinine. In addition to its membrane-stabilizing properties inherent to Class I agents, it also has indirect, anticholinergic (“atropine-like”) effects in the atria. It has efficacy against supraventricular and ventricular arrhythmias. Its main indication in veterinary medicine is to treat atrial fibrillation. It has the potential to convert atrial fibrillation to sinus rhythm and is used for this indication in horses. In dogs, it is used to facilitate synchronized cardioversion of atrial fibrillation. It is not typically used for rate control of chronic atrial fibrillation in dogs or horses, or to treat ventricular arrhythmias. The sulfate preparation of quinidine is absorbed rapidly after administration PO. The gluconate form is absorbed more slowly. It can be given IM but is painful. Although 90% of quinidine is protein-bound, distribution is rapid to most tissues. The half-life varies among species and is ~6 hr in dogs and ~8 hr in horses.

Dosages of quinidine sulfate are as follows: in dogs, 5–10 mg/kg, IV, qid, or 6–20 mg/kg, PO, tid-qid; and in horses, 22 mg/kg, PO, every 2 hr. Dosages of quinidine

gluconate are in dogs, 6–20 mg/kg, IM, qid, or 6–20 mg/kg, PO, tid-qid; and in horses, 1–1.5 mg/kg, IV, every 5–10 min. Individualized therapy is necessary because of significant pharmacodynamic variation among animals and the potential for toxicity. Cardiotoxicity can manifest in the form of ventricular arrhythmias. The atropine-like effects of quinidine may result in increased impulse conduction through the AV node to the ventricles and paradoxical acceleration in ventricular response in animals with atrial fibrillation. Quinidine, particularly in the sulfate form, can cause vasodilation and GI adverse effects (25% of dogs). In horses, swelling of the nasal mucosa, urticarial wheals, and laminitis are other potential adverse effects. The most important clinical problem limiting use of quinidine is exacerbation of heart failure after administration, likely as a consequence of its negative inotropic effects. In general, quinidine use should be avoided in dogs with severe myocardial failure or in dogs that have, or have had, heart failure. Quinidine should not be used in cats. Monitoring the ECG and serum quinidine concentration can reduce the likelihood of adverse effects.

Procainamide effects are similar to those of quinidine. However, its effects on the autonomic nervous system are significantly weaker (less anticholinergic effect). Procainamide has efficacy against ventricular and supraventricular arrhythmias and has been used for both indications in dogs. It is often used parenterally in combination with lidocaine to treat life-threatening ventricular arrhythmias. The parenteral formulation has also been used to treat supraventricular arrhythmias, including conversion of recent onset atrial fibrillation. The oral formulation is useful to treat ventricular arrhythmias and supraventricular arrhythmias secondary to accessory pathways. It has little efficacy in long-term management of atrial fibrillation. Procainamide is rapidly and almost completely absorbed after administration PO. Only ~20% is protein bound. Procainamide is extensively biotransformed by the liver to metabolites that are generally inactive in dogs. Both oral (“regular”) and sustained-release and parenteral formulations (IV and IM administration) are available. The “regular” formulation necessitates dosing every 4 hr for maintenance in dogs, severely limiting its use for long-term treatment. The sustained-release product has fallen out of favor in people, limiting its availability; it is not currently available in the USA.

Procainamide is dosed in dogs at 2 mg/kg, slow IV bolus, to a maximum cumulative

dose of 25 mg/kg over 10–15 min, continuing if needed as a CRI at 25–40 mcg/kg/min or at 10–20 mg/kg, tid-qid, IM or SC. The oral (regular) formulation is dosed at 4–6 mg/kg, PO, every 2–4 hr (maintenance dose every 4 hr), and the sustained-release formulation at 10–20 mg/kg, PO, tid.

Toxicities include hypotension and AV block (IV administration only), proarrhythmia (longterm administration), alteration in coat color (longterm administration), and GI disturbances with the oral formulations.

Class IB Drugs: Class IB drugs used in veterinary medicine include lidocaine, mexiletine, tocainide, and phenytoin.

Lidocaine is used predominantly for acute treatment of ventricular arrhythmias. It has no efficacy against supraventricular arrhythmias and minimal effects on the autonomic nervous system. It is ideal for acute treatment because it has a rapid onset of action and short half-life (~1 hr in a dog) and is effective and safe. The short half-life facilitates rapid changes in serum concentrations and, therefore, titration to effect. Lidocaine is extensively metabolized by the liver; thus, hepatic disease and reduced hepatic blood flow can prolong the half-life. Hypokalemia seriously impairs the efficacy of lidocaine. Lidocaine is available only as a parenteral formulation for IV administration. It should not be infused through the same catheter or line as other medications. The typical clinical approach in dogs is to administer 2 mg/kg, IV boluses over ~1 min to effect (slowing the ventricular arrhythmia or conversion to sinus rhythm) or to a cumulative dose of 8 mg/kg over ~30 min. Given the very short half-life, repeat boluses or a CRI (25–75 mcg/kg/min) is needed to maintain rhythm control. Lidocaine is rarely indicated in cats, because clinically significant or life-threatening ventricular arrhythmias are rare in this species. The dosage in cats is 0.1–0.4 mg/kg, IV bolus over ~1 min, then increase to a total dose of 0.25–1 mg/kg, IV slowly, if no response. This can be followed by a CRI (10–20 mcg/kg/min). Lidocaine has few undesirable effects. Toxicity is manifest in dogs primarily as GI and CNS signs. Drowsiness or agitation may progress to muscle twitching and convulsions at higher plasma concentrations. Hypotension may develop if the IV bolus is given too rapidly. In cats, which are more susceptible to toxicity, cardiac suppression and CNS excitation may be seen.

Mexiletine is an oral analogue of lidocaine used to treat ventricular arrhythmias in dogs. It is rarely used as monotherapy for ventricular arrhythmias.

It is most often an adjunctive treatment in severe, chronic ventricular arrhythmias not well controlled by sotalol alone or in dogs that do not tolerate sotalol. It has fallen out of favor for treatment of people; thus, its availability is limited and cost is increasing. It should be administered at its lowest effective dose with food to limit toxicity. Common adverse effects include anorexia, vomiting, tremors, and hepatic toxicity. Hepatic enzymes should be evaluated before treatment and periodically (approximately every 6 mo) during chronic treatment as well as any time GI disturbances develop during treatment. The dosage in dogs is 4–6 mg/kg, PO, tid.

Tocainide is an analogue of lidocaine used to treat ventricular arrhythmias in dogs. Similar to mexiletine, it is rarely used as monotherapy for ventricular arrhythmias. It is most often an add-on treatment of choice for severe chronic ventricular arrhythmias not well controlled by sotalol alone, in dogs that do not tolerate sotalol, or if mexiletine is not available or cost prohibitive. It has fallen out of favor for treatment of people; thus, its availability is limited and cost is increasing. Potential adverse effects include CNS and GI disturbances (35% of dogs), hypotension, bradycardia, tachycardia, other arrhythmias, and progressive corneal edema. Because of these adverse effects, use of tocainide is limited if other efficacious agents are available. Tocainide has been used in dogs at 15–20 mg/kg, PO, tid.

Phenytoin has a limited spectrum of antiarrhythmic activity. Its primary use is in management of digitalis-induced arrhythmias, because it abolishes digitalis-induced abnormal automaticity. The recommended dosage in dogs is 30 mg/kg, PO, tid, or 10 mg/kg, IV, over 5 min.

Class IC Drugs: Examples of drugs in this class include encainide, flecainide, and propafenone. These drugs are not typically used in veterinary medicine.

Class II Drugs

Class II antiarrhythmic drugs are the β -adrenergic receptor blocking agents. β -Blockers are classified as nonselective (block both β_1 and β_2 receptors) or selective (block predominantly β_1 receptors). As a class, all β -blockers are dose-dependent negative inotropes and chronotropes. Although characterized as class II antiarrhythmic agents, β -adrenergic blockers are used for a variety of indications in veterinary medicine, including control of

inappropriate or undesirable sinus tachycardia, treatment of ventricular and supraventricular arrhythmias, management of chronic hypertension in dogs and cats, and palliation of adverse effects of uncontrolled hyperthyroidism in cats and pheochromocytoma in dogs. They are well recognized for their cardioprotective effects in people with heart failure, leading to improved survival. Data and experience supporting this indication in veterinary medicine is lacking in dogs and cats, and the relative risks of initiation of a β -blocker in the face of heart failure should not be ignored. The earliest generation of this class was nonselective, blocking both β_1 and β_2 receptors (eg, propranolol). Subsequent generations became selective β_1 -receptor blockers in an attempt to limit the adverse effects associated with β_2 -receptor blockade (eg, atenolol). Third-generation β -blockers (eg, carvedilol) were developed to be more complete adrenergic blockers and are β_1 , β_2 , and α_1 -receptor blockers. Carvedilol may also have some important antioxidant effects that have contributed to its proven efficacy for treatment of heart failure in people.

Propranolol, the prototype, is competitive and nonselective, blocking both β_1 and β_2 receptors. The dosage in dogs is 0.2–1 mg/kg, PO, tid (titrate dose to effect) and in cats is 0.4–1.2 mg/kg (2.5–5 mg/cat), PO, tid. Use of propranolol should be avoided in dogs and cats with evidence of primary respiratory disease (eg, asthma).

Atenolol is a β_1 -selective blocking agent and is the most commonly used β -blocker in veterinary medicine. Because it is β_1 -selective, it has less potential to cause or contribute to bronchospasm in predisposed dogs and cats, although the β_1 -selectivity is likely limited or absent at high doses. The dosage in dogs is 0.2–1 mg/kg, PO, bid, and in cats 1–2.5 mg/kg, PO, bid, or 6.25–12.5 mg/cat, PO, bid. Some references suggest cats can be dosed every 24 hr, but most cardiologists believe that continuous β -blockade (the clinical target) is not possible with daily dosing. In both dogs and cats, titrating up gradually is required, especially if atenolol is initiated in the face of active or stable CHF or in DCM. In general, dogs and cats without CHF and normal systolic function can tolerate higher initial and target dosages. Abrupt discontinuation should be avoided; if cessation is indicated, titrating down gradually is recommended. If CHF develops in an animal receiving atenolol, the dosage may need to be reduced and the drug eventually discontinued, but unless the

CHF is life-threatening, abrupt cessation should still be avoided. Potential adverse effects are dose related and more likely if underlying systolic function is present. Adverse effects include myocardial depression, bradycardia (sinus and AV block), and hypotension.

Carvedilol is a third-generation β -blocker that has a more complete adrenergic blocking spectrum. Carvedilol blocks β_1 , β_2 , and α_1 receptors and has some ancillary antioxidant effects. It is routinely used in treatment of heart failure in people. Its oral bioavailability is highly variable in dogs. Carvedilol has been mainly evaluated in veterinary medicine for its potential survival benefits in canine DCM and cardiovascular disease with and without CHF, but experience to date is limited and thus it is not routinely used for this indication. If β -blockers are used for this indication, the general rule of thumb is to never initiate in the face of active heart failure (pulmonary edema), start low (initial dose), go slow (and titrate up), and aim high (target dose tolerated). The initial dosage in dogs is 0.15–0.25 mg/kg, PO, bid, titrated up by increasing the dose ~25% every 2 wk while monitoring for clinical signs suggestive of decompensation. The target dosage is 1 mg/kg, PO, every 2 hr (if tolerated). Higher target doses may be tolerated in dogs concurrently receiving pimobendan and in dogs with cardiovascular disease (vs those with DCM).

Class III Drugs

The predominant electrophysiologic effect of class III drugs is potassium channel blockade leading to prolongation of the cardiac action potential and its refractory period. The two drugs in this class commonly used in veterinary medicine are sotalol and amiodarone.

Sotalol is an oral class III drug with nonselective β -blocking activity. Sotalol is the most commonly used long-term treatment for hemodynamically significant ventricular arrhythmias in dogs and cats. It is often used as monotherapy for this indication but can be combined with mexiletine if rhythm control is suboptimal with sotalol alone. It has some efficacy in treatment of atrial fibrillation (rate control), but it is not as efficacious as other agents and is not commonly used for this indication. Sotalol is safe and well tolerated and is often used in combination with other drugs commonly used to treat heart disease and heart failure, including ACE inhibitors,

furosemide, spironolactone, and pimobendan. Because it has β -blocking effects, it should not be combined with other β -blockers (eg, atenolol) or other negative inotropes (eg, diltiazem). In addition, it should not be combined with another class III agent (eg, amiodarone). The dosage in dogs and cats is 1–2.5 mg/kg, PO, bid. It should be used with caution and at the lower end of the dosage range in patients with CHF or DCM or when combined with mexiletine. In this situation, titrating up (dosage increases every 10–14 days) to a higher target dose may be attempted if lower doses are not efficacious. Dogs and cats with normal systolic function can tolerate higher initial and target doses. Possible adverse effects include negative inotropy, bradyarrhythmia (sinus and AV block), and proarrhythmia.

Amiodarone is a class III drug with a variety of other properties. Its predominant electrophysiologic effect is to prolong the refractory period of atrial and ventricular myocardium and the AV junction. In addition, it has class I effects (sodium channel-blocking properties), some class II effects (β - and α -receptor blockade), and some class IV effects (calcium channel blockade). Amiodarone is used to treat life-threatening ventricular arrhythmias (rhythm control) and atrial fibrillation (rate control) in dogs refractory to other, more common treatments. In some cases, it is used because of its effectiveness in treatment of both ventricular and supra-ventricular arrhythmias. It is rarely used as a first-line drug.

Amiodarone has unusual pharmacokinetics. After repeated administration in dogs, it has a long half-life of 3.2 days, with myocardial concentrations reaching 15 times that of plasma. The long half-life suggests a long time is needed to produce a significant effect once treatment is initiated as well as for effects to end if treatment is discontinued. However, some clinical effect appears to occur within hours of PO administration, especially if a higher loading dose is used, which is likely a consequence of the large and variable number of metabolites.

Amiodarone is often used in combination with other drugs commonly used to treat heart disease and heart failure, including ACE inhibitors, furosemide, spironolactone, and pimobendan. Because it has β -blocking effects it should not be combined with other β -blockers (eg, atenolol) or other negative inotropes (eg, diltiazem). In addition, it should not be combined with another class III agent (eg, sotalol). Amiodarone has a

number of known common adverse effects that limit its longterm (>6 mo) use clinically. Adverse effects seem to be related to dose and duration of treatment and include significant increases in liver enzymes, GI signs, thyroid dysfunction, blood dyscrasias (neutropenia), and proarrhythmia. The liver effects seem to be the most common adverse effect encountered clinically and are typically reversible after cessation of therapy. The oral dosage in dogs is 8–10 mg/kg, PO, once to twice daily for 7–10 days, and then decreased to 4–6 mg/kg/day for longterm treatment; the parenteral dosage in dogs is 2–5 mg/kg, IV, infused over 30–60 min. Formulations preserved with polysorbate 80 should not be used IV because of risk of anaphylactoid reaction and angioedema.

Class IV Drugs

The predominant electrophysiologic effect of class IV antiarrhythmic drugs is blockade of the slow calcium channels in cardiac cells and vascular smooth muscle. The two drugs in this class commonly used in veterinary medicine are diltiazem and amlodipine. The relative affinity of a drug in this class for cardiac versus vascular tissue determines its predominant effect. Amlodipine (see p 2534) is most active in vascular smooth muscle, where it causes vasodilation and is thus considered to be a vasodilator. Diltiazem is most active in cardiac cells.

Diltiazem blocks entry of calcium into cardiomyocytes during the action potential, leading to a dose-dependent reduction in calcium release from the sarcoplasmic reticulum, limiting the availability of calcium to the contractile apparatus, and resulting in negative inotropy and positive lusitropy. It also blocks calcium channels in the specialized conduction tissue in the heart, on which automaticity of intrinsic pacemaker cells and AV conduction depend for normal function. Blockade of these calcium channels can therefore slow heart rate and AV conduction. Diltiazem is therefore typically indicated for treatment of atrial fibrillation (rate control) and other supraventricular arrhythmias in dogs and cats. Another historical indication is for treatment of feline hypertrophic cardiomyopathy. However, limited practicality in combination with its unconfirmed efficacy for feline hypertrophic cardiomyopathy has caused diltiazem to fall into disfavor for this indication. Diltiazem has no effect on ventricular arrhythmias.

The dosage in dogs is 0.05–0.2 mg/kg, IV, over 5 min, which can be repeated to a

cumulative dose of 0.3 mg/kg, after which the dog should be reassessed or an oral formulation initiated. In dogs, the dosage of the standard oral formulation is 0.5–2 mg/kg, PO, tid, and of the sustained-release formulation 1–4 mg/kg, PO, bid. In cats, the dosage of the standard oral formulation is 7.5 mg/cat, PO, tid, and of the sustained-release formulation 30–60 mg/cat, PO, once to twice daily. Initial doses should be at the lower end of the dose range and titrated up to a clinically effective dose. Blood pressure and heart rate and rhythm should be monitored during IV administration. Dogs and cats without CHF and with normal systolic function can tolerate higher initial and target dosages. The sustained-release formulation cannot be made into suspensions but can be reformulated into lower-dose capsules.

Possible adverse effects include systemic hypotension, negative inotropy and bradycardia (sinus or AV block), and exacerbation of CHF. GI signs are the common noncardiac adverse effect and are more common in cats, especially with sustained-release preparations. Diltiazem is often used in combination with other drugs commonly used to treat heart disease and heart failure, including ACE inhibitors, furosemide, spironolactone, and pimobendan. Because diltiazem is a negative inotrope and chronotrope, it should not be administered concurrently with a β -blocker.

Amlodipine is selective for calcium-channel blockade in vascular smooth muscle, with minimal effects on cardiac calcium transport. Amlodipine is recommended for hypertension in cats and dogs.

DRUGS ACTING ON THE BLOOD OR BLOOD-FORMING ORGANS

Hematinics

Anemia can be treated pharmacologically by providing components needed for RBC production, including hemoglobin synthesis, and by stimulating bone marrow formation of RBCs.

Vitamin B₁₂ is essential for DNA synthesis. Deficiency causes inhibited nuclear maturation and division. RBC maturation arrest in the bone marrow leads to megaloblastic or pernicious anemia. Vitamin B₁₂, a porphyrin-like compound consisting of a ring structure that contains centrally located cobalt, is derived from the diet and microbial synthesis in the GI tract. However, except for ruminants, microbial production occurs in the large intestine, from which vitamin B₁₂

is not readily absorbed. Dietary deficiency of B₁₂ is rare; deficiency usually results from poor absorption from the GI tract.

Vitamin B₁₂ absorption is complex and depends on gastric acid, pepsin, and intrinsic factor secreted from gastric parietal cells or pancreatic duct cells. Intrinsic factor binds to and protects vitamin B₁₂ from digestion. In this form, B₁₂ binds to highly specific receptor sites in the brush border of the ileum, where it enters enterocytes by pinocytosis. Interference with its absorption in the ileum results in continuous depletion, although many months of defective absorption are necessary before deficiency develops. Vitamin B₁₂ is bound in the plasma to transcobalamin. It is stored in large quantities in the liver and slowly released as needed. It is excreted into the bile but undergoes enterohepatic cycling.

Vitamin B₁₂ (dogs: 100–200 mcg/day, PO or SC; cats: 50–100 mcg/day, PO or SC) is available in oral and parenteral preparations of cyanocobalamin. There are no significant toxicities associated with therapy. Indications for therapy are limited to cases of vitamin B₁₂ malabsorption, such as ileectomy, gastrectomy, or deficiency malabsorption syndromes (eg, exocrine pancreatic insufficiency). Chronic administration of H₂-receptor blockers (cimetidine, ranitidine, famotidine) can also lead to vitamin B₁₂ deficiency, because an acid environment is necessary for its absorption.

Folic acid is needed for DNA and RNA synthesis. Anemia associated with folic acid deficiency is characterized as megaloblastic. Sources of folic acid in the diet include yeast, liver, kidney, and green vegetables, although it can also be formed by microbes. Folic acid is stored in the liver but not as avidly as vitamin B₁₂. Because folic acid is destroyed by catabolic processes every day, serum levels decrease rapidly in the presence of deficient diets. Absorption of folic acid is not as sensitive as that of vitamin B₁₂, although jejunal pathology can result in folate deficiency.

Folic acid (dogs: 5 mg/day, PO; cats: 2.5 mg/day, PO) is available in both oral and parenteral formulations. Significant toxicity is not associated with therapy. Indications for therapy include inadequate intake due to administration of selected drugs (eg, methotrexate, potentiated sulfa drugs, some anticonvulsants [eg, primidone and phenytoin]), liver disease, malabsorption, or other chronic debilitating diseases.

Iron is necessary for hemoglobin formation. It is available in the diet either

as a heme form, which is a small percentage of the total but readily absorbed, or a nonheme form. Absorption of the nonheme form is profoundly affected by diet. Iron is absorbed from the proximal jejunum, where it immediately combines in the enterocyte to the globulin transferrin. It is transported in the plasma in this form, but the binding is loose and iron can be easily transferred to tissues. Iron enters cells via specific receptors that interact with transferrin.

In the cell, iron combines with the protein apoferritin to become ferritin, the soluble form of iron storage. Smaller quantities are also stored as the insoluble hemosiderin; the amount of this storage form increases when the total amount of iron in the body is much more than apoferritin can accommodate. There is no mechanism for the excretion of iron other than via the GI tract. GI elimination occurs by exfoliation of enterocytes containing iron, biliary elimination, and elimination of dietary iron that has not been absorbed.

Indications for iron therapy are limited to treatment or prevention of iron deficiency (eg, blood loss, pregnancy). Iron is available in both oral and parenteral preparations.

Oral preparations should be ferrous salts, such as sulfate (dogs: 100–300 mg/day; cats: 50–100 mg/day), gluconate, and fumarate.

Therapy can be continued for several months to replenish body iron stores.

Response to iron therapy can be assessed by monitoring circulating hemoglobin concentrations. Adverse effects are dose-related. Parenteral preparations are indicated for initial treatment of iron deficiency or if oral preparations cannot be tolerated or are not feasible (eg, in neonatal pigs). Iron dextrans can be given as a single IM injection (100 mg) at 2–4 days of age in newborn piglets. Toxicity may be seen and is manifest as pale skin, bloody diarrhea, and shock (see p 3077). When efficacy of parenteral preparations is compared, dextran complexes and hydrogenated dextrans are more effective than dextrans. Hemoglobin formation requires pyridoxine and the trace elements copper and cobalt (necessary for B₁₂ synthesis by ruminal microflora). "Shotgun" preparations contain a combination of hematonic agents; the efficacy of such products is questionable. As with any hematonic preparation, provision of these compounds will be ineffective if the nutritional status of the animal is poor.

Epoetin alfa is the synthetic form of the human glycoprotein erythropoietin (ERP). Epoetin alfa is indicated in treatment of anemia associated with chronic renal failure in dogs and cats. The initial dosage

is 100 U/kg, SC, 3 times/wk for 4 mo, while monitoring PCV, followed by a maintenance dosage of 75–100 U/kg, SC, 2–3 times/wk. The most significant adverse effects in dogs and cats are development of antibodies to ERP, resistance to treatment, and worsening of anemia. Other potential adverse effects include iron deficiency, hypertension, fever, local cellulitis, arthralgia, mucocutaneous ulcers, polycythemia, and CNS disturbances (seizures).

Anabolic steroids are compounds structurally related to testosterone that have similar protein-anabolic activity but minimal androgenic effects, such as masculinization. As part of their anabolic activity, these compounds increase the circulating RBC mass and possibly granulocytic mass. Clinical indications for use of anabolic steroids include chronic, nonregenerative anemias. Response to therapy is variable, and the time to clinical improvement is long, frequently ≥3 mo. The proposed mechanisms of action include increased ERP production via ERP-stimulating factor, differentiation of stem cells into ERP-stimulating factor-sensitive cells (eg, hemocytoblasts), and direct stimulation of erythroid-progenitor cells. The effect of anabolic steroids requires adequate ERP levels and sufficient cells in the bone marrow. Thus, the effectiveness of anabolic steroids in treating anemia may be limited, depending on the cause.

Anabolic steroids can be divided into two categories depending on the presence or absence of an alkyl group at the 17-carbon position. They are available as oral and parenteral preparations, including oil-based products intended for slow release. The absorption and disposition of anabolic steroids depend on the type of preparation and the animal species. Most are eliminated after hepatic metabolism. The alkylated products are more effectively absorbed when given PO and are more effective stimulants of bone marrow. Alkylated anabolic steroids include oxymetholone (dogs and cats: 1–5 mg/kg, PO, every 18–24 hr). Nonalkylated anabolic steroids include nandrolone decanoate (dogs: 1–1.5 mg/kg/wk, IM; cats: 1 mg/kg/wk, IM; horse: 1 mg/kg, IM, once every 4 wk). Boldenone undecylenate is approved for horses at 1.1 mg/kg, IM, every 3 wk. Adverse effects of anabolic steroids include sodium and water retention, virilization, and hepatotoxicity. The alkylated products are more hepatotoxic than the nonalkylated products, particularly in cats. Cholestatic liver damage develops early and can be significant but frequently is reversible.

Hemostatics

Lyophilized concentrates of one or more clotting factors are available as topical or local hemostatics. Most act to provide an artificial factor or structural matrix that facilitates control of capillary bleeding. An intact hemostatic mechanism is necessary. These absorbable products are indicated for capillary oozing from small, superficial vessels. Concentrated factors include thromboplastin, thrombin (available as a powder, solution, or sponge), collagen, and fibrinogen. Artificial matrices include fibrin foam, absorbable gelatin sponge, and oxidized cellulose.

Astringents act locally by precipitating proteins. These agents do not penetrate tissues and, thus, are restricted to surface cells. They can be damaging to surrounding tissues. Examples include ferric sulfate, silver nitrate, and tannic acid.

Epinephrine and norepinephrine are hemostatics by virtue of their vasoconstrictive effects. They may be included in topical medications to decrease blood flow to the tissues, or applied intranasally in tampons to decrease epistaxis.

Systemic hemostatics include fresh blood or blood components administered to animals that have a coagulation factor deficiency. Examples include fresh plasma, fresh frozen plasma, cryoprecipitate, and platelet-rich plasma.

Vitamin K is a hemostatic only in instances of vitamin K deficiency. It is necessary for hepatic synthesis of coagulation factors II, VII, IX, and X. The principal indication is treatment of rodenticide toxicity, moldy sweet clover poisoning (dicumarol), and sulfaquinoxaline toxicity.

Vitamin K₁ (phytonadione) is a plant form of vitamin K that is safer and more effective with more rapid restoration of coagulation factors than other analogues such as vitamin K₃ (menadione). The preferred routes to administer phytonadione are SC and PO, although it can be given by slow IV (anaphylactic reactions have been reported) or IM injections. After IM administration, bleeding may occur at the injection site. The dosage regimen selected depends on the nature of the anticoagulant toxicity. Vitamin K₁ must be given as long as the anticoagulant is present in the body at toxic levels; this duration varies depending on the rodenticide. Second-generation coumarin derivatives or indanediones are potent and have long half-lives. Several weeks of vitamin K₁ therapy may be necessary after ingestion of these long-acting rodenticides. Coagulation status should be monitored

during therapy. The lag period after administration of phytonadione and synthesis of new clotting factors is 6–12 hr.

Desmopressin is a synthetic analogue of vasopressin and is used to treat diabetes insipidus. In animals with von Willebrand disease, desmopressin transiently increases von Willebrand factor and shortens bleeding time. It may be useful in dogs with von Willebrand disease (0.4 mcg/kg, SC; 1 mcg/kg, IV, diluted in 20 mL of saline and given over 10 min), to permit surgical procedures or control capillary bleeding.

Anticoagulants

Anticoagulants interfere either directly or indirectly with the clotting cascade.

Heparin is a heterogeneous mixture of sulfated (anionic) mucopolysaccharides named because of its initial discovery in high concentrations in the liver. It is prepared from porcine intestinal mucosa and bovine lung. It acts indirectly to facilitate endogenous anticoagulants, specifically antithrombin III and heparin cofactor II. These molecules form stable complexes with (and thus inactivate) clotting factors, especially thrombin. Heparin is released in its active form after inactivation of the clotting factor and thus can interact with other molecules. The effect is greater with low concentrations of heparin. Heparin is also antithrombotic due to binding to endothelial cell walls, thus impairing platelet aggregation and adhesion.

Clinical indications for heparin therapy include the prevention or treatment of venous or pulmonary embolism and embolization associated with atrial fibrillation. It is also used as an anticoagulant for diagnostic use and blood transfusions. Heparin is used in conjunction with blood and/or plasma to treat disseminated intravascular coagulation (DIC) and other hypercoagulable conditions. It has also been used to clear hyperlipidemia.

Heparin is available as a sodium or calcium salt. Absorption and distribution of heparin are limited by the large size and polarity of the molecule. Oral absorption is poor; hence, it is a parenteral anticoagulant. Although anticoagulant activity is first order, half-life of the drug is dose-dependent, steady-state concentrations are difficult to achieve, and pharmacokinetics vary among individuals. Heparin is metabolized by heparinase in the liver and by reticuloendothelial cells. Metabolites of heparinase activity are excreted in the urine. The half-life is prolonged in renal or hepatic failure.

Heparin can be given IV (either intermittently or as a constant infusion) or SC. Deep SC or intrafat injection prolongs persistence of therapeutic concentrations. Large hematomas can develop after deep IM injection. High-dose heparin therapy (dogs: 150–250 U/kg, SC, tid; cats: 250–375 U/kg, SC, bid) has been recommended for established thromboembolism. Lower dosages (dogs and cats: 75 U/kg, SC, tid; horses: 25–100 U/kg, SC, tid) are indicated in management of DIC. Blood coagulation times (eg, activated partial thromboplastin time) should be monitored during therapy. Adverse effects and toxicities of heparin are limited to potential hemorrhage and, because heparin is a foreign protein, possible allergic reactions. Heparin is contraindicated in bleeding animals and in DIC unless replacement blood or plasma therapy is also given.

Low-molecular-weight heparins (LMWHs, eg, dalteparin and enoxaparin) are alternatives to “unfractionated heparin” and are used extensively in people as anticoagulants for various thromboembolic conditions. LMWHs differ from heparin in that the molecular weights are approximately one-tenth that of heparin, dosing can be once to twice daily in people, there is no need to monitor activated partial thromboplastin time, the risk of bleeding and thrombocytopenia is smaller, and the effect on thrombin is less than that of heparin. LMWHs target antifactor Xa activity. Limited efficacy, safety, and dosing data are available to guide use in veterinary medicine. However, a suggested dosage regimen for dalteparin in dogs and cats is 100–200 IU/kg, SC, once to twice daily, and a suggested dosage regimen for enoxaparin in dogs and cats is 1–2 mg/kg, SC, bid, while monitoring prothrombin time. Individual responses to LMWHs appear to be quite variable in cats.

Vitamin K antagonists (oral anticoagulants) differ from heparin primarily in their duration of activity and magnitude of effect. Their primary importance has been because of their toxic rather than therapeutic effects. Therapeutic indications include oral long-term treatment and prevention of recurrence of thrombotic conditions (eg, aortic or pulmonary thromboembolism and venous thrombosis) in cats, dogs, and horses.

There are several groups of vitamin K antagonists. They interfere with the hepatic synthesis of vitamin K–dependent clotting factors by blocking the reduction of vitamin K epoxide after clotting factor synthesis, thus effectively reducing the concentration

of vitamin K. Their anticoagulant activity (and therefore therapeutic or toxic effect) is delayed for 8–12 hr after administration or accidental ingestion because of the persistence of factors synthesized before administration. Factor VII has the shortest half-life and is the first factor to become deficient.

The vitamin K antagonists are rapidly and completely absorbed after administration PO. Levels peak in 1 hr. They are almost totally protein bound in plasma, and their volume of distribution is limited to the plasma volume. They are metabolized by the liver to primary metabolites and then conjugated to glucuronides. They undergo an enterohepatic cycle. A variety of factors can increase the activity of these drugs, including hypoproteinemia, antimicrobial therapy, hepatic disease, hypermetabolic states, pregnancy, and the nephrotic syndrome. The potential for drug interactions is significant. Because they are highly protein bound, they can be displaced by other drugs that are protein bound (eg, acetylsalicylic acid and phenylbutazone), and their anticoagulant effects can be increased to the point of toxicity. Drug interactions also are seen with other antihemostatics.

Warfarin sodium is the most commonly used therapeutic preparation. The dosage is 0.1–0.2 mg/kg/day, PO, for dogs and cats, and 0.067–0.167 mg/kg/day, PO, for horses. Toxicity, manifest as hemorrhage, is a major concern with vitamin K antagonists. Coagulation times (particularly prothrombin time), CBCs, and clinical evidence of bleeding (eg, occult blood in feces and urine) must be monitored carefully during warfarin therapy.

Fibrinolytic agents increase the activity of plasmin (fibrinolysin), the endogenous compound responsible for dissolving clots. The inactive precursor of plasmin is plasminogen, which exists in two forms: plasma soluble form and fibrin (clot) bound form. Streptokinase and streptodornase are synthesized by streptococci and activate both forms of plasminogen. They are used locally as a powder, infusion, or irrigation in treatment of selected chronic wounds (eg, burns, ulcers, chronic eczemas, ear hematomas, otitis externa, osteomyelitis, chronic sinusitis, or other chronic lesions) that have not responded to other therapy. Tissue-type plasminogen activator (tPA) preferentially activates the fibrin-bound form of plasminogen. Unlike parenterally administered streptokinase, tPA does not induce a systemic proteolytic state. Selective clot lysis occurs without

increasing circulating plasmin; thus, tPA has a lower risk of bleeding than does parenteral streptokinase. Although tPA has been used to treat aortic thromboembolism in cats (0.25–1 mg/kg/hr, IV, for a total dosage of 1–10 mg/kg), both the risk of death due to reperfusion (and release of toxic metabolites) and the expense of this genetically engineered product may limit its use.

Antithrombotic drugs affect platelet activity, which is normally controlled by substances (such as prostaglandins) generated both outside and within the platelet. Platelet activity can be modulated by interacting with these substances. NSAIDs inhibit the formation of cyclooxygenase, the enzyme responsible for synthesis of prostaglandin products from arachidonic acid that has been released into cells and platelets. The formation of all prostaglandins is inhibited, including that

of thromboxane, a potent platelet aggregator and vasoconstrictor. In addition to its inhibitory effects on cyclooxygenase, aspirin irreversibly acetylates thromboxane synthetase, the specific enzyme responsible for synthesis of thromboxane. Aspirin is a potent inhibitor of platelet activity; new platelets must be generated before the effects of aspirin on platelet activity disappear. At higher dosages, aspirin inhibits prostacyclin, a prostaglandin product that counteracts the thrombogenic effects of thromboxane. Thus, aspirin must be used cautiously for antiplatelet effects. The antiplatelet dosage for dogs is 5–10 mg/kg, PO, every 24–48 hr, and for cats 80 mg, PO, every 48–72 hr. Clopidogrel is an antithrombotic agent used in small animals in treatment of autoimmune hemolytic anemia and in cats with aortic/pulmonary thromboembolism.

SYSTEMIC PHARMACOTHERAPEUTICS OF THE DIGESTIVE SYSTEM

See also PRINCIPLES OF THERAPY OF GI DISEASE, p 161.

THE MONOGASTRIC DIGESTIVE SYSTEM

DRUGS AFFECTING APPETITE

Disorders of appetite are very common in veterinary patients. Obesity from overfeeding is common in companion animals and is best managed by educating the owner and regulating the animal's diet. Anorexia is a common clinical problem seen with many systemic diseases, which exacerbates disease-induced catabolism. In the anorexic animal that does not respond to coaxing with small quantities of highly palatable foods, drug therapy may be used to stimulate appetite. The effect of specific drugs on food intake can involve hunger, satiety, or enhancement of the positive evaluation of taste.

Appetite Suppression: Dirlotapide is a microsomal triglyceride transfer protein (MTP) inhibitor developed specifically for weight loss in dogs. MTP catalyzes the assembly of triglyceride-rich apolipoprotein B-containing lipoproteins to form

chylomicrons in the intestinal mucosa and very low-density lipoproteins in the liver. After oral administration, dirlotapide has in vivo selectivity for intestinal MTP. The mechanism of weight loss action is not completely understood, but dirlotapide appears to reduce fat absorption and send a satiety signal from lipid-filled enterocytes. Dirlotapide also decreases appetite in a dose-dependent manner, probably via increased release of peptide YY into the circulation. The decrease in food intake is responsible for most of the weight reduction effect.

Dirlotapide is available systemically, but absorption in dogs is highly variable. Absorbed dirlotapide is metabolized in the liver; parent drug and metabolites are secreted in the bile, with potential for enterohepatic circulation. Although blood concentrations do not directly correlate with effectiveness (effectiveness has been linked to drug concentrations in the gut), they seem to correlate with systemic toxicity.

Dirlotapide is available as a 5 mg/mL solution for oral administration. The dosage is adjusted according to the weight loss of each individual dog. The initial dosage of 0.5 mg/kg is doubled after 14 days and then

adjusted monthly; the maximum permitted daily dosage is 1 mg/kg, although dosages as high as 10 mg/kg have been administered to dogs without severe adverse effects in safety studies. Dirlotapide can be used without changing the dog's current feeding or exercise regimens, but food intake should be monitored during weight stabilization to establish feeding and exercise routines that will minimize weight gain after treatment. Anorexia, emesis, and loose feces occur in some dogs. The incidence of emesis generally increases with dose and decreases with treatment time. Increases in hepatic transaminase activity were seen in dogs treated with >1.5 mg/kg/day but were not associated with clinical signs or histopathologic evidence of hepatic degeneration or necrosis.

Dirlotapide should not be used in cats. It increases the risk of hepatic lipidosis during weight loss in obese cats. Dirlotapide is not recommended for use in dogs currently receiving longterm glucocorticoid therapy or in dogs with liver disease. In people, adverse reactions associated with ingesting dirlotapide include abdominal distention, abdominal pain, diarrhea, flatulence, headache, increased serum transaminases, nausea, and vomiting.

Appetite Stimulation: Anabolic steroids are synthetic derivatives of testosterone that have enhanced anabolic effects with reduced androgenic effects. Anabolic steroids do not directly affect hunger, satiety, or sensory perception of food. Instead, they antagonize the catabolic effect of glucocorticoids and the negative nitrogen balance associated with surgery, illness, trauma, and aging. In all cases, improved nitrogen balance depends on adequate protein/calorie intake and

treatment of the underlying disease.

Anabolic steroids stimulate hematopoiesis, appetite, and weight gain. Adverse effects of anabolic steroid therapy include hepatotoxicity, masculinization, and early closure of bony epiphyses in young animals. Anabolic steroids are contraindicated in animals with congestive heart failure because of sodium and water retention. Because of human abuse potential, anabolic steroids are controlled substances. Although once (in)famous for abuse in people and horses, stanozolol and boldenone undecylenate are no longer marketed by veterinary pharmaceutical companies in North America. Currently, any anabolic product for veterinary use can only be obtained from a compounding pharmacy. Use of anabolic steroids in performance horses is prohibited by most equine sport organizations, and detection times can be >2 mo.

Glucocorticoids increase gluconeogenesis and antagonize insulin for an overall hyperglycemic effect. Appetite is stimulated by the steroid-induced euphoria. Continued use of glucocorticoids has catabolic effects because skeletal muscle and collagen proteins are broken down to provide the precursors for gluconeogenesis.

When used as anxiolytics, the **benzodiazepines** (BZD) became well known for their appetite stimulation effects independent of their anxiolytic activity. Stereospecific binding of a BZD to GABA A receptors in the parabrachial nucleus produces a strong dose-dependent (ie, voracious) increase in food consumption. Hunger level and degree of satiety has no effect on BZD-induced food intake. So, it appears that the BZDs do not modulate hunger or satiety directly but act specifically to enhance taste and other sensory characteristics of food. By manipulating the stereospecificity of the

TABLE 2 DRUGS USED TO STIMULATE APPETITE

Drug	Dosage
Diazepam	Cats: 0.005–0.4 mg/kg, IV
Oxazepam	Cats: 2 mg, PO, bid
Cyproheptadine	Cats: 1–4 mg, PO, bid
Mirtazapine	Cats: 3.75 mg/cat (¼ of a 15-mg tablet), PO, every 3 days Dogs: ¼ of a 15-mg tablet for dogs <7 kg, ½ of a 15-mg tablet for dogs 8–15 kg, 15 mg for dogs 16–30 kg, 30 mg for dogs >30 kg; no higher than 30 mg per dog
Megestrol acetate	Dogs: 5 mg/kg/day, PO
Prednisone/prednisolone	1 mg/kg, PO, every other day

BZD drugs, appetite-selective partial agonist compounds have been developed that have actions dissociated from the other major effects of full agonists (eg, amnesia, sedation, incoordination, anxiolysis). Likewise, inverse agonists of the BZD receptors reduce food consumption. BZD receptor antagonists block the appetite-stimulating effects of the full or partial agonists, as well as the appetite-suppressive effects of the inverse agonists. So, there is a bidirectional control of food intake mediated by a common subset of BZD receptors. Levels of food intake, ranging from voracious consumption at one extreme to complete anorexia at the other, with every level in between, can be achieved by the relative concentration of agonists and inverse agonists binding to those BZD receptors specifically involved in the control of appetite. **Diazepam** is an appetite stimulant when administered IV to cats. If responsive, cats begin eating within a few seconds of IV administration, so palatable food should be available before injection. **Oxazepam**, a metabolite of diazepam, can be given orally to cats. Diazepam is the more effective appetite stimulant but also causes a greater sedative effect than oxazepam.

Cyproheptadine is an antihistamine with serotonin-antagonist action used clinically in cats as an appetite stimulant. It acts as a 5-HT₂ receptor antagonist. The lateral hypothalamus normally excretes endogenous opiates, which stimulate eating. The release of these endogenous opiates is inhibited by serotonin and cholecystokinin release, thus inhibiting eating. Cats are very sensitive to changes in serotonin concentrations, so serotonin antagonists are very potent in cats. CNS excitement and aggressive behavior may occur in some cats.

Mirtazapine is an antidepressant used to treat moderate to severe depression in people. Mirtazapine is not a serotonin or norepinephrine reuptake inhibitor (SSRIs such as fluoxetine are noted to decrease appetite). It is an antagonist of presynaptic α_2 -adrenergic autoreceptors and heteroreceptors on both norepinephrine and serotonin (5-HT) presynaptic axons, plus is a potent antagonist of postsynaptic 5-HT₂ and 5-HT₃ receptors. This mechanism of action maintains equivalent antidepressant efficacy but minimizes many of the adverse effects common to both tricyclic antidepressants and SSRIs. Because of its unique pharmacologic profile, mirtazapine usually does not cause anticholinergic effects, serotonin-related adverse effects, or

adrenergic adverse effects (orthostatic hypotension and sexual dysfunction). Antihistaminic drowsiness is a common effect. Mirtazapine is used for disease conditions in which inappetence and nausea go together, such as in the treatment of GI disease or liver or kidney disease. Mirtazapine can also be used to alleviate the nausea and appetite loss that accompanies chemotherapy. α -Adrenergic receptors in the chemoreceptor trigger zone are important in inducing emesis in cats. Clinically, mirtazapine is an effective appetite stimulant and antiemetic for cats with chronic kidney disease and appears to be a useful adjunct in nutritional management of these cats. There is little pharmacokinetic information on mirtazapine in dogs and cats, but mirtazapine shows sexual effects in hepatic metabolism in people, so it is likely there is similar variation in metabolism in dogs and cats and the potential for variation in efficacy.

Mirtazapine is typically given once a day to dogs and twice a week to cats. It should be used with caution in dogs and cats with severe liver or kidney disease, because mirtazapine clearance will be reduced. In cats and small dogs, it is difficult to reduce the dose, because the smallest tablet manufactured cannot be accurately cut much smaller than the regular dosing schedule allows. In this situation, a compounding pharmacy could be employed to create a lower dose, or the dosing schedule can be extended. This is especially important for cats with liver disease.

Megestrol acetate is a synthetic progestin. It has significant antiestrogen and glucocorticoid activity, with resulting adrenal suppression. It is used to stimulate appetite and promote weight gain in people with cancer and cachexia (related to acquired immunodeficiency syndrome) and may have a similar effect in anorectic cats and dogs. Megestrol acetate is contraindicated in pregnant animals and in animals with uterine disease, diabetes mellitus, or mammary neoplasia. In cats, megestrol acetate can induce a profound adrenocortical suppression, adrenal atrophy, and diabetes mellitus, which may or may not be reversible. Toxicity is less of a problem in dogs.

Other drugs used as appetite stimulants include **B vitamins** and **glucocorticoids**. B vitamin preparations are administered orally and parenterally to debilitated animals, especially horses, to promote appetite. Glucocorticoids increase gluconeogenesis and antagonize insulin for an overall hyperglycemic effect. Appetite is

stimulated by the steroid-induced euphoria. Continued use of glucocorticoids results in catabolic effects, as skeletal muscle and collagen proteins are broken down to provide the precursors for gluconeogenesis.

DRUGS TO CONTROL OR STIMULATE VOMITING

Animals possess an arsenal of special abilities for survival, many of which are used for food consumption. Ingesting food can lead to exposure of internal organs to possible food-related disorders, including viral and bacterial infection, toxins, and allergens. Smell and taste are not always effective in determining the quality of food, so nausea, vomiting, and diarrhea are additional mechanisms of defense of the GI system.

Humorally mediated emesis results from emetogenic substances in the systemic circulation that activate the chemoreceptor trigger zone (CRTZ) in the area postrema. The CRTZ lies outside the blood-brain barrier. Neurally mediated emesis results from activation of an afferent neural pathway typically coming from the abdominal viscera and synapsing at one or more nuclei in the emetic center. Most pharmacologic interventions focus on the humoral pathway of emesis, based on neurotransmitter interactions at the CRTZ. The neural pathway has received less emphasis, even though it is a much more important pathway.

Nausea is an aversive experience that often accompanies emesis; it is a distinct perception, different from pain or stress. Nausea is more difficult to treat than emesis using antiemetic drugs. This became apparent with the excellent control of drug-induced emesis from cancer chemotherapy, but human patients still experience nausea. This suggests that nausea and vomiting are separate physiologic processes.

Motion-induced emesis appears to have a very early evolutionary origin, because it is present in most animal models of emesis. Motion sickness is thought to result from sensory conflict regarding the body's position in space, yet there is no satisfactory theory as to why people and animals have this mechanism in the first place.

Nausea and vomiting, as defense systems of the GI tract, by necessity must have a low threshold for activation. Cats are well known for their tendency to vomit, particularly when attempting to dislodge hairballs from the throat or upper GI tract. Chronic vomiting in cats may indicate

underlying thyroid, liver, or kidney dysfunction and should be investigated. Dogs also vomit often (frequently after eating grass) and often eat their own vomit.

Neurotransmitters of Emesis:

Acetylcholine (muscarinic receptors) and substance P (NK-1 receptors) act on the emetic center. The CRTZ is stimulated by dopamine (D2 receptors), α_2 -adrenergic drugs (NE receptors), serotonin (5-HT3 receptors), acetylcholine (M1 receptors), enkephalins, and histamine (H1 and H2 receptors).

α -Adrenergic receptors in the CRTZ are important in inducing emesis in cats.

α_2 -Adrenergic agonists (eg, xylazine) are more potent emetics in cats than in dogs.

5-HT1A antagonists (eg, buspirone) and α_2 -adrenergic antagonists (eg, acepromazine, yohimbine, mirtazapine) suppress vomiting in cats.

CRTZ D2 dopamine receptors are not as important in mediating humoral emesis in cats as they are in dogs. Apomorphine, a D2 dopamine receptor agonist is a more reliable emetic in dogs than cats, and D2 dopamine receptor antagonists (eg, metoclopramide) are not very effective antiemetic drugs in cats.

Histamine H1 and H2 receptors are found in the CRTZ of dogs but not cats. Histamine is a potent emetic in dogs but not cats, and H1 antagonists (eg, diphenhydramine) are ineffective for motion sickness in cats.

Muscarinic M1 receptors are found in the vestibular apparatus of cats. Mixed M1/M2 antagonists (eg, atropine) inhibit motion sickness in cats.

Substance P binds to NK-1 receptors, which are found in the gut and the emetic center of the CNS. Substance P induces emesis, and selective substance P antagonists (eg, maropitant) are potent antiemetics in both dogs and cats with a broad spectrum of activity against a variety of emetic stimuli.

Emetic Drugs: Emetic drugs are usually administered in emergency situations after ingestion of a toxin (see TABLE 3). They generally remove <80% of the stomach contents. The most reliable emetic drugs act centrally to stimulate the vomiting center, either directly or via the CRTZ.

Apomorphine is an opioid drug that acts as a potent central dopamine agonist to directly stimulate the CRTZ. Therefore, it is less effective in cats than in dogs. It can be administered PO, IV, or SC; the IM route is not as effective. It can also be applied directly to conjunctival and gingival

TABLE 3 EMETIC DRUGS

Drug	Dosage
Apomorphine	Dogs: 4 mg/kg, PO; 0.02 mg/kg, IV; 0.3 mg/kg, SC; 0.25 mg in the conjunctival sac
Xylazine	Cats: 0.4–0.5 mg/kg, IV or IM
Hydrogen peroxide	Dogs: 5–10 mL, PO

membranes, using the tablet formulation, which can easily be removed once emesis is initiated. Vomiting usually occurs in 5–10 min. Although apomorphine directly stimulates the CRTZ, it has a depressant effect on the emetic center. Therefore, if the first dose does not induce emesis, additional doses are not helpful. Because the vestibular apparatus may also be involved in apomorphine-induced vomiting, sedate and motionless animals will not vomit as readily as active animals. Excitement that results from apomorphine in cats can be treated with the opioid antagonist naloxone.

Xylazine is an α_2 -adrenergic agonist used primarily for its sedative and analgesic action. It is a reliable emetic, particularly in cats, in which it stimulates the CRTZ. Because xylazine can produce profound sedation and hypotension, animals should be closely monitored after administration.

Hydrogen peroxide (3%) applied to the back of the pharynx stimulates vomiting via the ninth cranial nerve. Small doses (5–10 mL) of hydrogen peroxide can be administered via oral syringe until emesis occurs. It should be administered cautiously, especially in cats, because aspiration of hydrogen peroxide foam causes severe aspiration pneumonia. When small amounts are administered, 3% hydrogen peroxide is relatively nontoxic. Stronger concentrations (eg, hair dye peroxide) are more toxic.

Other products have been used but are not recommended to induce emesis in dogs and cats. **Syrup of ipecac** is no longer recommended for “home use” in people or animals. The active ingredient is emetine, a toxic alkaloid, which produces vomiting by acting as a stomach irritant. If repeated use fails to induce emesis, then gastric lavage is necessary to remove the emetine to prevent additional toxicosis. Although sometimes suggested, **sodium chloride (salt)** and **powdered mustard** should not be used. Mustard is rarely effective and can be inhaled and cause lung damage, whereas salt toxicity can easily occur if overdosed and can result in fatal cerebral edema.

Antiemetic Drugs: Protracted vomiting is physically exhausting and can cause dehydration, acid-base and electrolyte disturbances, and aspiration pneumonia. Antiemetic drugs are used to control excessive vomiting once an etiologic diagnosis has been made, to prevent motion sickness and psychogenic vomiting, and to control emesis from radiation and chemotherapy (see TABLE 4). Antiemetics may act peripherally to reduce afferent input from receptors or to inhibit efferent components of the vomiting reflex response. They may also act centrally to block stimulation of the CRTZ and emetic center.

The **phenothiazine tranquilizers** are α_2 -adrenergic antagonists and antagonize the CNS stimulatory effects of dopamine and decrease vomiting from a variety of causes, including motion sickness in cats. These drugs also have antihistaminic and weak anticholinergic action. Phenothiazine tranquilizers used as antiemetics include acepromazine, chlorpromazine, and prochlorperazine. Potential adverse effects include hypotension due to α -adrenergic blockade, excessive sedation, extrapyramidal signs, and a lowering of the seizure threshold in animals with epilepsy. Extrapyramidal signs can be counteracted with an antihistamine (eg, diphenhydramine).

The **anticholinergic drugs** block cholinergic afferent pathways from the GI tract and the vestibular system to the vomiting center. Alone, they are less effective than the other emetics. Aminopentamide is approved for use in dogs and cats in the USA as an injectable formulation and oral tablets. It should be more efficacious in the treatment of motion sickness in cats than in dogs, because muscarinic M1 receptors are found in the vestibular apparatus of cats. Aminopentamide has low efficacy for other causes of vomiting.

The **antihistamines** can block both cholinergic and histaminic nerve transmission responsible for transmission of the vestibular stimulus to the vomiting center of

TABLE 4 ANTIEMETIC DRUGS

Drug	Dosage
Acepromazine	0.025–0.2 mg/kg, IV, IM, SC, maximum 3 mg; 1–3 mg/kg, PO
Chlorpromazine	0.5 mg/kg, IV, IM, SC, tid-qid
Prochlorperazine	0.1 mg/kg, IM, tid-qid; 1 mg/kg, PO, bid
Aminopentamide	0.022 mg/kg, PO, SC, or IM, bid-tid
Dimenhydrinate	4–8 mg/kg, PO, tid
Diphenhydramine	2–4 mg/kg, PO, tid
Butorphanol	0.2–0.4 mg/kg, IM, once to twice daily
Metoclopramide	0.1–0.5 mg/kg, IM, SC, or PO, tid; 0.01–0.02 mg/kg/hr, IV infusion
Ondansetron	0.1–0.2 mg/kg, PO, once to twice daily; 0.1–0.15 mg/kg, IV, bid-tid
Granisetron	0.5–1 mg/kg, PO, bid; 0.1–0.15 mg/kg, IV, bid-tid
Dolasetron	0.6–1 mg/kg/day, IV
Maropitant	2 mg/kg, PO or 1 mg/kg/day, SC, for up to 5 days (acute vomiting); 8 mg/kg/day, PO, for up to 2 days (motion sickness)

dogs. The commonly used histamine (H₁) blocking drugs are diphenhydramine and dimenhydrinate (diphenhydramine plus 8-chlorotheophylline). They may cause mild sedation, especially diphenhydramine, but paradoxical CNS stimulation may also occur, presumably from anticholinergic effects.

Metoclopramide exerts its antiemetic effects via three mechanisms. At low doses, it inhibits dopaminergic transmission in the CNS, whereas at high doses, it inhibits serotonin receptors in the CRTZ. Peripherally, metoclopramide increases gastric and upper duodenal emptying. Metoclopramide is a useful antiemetic for dogs. Because CRTZ D₂ dopamine receptors are not very important in mediating humoral emesis in cats, metoclopramide is less effective in cats than in dogs. It is used to control emesis induced by chemotherapy, nausea and vomiting associated with delayed gastric emptying, reflux gastritis, and viral enteritis. There is tremendous individual variability in metoclopramide pharmacokinetics, and oral bioavailability is only ~50% because of a significant first-pass effect. At high doses or with rapid IV administration, metoclopramide causes CNS excitement by dopamine antagonism (similar to the phenothiazine tranquilizers). Extrapyramidal signs can be counteracted with an antihistamine such as diphenhydramine. Metoclopramide should not be administered if a GI obstruction or perforation is suspected.

The **serotonin antagonists** ondansetron, granisetron, and dolasetron are specific inhibitors of serotonin subtype 3 receptors in the CRTZ. These receptors are located peripherally on vagal nerve terminals and centrally in the area postrema of the brain. Cytotoxic drugs and radiation damage the GI mucosa, causing release of serotonin. These are the most effective antiemetics used in people undergoing radiation and chemotherapy, and they have been used in cats and dogs receiving chemotherapy. Although very effective at controlling vomiting associated with chemotherapy and drug-induced vomiting, these drugs do not prevent or relieve nausea, which may be more debilitating than vomiting. They are not effective for emesis caused by motion sickness. All serotonin subtype 3 antagonists have been associated with prolongation of the QT interval in people. Adverse effects of dolasetron include ECG changes (PR and QT prolongation, QRS widening) caused by dolasetron metabolites that block sodium channels.

Butorphanol is an effective antiemetic for dogs receiving cisplatin chemotherapy. It causes only mild sedation. It is believed to exert its antiemetic effect directly on the vomiting center.

Maropitant is a neurokinin 1 (NK-1) receptor antagonist approved to treat and prevent emesis in dogs and cats. Substance P is a regulatory peptide that binds to the NK-1 receptors and induces emesis. NK-1

receptor antagonists are believed to provide antiemetic activity by suppressing activity at the nucleus of the solitary tract, where vagal afferents from the GI tract converge with inputs from the CRTZ and other regions of the brain involved in the control and initiation of emesis. Despite its selectivity for the NK-1 receptor, maropitant blocks apomorphine, cisplatin, and syrup of ipecac-induced vomiting in dogs, which suggests that activation of the nucleus of the solitary tract is a final common step in the initiation of emesis. Despite being very effective antiemetics in people, NK-1 receptor antagonists have little effect on chemotherapy-associated nausea in people or hydromorphone-induced nausea in dogs.

Maropitant injectable is approved for vomiting in cats ≥ 16 wk old and acute vomiting in dogs ≥ 8 wk old at 1 mg/kg/day. Maropitant tablets are approved for acute vomiting in dogs ≥ 8 wk old (2 mg/kg), and to prevent vomiting due to motion sickness in dogs ≥ 16 wk older (8 mg/kg). Dogs should not be fed for 1 hr before giving maropitant. The best time to give maropitant is 2 hr before travelling, with a small amount of food. The tablets should not be wrapped tightly in fatty food such as cheese or meat, because this may keep the tablets from dissolving and delay the effect of maropitant.

Adverse effects are rare with maropitant, but the most common ones are excessive

drooling, lethargy, lack of appetite, and diarrhea. Maropitant injections may also cause a stinging sensation; this can be minimized by keeping the injectable solution refrigerated and, once the drug is drawn up, injecting right away at the refrigerated temperature. A few dogs may vomit after treatment. Giving maropitant with a small amount of food will help avoid this.

THERAPY OF GASTROINTESTINAL ULCERS

GI ulceration is a common problem in small and large animals, in association with physiologic stress (endogenous cortisol), dietary management, or as a sequela of administration of ulcerogenic drugs (see p 393 and see p 218). *Helicobacter* organisms, the most frequent cause of ulcers in people, appear to be involved in some cases of gastritis in animals (see p 394). Antiulcerative drugs include antagonists that interact with stimulatory receptors (histamine H_2 -receptor antagonists, muscarinic receptor antagonists, and gastrin receptor antagonists), agonists that interact with inhibitory receptors (somatostatin and prostaglandin E analogues), and irreversible inhibitors of H^+/K^+ -ATPase (proton pump inhibitors). Antiulcerative drugs are listed in TABLE 5.

TABLE 5 ANTIULCERATIVE DRUGS

Drug	Dosage
Antacids	2–10 mL, PO, every 2–4 hr
Sucralfate	Cats: 250 mg, bid-tid Dogs: 500 mg to 1 g, tid-qid Foals: 1–2 g, qid
Cimetidine	Dogs: 5–10 mg/kg, PO, qid Horses: 4 mg/kg, IV, bid; 18 mg/kg, PO, bid
Ranitidine	Dogs: 0.5 mg/kg, PO, SC, or IV, bid Horses: 1.3 mg/kg, IV, bid; 11 mg/kg, PO, bid
Famotidine	Dogs: 0.5–1 mg/kg/day, PO or IV Horses: 0.4 mg/kg, IV, bid; 3 mg/kg, PO, bid
Omeprazole	Dogs: 0.5–1 mg/kg/day, PO Horses: 4 mg/kg/day, PO, for treatment; 2 mg/kg/day, PO, to prevent recurrence
Misoprostol	Dogs: 2–5 mcg/kg, PO, tid-qid

Antacids: The common antacids are bases of aluminum, magnesium, or calcium (aluminum hydroxide, magnesium oxide or hydroxide, and calcium carbonate). These drugs neutralize stomach acid to form water and a neutral salt. They are usually not absorbed systemically. In addition to their acid-neutralizing ability, antacids decrease pepsin activity, binding to bile acids in the stomach and stimulating local prostaglandin (PGE_2) production. Over-the-counter antacid preparations are combinations of magnesium hydroxide and aluminum hydroxide; such combinations optimize the buffering capabilities of each compound and balance the constipating effect (from aluminum hydroxide) and the laxative effect (from magnesium hydroxide). Up to 20% of the magnesium can be absorbed after administration PO and can cause hypermagnesemia in animals with renal insufficiency. Antacids frequently interfere with the GI absorption of concurrently administered drugs (eg, digoxin, tetracyclines, fluoroquinolones). Aluminum-containing antacids impair absorption of phosphate. Because they are difficult to administer and require frequent dosing, they are not as popular as newer therapies.

Sucralfate: Sucralfate is an antilcerative drug that has a cytoprotective effect on GI mucosa. It disassociates in the acid environment of the stomach to sucrose octasulfate and aluminum hydroxide. Sucrose octasulfate polymerizes to a viscous, sticky substance that creates a protective effect by binding to ulcerated mucosa. This prevents "back diffusion" of hydrogen ions, inactivates pepsin, and adsorbs bile acid. In addition, sucralfate increases the mucosal synthesis of prostaglandins, which have a cytoprotective role. Because sucralfate is not absorbed, it causes virtually no adverse effects. Dosage regimens are extrapolated from human dosages. Although sucralfate is frequently administered to horses and small animals as an ulcer preventive, there is little evidence of efficacy in animals, and it may prevent the absorption of truly useful drugs. Animals in renal failure may have increased aluminum absorption.

H_2 -Receptor Antagonists: Cimetidine, ranitidine, and famotidine are the commonly used H_2 -receptor antagonists. Ranitidine is 3–13 times as potent on a molar basis as cimetidine in inhibiting gastric acid secretion. Famotidine is 20–150 times as potent as cimetidine. In people, food tends to delay the absorption of

cimetidine, has minimal effect on ranitidine, and slightly enhances absorption of famotidine. Some evidence suggests that cimetidine strengthens the gastric mucosal defenses against ulceration and enhances cytoprotection. Cimetidine reduces the metabolism of other drugs (warfarin, phenytoin, lidocaine, metronidazole, theophylline) by inhibiting hepatic microsomal enzyme systems. Ranitidine interacts differently than cimetidine and only minimally (10%) inhibits hepatic metabolism of some drugs. Famotidine seems to have no effect on metabolism of other drugs. Antacids should be given 1 hr before or after cimetidine to avoid interactions. Famotidine may be given with antacids; ranitidine may be given with low doses of antacids. Sucralfate may alter absorption of cimetidine and ranitidine.

Cimetidine suppresses gastric acid secretion in dogs for 3–5 hr. Because ranitidine has a longer elimination half-life, it suppresses acid for up to 8 hr and it may be administered less frequently. Famotidine can be administered once a day. Oral bioavailability in horses for these drugs is only 10%–30%, so large oral doses must be administered.

Proton Pump Inhibitors: Proton pump inhibitors (PPIs) irreversibly block the H^+/K^+ -ATPase proton pump of the gastric parietal cell. They are given in an inactive form, which is neutrally charged (lipophilic) and readily crosses cell membranes into intracellular compartments (like the parietal cell canaliculus) that have acidic environments. The inactive drug is protonated, rearranges into its active form, and irreversibly binds to and deactivates the proton pump. The most widely used PPI is **omeprazole**. In dogs and horses, a single dose of omeprazole inhibits acid secretion for 3–4 days, despite a relatively short plasma half-life. This is because of accumulation of the drug in parietal cell canaliculi and the irreversible nature of proton pump inhibition. A specific equine product has been developed, because oral bioavailability of the human omeprazole formulation or compounded formulations is poor in horses. Although ulcers in horses will heal while on omeprazole therapy, they tend to recur once therapy is discontinued. Human formulations are used in dogs and cats. In people, adverse effects from suppression of gastric acid secretion include hypergastrinemia, which causes mucosal cell hyperplasia, hypertrophy of the gastric rugae, and eventually development of carcinoids. It has also been

associated with acute renal failure and disorders of calcium homeostasis, including fractures associated with longterm use. Studies in rodents show that PPIs can exacerbate NSAID-induced intestinal damage from significant shifts in enteric microbial populations. Prevention or reversal of this dysbiosis may be an important clinical consideration for reducing the incidence and severity of NSAID enteropathy. Therefore, omeprazole is contraindicated for chronic therapy. Omeprazole is also a microsomal enzyme inhibitor (to a similar extent as cimetidine). For animals that cannot receive oral medications, IV injectable formulations approved for people (pantoprazole and esomeprazole) can be considered for use.

Acid Rebound: Acid rebound is an increase in gastric acid secretion above pretreatment levels after discontinuation of antiulcer therapy. Rebound is reported after the use of histamine H_2 -receptor antagonists and PPIs and is thought to be due to increased serum gastrin and/or upregulation of the H_2 -receptors. An increased gastrin level, or hypergastrinemia, is a secondary effect that occurs during chronic inhibition of gastric acid secretion, such as with longterm antiulcer therapy. Gastrin is the primary regulator of gastric acid secretion, which is mediated by histamine released by the enterochromaffin-like (ECL) cell. Increased plasma gastrin stimulates and upregulates ECL cells to produce and release more histamine to stimulate parietal cells. In addition, an increase in parietal cell mass may occur with the chronic use of H_2 -blockers or PPIs, and this may be an

additional mechanism for increased acid secretion that occurs after discontinuation of therapy.

Misoprostol: Misoprostol is a synthetic prostaglandin E_1 analogue used in dogs to reduce the risk of GI ulcers induced by chronic NSAID therapy. Misoprostol suppresses gastric acid secretion by inhibiting the activation of histamine-sensitive adenylate cyclase. It has a cytoprotective effect from stimulation of bicarbonate and mucus secretion, increased mucosal blood flow, decreased vascular permeability, and increased cellular proliferation and migration. Misoprostol is clinically effective in preventing GI bleeding and ulceration from NSAID therapy but not from methylprednisolone sodium succinate, and it is less efficacious than H_2 -receptor antagonists or PPIs for treatment of ulcers. Adverse effects of misoprostol are mainly limited to diarrhea and flatulence. Magnesium-containing antacids may aggravate the diarrhea. Misoprostol is contraindicated in pregnant dogs, because it can induce abortion.

DRUGS USED IN TREATMENT OF DIARRHEA

Therapy for diarrhea includes fluids, electrolyte replacement, maintenance of acid/base balance, and control of discomfort. Antiparasitic drugs or dietary therapy can also play an important role in treatment of some types of diarrhea. Additional therapy may include intestinal protectants, motility modifiers, antimicrobials, anti-inflammatory drugs, and antitoxins (see TABLE 6).

TABLE 6 ANTIDIARRHEAL DRUGS

Drug	Dosage
Kaolin-pectin	1–2 mL/kg, PO, qid
Activated charcoal	2–8 g/kg, PO
Bismuth subsalicylate	1–3 mL/kg/day in divided doses, PO
Aminopentamide	0.1–0.4 mg, IM, SC, or PO, bid
Isopropamide	0.2–1 mg/kg, PO, bid
Propantheline	0.25–0.5 mg/kg, PO, bid-tid
Paregoric	0.06 mg/kg, PO, tid
Diphenoxylate	0.05–0.1 mg/kg, PO, qid
Loperamide	0.08 mg/kg, PO, tid-qid

Mucosal Protectants and Adsorbents:

Kaolin-pectin formulations are popular for symptomatic therapy of diarrhea. Kaolin is a form of aluminum silicate, and pectin is a carbohydrate extracted from the rind of citrus fruits. The manufacturers claim that kaolin-pectin acts as a demulcent and adsorbent in the treatment of diarrhea. This action is claimed to be related to the binding of bacterial toxins (endotoxins and enterotoxins) in the GI tract. However, clinical studies have not demonstrated any benefit from administration of kaolin-pectin. It may change the consistency of the feces but neither decreases the fluid or electrolyte loss nor shortens the duration of illness. Nevertheless, it is often administered to small animals, foals, calves, lambs, and kids. Kaolin-pectin products may adsorb or bind other drugs administered PO and reduce bioavailability.

Activated charcoal is derived from wood, peat, coconut, or pecan shells. The material is heated and treated in such a way that many large pores are formed, which dramatically increases the internal surface area. Activated charcoal is available in a variety of pore sizes. The formulations sold for drug and toxicant adsorption typically have pore sizes of 10–20 Å. Activated charcoal is very effective for adsorbing bacterial enterotoxins and endotoxins that cause some types of diarrhea. It also adsorbs many drugs and toxins and prevents GI absorption, so it is a common nonspecific treatment for intoxications. Activated charcoal is not absorbed, so overdose is not a problem.

Although other “mucosal protectants” have questionable efficacy, **bismuth subsalicylate** is considered by many human gastroenterologists to be the symptomatic treatment of choice for acute diarrhea. Its efficacy has been proved in controlled clinical trials in people with acute diarrhea (enterotoxigenic *Escherichia coli* or “traveller’s diarrhea”). Bismuth adsorbs bacterial enterotoxins and endotoxins and has a GI protective effect. The salicylate component has antiprostaglandin activity. Practically all of the salicylate is absorbed systemically when administered to dogs and cats. Some animals may dislike the taste of bismuth subsalicylate, and owners should be warned that it will turn the feces black. This may interfere with evaluating the feces for hemorrhage. Salicylate toxicosis is possible, especially in cats.

Motility-modifying Drugs: Anticholinergic drugs are common ingredients in antidiarrheal preparations, because they

significantly decrease intestinal motility and secretions. Their parasympatholytic effects decrease segmental and propulsive intestinal smooth muscle contractions and relax spasms of smooth muscle. Although they do not alter the course of the disease, anticholinergic drugs decrease the urgency associated with some forms of diarrhea in small animals, the amount of fluid secreted into the intestine, and abdominal cramping associated with hypermotility. Because few of the types of diarrhea seen in animals can be classified as “hypermotile,” use of anticholinergic drugs is limited in veterinary medicine. Intestinal motility is already impaired in many animals with diarrhea, and these drugs may actually worsen the diarrhea. The anticholinergic drugs also have profound systemic pharmacologic effects. If they are administered in sufficient doses to affect intestinal motility, possible adverse effects include severe ileus, xerostomia, urine retention, cycloplegia, tachycardia, and CNS excitement. Chronic administration may lead to serious intestinal atony.

Atropine is the best known anticholinergic drug, but because it has many other systemic effects, it is not ordinarily used for an antidiarrheal effect. To avoid CNS excitement, quaternary amines such as aminopentamide, isopropanide, and propantheline are preferred, because they do not cross the blood-brain barrier readily.

Hyoscine butylbromide is an antispasmodic and anticholinergic drug that relaxes the smooth muscle of the GI tract. It is approved for treatment of uncomplicated, spasmodic colic in horses. Initial relief of colic pain is seen within 5–10 minutes, with a duration of action of 3–4 hr. Because of its parasympatholytic effects, it causes transient tachycardia; therefore, heart rate monitoring is not an effective indicator of response to treatment for up to 30 min after treatment. It will also decrease gut sounds for 30 min after administration. Rectal relaxation will also make rectal palpation easier. It may also be beneficial in cases of choke, and it will relieve acute bronchoconstriction in horses with recurrent airway obstruction. Hyoscine butylbromide can be administered concurrently with NSAIDs and sedatives.

Opiates have both antisecretory and antimotility effects by action on the μ (mu) and δ (delta) receptors of the GI tract. They decrease propulsive intestinal contractions and increase segmentation for an overall constipating effect. They also increase GI sphincter tone. There is some evidence that opiates inhibit colonic motor activity in

horses. In addition to affecting motility, opiates stimulate absorption of fluid, electrolytes, and glucose. Their effects on secretory diarrhea are probably related to inhibition of calcium influx and decreased calmodulin activity. They are frequently used for treatment of diarrhea in dogs, but their use in cats is controversial because they may cause excitement. The constipating effects of morphine and codeine have been known for many years, but they are not used clinically as antidiarrheal drugs. Paregoric is a tincture of opium product and a controlled substance (5 mL of paregoric corresponds to ~2 mg of morphine). Diphenoxylate and loperamide are two synthetic opiates that have specific action on the GI tract without causing other systemic effects. They have been used in small animals and large animal neonates. Diphenoxylate is a controlled substance in a formulation that contains atropine to discourage abuse; at therapeutic doses, there is no effect from the atropine. Opiates can have potent effects on the GI tract and should be used cautiously. Loperamide is available over-the-counter.

Loperamide should not be used in dog breeds known to be sensitive to ivermectin (Collies, Australian Shepherds, Old English Sheepdogs) without genetic testing. These dogs may have a gene mutation (ABCB-1 gene deletion) that causes a functional defect in P-glycoprotein, which controls drug movement in many tissues. In people and genetically normal dogs, large doses of loperamide do not cause the typical CNS effects of opioids, because loperamide does not achieve high concentrations within the CNS because of P-glycoprotein-mediated efflux of loperamide. Dogs with the ABCB-1 gene deletion show signs of ptalism, panting, ataxia, and recumbency at doses of loperamide that do not affect healthy dogs. These drugs are contraindicated in infectious diarrhea, because slowing GI transit time may increase the absorption of bacterial toxins. In dogs, constipation and bloat are the most common adverse effects. Potentially, paralytic ileus, toxic megacolon, pancreatitis, and CNS effects can develop, especially in cats.

Antimicrobial Therapy: The efficacy of antimicrobials in the therapy of diarrhea is unknown or unproved in most clinical situations. In most cases of diarrhea in small animals, a bacterial etiology is not identified. In large animals, antimicrobial therapy has not been shown to alter the course of bacterial enteritis, and in some cases, is thought to perpetuate the disease

by producing "carrier" animals (eg, salmonellosis). Nonabsorbed antimicrobials are frequently combined with motility modifiers, adsorbents, and intestinal protectants in some preparations. Many of these combinations are irrational. Antimicrobials frequently are a treatment for diarrhea in animals, but there are few conditions that have a known etiology for which antimicrobial therapy is indicated. *Campylobacter* enteritis, from infection with *Campylobacter jejuni*, is seen in cats and dogs and can be zoonotic. Treatment alleviates clinical signs, but animals usually remain carriers. Suggested antimicrobial therapy includes erythromycin, enrofloxacin, clindamycin, tylosin, tetracycline, or chloramphenicol. Intestinal bacterial overgrowth is usually due to *Escherichia coli* or *Clostridium* spp, so therapy is initiated with an oral drug effective in the GI lumen with anaerobic activity (eg, metronidazole, amoxicillin, ampicillin, tylosin, or clindamycin). Equine monocytic ehrlichiosis (see p 283) is caused by the rickettsial organism *Neorickettsia (Ehrlichia) risticii* but clinically resembles salmonellosis. Treatment of choice is IV oxytetracycline. Oral doxycycline can be used in mildly affected horses.

Enteritis from a variety of pathogens is common in young animals. When integrity of the intestinal mucosa is lost, septicemia or endotoxemia is likely. Signs of sepsis include severe bloody diarrhea, fever, scleral injection, dehydration, and alteration in the leukogram (early leukopenia in endotoxic shock, followed by leukocytosis). If septicemia or endotoxemia is suspected, systemic antimicrobials are warranted along with NSAIDs. Neonates with diarrhea deteriorate rapidly before culture and sensitivity results are available. Therefore, broad-spectrum antimicrobial therapy should be initiated. Suggested antimicrobials (depending on species) include fluoroquinolones, a penicillin or cephalosporin plus an aminoglycoside (gentamicin, amikacin), ampicillin or amoxicillin, tetracyclines, potentiated sulfonamides, chloramphenicol, or florfenicol. In septic animals, GI absorption is likely to be altered, so parenteral administration is preferred.

Nonsteroidal Anti-inflammatory Drugs (NSAIDs): The antiprostaglandin activity of NSAIDs may be beneficial with some types of diarrhea and may be important in treatment of septicemia or endotoxemia. Prostaglandins are important intracellular messengers for stimulating

hypersecretion by the intestinal mucosa, possibly by stimulating an increase in cAMP. Antiprostaglandin drugs may directly inhibit fluid and electrolyte hypersecretion by the intestinal cells. NSAIDs should be administered cautiously, because they have adverse GI, hepatic, and renal effects.

DRUGS USED IN TREATMENT OF CHRONIC COLITIS

The specific cause of chronic colitis in animals is frequently unknown; therefore, it is difficult to prescribe a specific treatment for the underlying disorder (see TABLE 7). Colitis is often classified as plasmacytic/lymphocytic, eosinophilic, histiocytic, or granulomatous. The goal of colitis therapy is to restore normal intestinal motility and to relieve inflammation, spasm, or ulceration. In small animals, dietary therapy is a major component of therapy for chronic colitis (see p 377).

Sulfasalazine is composed of sulfapyridine and 5-aminosalicylic acid (mesalamine) joined by an azo bond. The bond is broken by bacteria in the colon to release the two drugs. The sulfonamide component is absorbed into the circulation, whereas the salicylic acid component is active locally in the GI tract. Less than half of the salicylate component is absorbed systemically. Clinical efficacy appears to be primarily due to the anti-inflammatory effect of the salicylate component. There is evidence for antilipoxygenase activity, decreased interleukin-1, decreased prostaglandin synthesis, and oxygen radical scavenging activity. Sulfasalazine is commonly used in small animals in the therapy of ulcerative or idiopathic colitis or of plasmacytic-lymphocytic colitis once dietary causes have been excluded.

Because the salicylate component is only minimally absorbed, its systemic effects are minimal. The sulfonamide component may cause keratoconjunctivitis sicca in dogs, and the salicylate component may cause toxicity in cats. Dosage recommendations for sulfasalazine vary widely, and the dosage is gradually reduced after an initial response. New products have been developed to overcome the difficulty of the 5-aminosalicylic acid reaching the colon and the systemic adverse effects. Mesalamine is a pH-sensitive, coated 5-aminosalicylic acid. The polymer coating prevents release of the active drug until it reaches the colon. Olsalazine consists of two molecules of 5-aminosalicylic acid joined together by an azo bond. Mesalamine is also available as an enema. Rectal administration allows delivery of active drug to the colon. It appears useful in dogs with chemotherapy-induced hemorrhagic colitis or with idiopathic distal proctitis. It may also be useful in dogs with perianal fistulas.

Tylosin is a macrolide antimicrobial used successfully in some animals with colitis. It is commonly administered on a chronic basis as an alternative to sulfasalazine therapy. The mechanism of action is unknown, but it is suspected that its activity against mycoplasmas, spirochetes, and chlamydiae is important. Best results are attained when the powdered form, labeled for use in swine, is mixed with food or added to water. Some animals may find the bitter taste unpalatable.

Metronidazole has fair efficacy against *Giardia*, and it is also efficacious in some cases of diarrhea in which giardiasis was not definitively diagnosed. It is suspected that this efficacy is related to the activity of metronidazole against anaerobic

TABLE 7 DRUGS USED FOR CHRONIC COLITIS

Drug	Dosage
Sulfasalazine	10–30 mg/kg, PO, bid-tid
Tylosin	40–80 mg/kg/day
Metronidazole	10–30 mg/kg, PO, once to three times daily
Prednisone	2–4 mg/kg, PO, every other day
Budesonide	3 mg/m ² /day, PO
Raw linseed oil	1 oz/day in the feed
Azathioprine	50 mg/m ² , PO, daily for 2 wk, then every other day
Chlorambucil	2 mg/m ² , PO, every other day

bacteria. Metronidazole also has an immunosuppressive effect on the GI mucosa by decreasing the cell-mediated response. Adverse neurologic effects have been reported in dogs and cats treated with metronidazole. Diazepam appears effective for treatment of neurotoxicity.

The efficacy of **glucocorticoids** for treating colitis is probably related to their anti-inflammatory and immunosuppressive capabilities. Some cases of colitis may be due to autoantibodies and T lymphocytes directed against colonic epithelial cells. Glucocorticoids suppress the immune reaction and are used when biopsy results suggest eosinophilic or plasmacytic-lymphocytic colitis. They are used in dogs, cats, and horses, often when all other forms of therapy have failed. Immunosuppressive doses of oral prednisone or dexamethasone are usually administered and slowly tapered to every-other-day therapy with the lowest effective dose.

Budesonide is a glucocorticoid used in people to treat asthma, rhinitis, and inflammatory bowel disease. Budesonide has a high affinity for glucocorticoid receptors, high hepatic clearance, and high local and low systemic activity compared with prednisone or dexamethasone. The human formulation of budesonide consists of coated granules with a matrix of ethyl cellulose to target release into the lumen of the ileum or ascending colon. It is not known whether the human budesonide formulation provides release in the same anatomic site in dogs, but it appears clinically effective in some dogs.

N-3 fatty acids have been suggested for therapy in people with ulcerative colitis or Crohn disease. The addition of n-3 fatty acids to the diet makes fewer n-6 fatty acids available for the arachidonic acid cascade. Several formulations are available for small animals, and raw linseed oil may be added to horses' grain for this effect.

Potent immunosuppressive drugs such as **azathioprine** are used to manage some forms of colitis. Azathioprine is metabolized to 6-mercaptopurine, which is immunosuppressive by interfering with nucleic acid synthesis and by impairing lymphocyte proliferation. It may take several weeks or months of therapy for azathioprine to become maximally effective. Cats particularly should be monitored for adverse effects, including myelosuppression, hepatic disease, and acute pancreatic necrosis. Chlorambucil has been used in place of azathioprine in some difficult or refractory cases of feline inflammatory bowel disease. It is too expensive to use in all but very small dogs.

GASTROINTESTINAL PROKINETIC DRUGS

Prokinetic drugs increase the movement of ingested material through the GI tract (see TABLE 8). They are useful in the treatment of motility disorders, because they induce coordinated motility patterns. Unfortunately, some prokinetic drugs may produce a number of serious adverse effects that complicate their use.

The enteric nervous system of the GI tract can function independently of the CNS to control bowel function. Because there are no nerve fibers that actually penetrate the intestinal epithelium, the enteric nervous system uses enteroendocrine cells such as the enterochromaffin cells as sensory transducers. More than 95% of the body's serotonin is located in the GI tract, and >90% of that store is in the enterochromaffin cells scattered in the enteric epithelium from the stomach to the colon. The remaining serotonin is located in the enteric nervous system, where 5-HT acts as a neurotransmitter. From the enterochromaffin cells, serotonin is secreted into the lamina propria in high concentrations, which overflow into the portal circulation and intestinal lumen. The effect of serotonin on intestinal activity is coordinated by 5-HT receptor subtypes. The 5-HT_{1P} receptor initiates peristaltic and secretory reflexes, and so far no drugs have been developed to target this specific receptor. The 5-HT₃ receptor activates extrinsic sensory nerves and is responsible for the sensation of nausea and induction of vomiting from visceral hypersensitivity. Therefore, specific 5-HT₃ antagonists such as ondansetron and granisetron are very effective for treatment of vomiting seen with chemotherapy. Stimulation of the 5-HT₄ receptor increases the presynaptic release of acetylcholine and calcitonin gene-related peptide, thereby enhancing neurotransmission. This enhancement promotes propulsive peristaltic and secretory reflexes. Specific 5-HT₄ agonists such as cisapride enhance neurotransmission and depend on natural stimuli to evoke peristaltic and secretory reflexes. This makes these drugs very well tolerated, because they do not induce perpetual or excessive motility. It is also the reason for the limitations of these drugs, because they are not effective if enteric nerves have degenerated or become nonfunctional (as in cats with end-stage megacolon).

Metoclopramide is a central dopaminergic antagonist and peripheral 5-HT₃ receptor antagonist and 5-HT₄ receptor agonist with GI and CNS effects. In the

TABLE 8 PROKINETIC DRUGS

Drug	Dosage
Metoclopramide	Dogs and cats: 0.2–0.5 mg/kg, PO or SC, tid; 0.01–0.02 mg/kg/hr, IV infusion Horses: 0.125–0.25 mg/kg, diluted in 500 mL of polyionic solution and administered IV over 60 min
Domperidone	0.1–0.5 mg/kg, IM; 0.5–1 mg/kg, PO
Cisapride	Dogs: 0.1 mg/kg, PO, tid Cats: 2.5 mg/cat, tid for cats <5 kg, and 5 mg/cat for cats >5 kg
Erythromycin	0.5–1 mg/kg, PO, bid-tid
Ranitidine	1–2 mg/kg, PO, bid
Nitazidine	2.5–5 mg/kg, PO, bid
Lidocaine	Horses: 1.3 mg/kg, IV, as a bolus followed by a constant-rate infusion of 0.05 mg/kg/min

upper GI tract, metoclopramide increases both acetylcholine release from neurons and cholinergic receptor sensitivity to acetylcholine. Metoclopramide stimulates and coordinates esophageal, gastric, pyloric, and duodenal motor activity. It increases lower esophageal sphincter tone and stimulates gastric contractions, while relaxing the pylorus and duodenum. Inadequate cholinergic activity is incriminated in many GI motility disorders; therefore, metoclopramide should be most effective in diseases in which normal motility is diminished or impaired. Metoclopramide speeds gastric emptying of liquids but may slow the emptying of solids. It is effective in treating postoperative ileus in dogs, which is characterized by decreased GI myoelectric activity and motility. Metoclopramide has little or no effect on colonic motility.

Metoclopramide is primarily indicated for relief of vomiting associated with chemotherapy in dogs, as an antiemetic for dogs with parvoviral enteritis, and for treatment of gastroesophageal reflux and postoperative ileus. GI obstruction, such as intussusception in puppies with parvoviral enteritis, must be excluded before initiating metoclopramide therapy. Its prokinetic action is negated by narcotic analgesics and anticholinergic drugs, such as atropine. Drugs that dissolve or are absorbed in the stomach, such as digoxin, may have reduced absorption. Bioavailability may be increased for drugs absorbed in the small intestine. Because of accelerated food absorption, metoclopramide therapy may increase the insulin dose required in animals with diabetes.

Metoclopramide readily crosses the blood-brain barrier, where dopamine antagonism at the CRTZ produces an antiemetic effect. However, dopamine antagonism in the striatum causes adverse effects known collectively as extrapyramidal signs, which include involuntary muscle spasms, motor restlessness, and inappropriate aggression. Concurrent use of phenothiazine and butyrophenone tranquilizers should be avoided, because they also have central antidopaminergic activity, which increases the potential for extrapyramidal reactions. If recognized in time, the extrapyramidal signs can be reversed by restoring an appropriate dopamine: acetylcholine balance with the anticholinergic action of an antihistamine, such as diphenhydramine hydrochloride given IV at a dosage of 1 mg/kg.

Cisapride is chemically related to metoclopramide, but unlike metoclopramide, it does not cross the blood-brain barrier or have antidopaminergic effects. Therefore, it does not have antiemetic action or cause extrapyramidal effects (extreme CNS stimulation). Cisapride is a serotonin 5-HT₄ agonist with some 5-HT₃ antagonist activity, so it enhances the release of acetylcholine from postganglionic nerve endings of the myenteric plexus and antagonizes the inhibitory action of serotonin (5-HT₃) on the myenteric plexus, resulting in increased GI motility and increased heart rate. Cisapride is more potent and has broader prokinetic activity than metoclopramide, increasing the motility of the colon, as well as that of the esophagus, stomach, and small intestine.

Cisapride is especially useful in animals that experience neurologic effects from metoclopramide. Cisapride is very useful in managing gastric stasis, idiopathic constipation, and postoperative ileus in dogs and cats. Cisapride may be especially useful in managing chronic constipation in cats with megacolon; in many cases, it alleviates or delays the need for subtotal colectomy. Cisapride is also useful in managing cats with hairball problems and in dogs with idiopathic megaesophagus that continue to regurgitate frequently despite a carefully managed, elevated feeding program. In comparative studies of GI motility in people and animals, cisapride is clearly superior to other treatments.

Initially, the only adverse effects reported in people were increased defecation, headache, abdominal pain, and cramping and flatulence; cisapride appeared to be well tolerated in animals. As cisapride became widely used in management of gastroesophageal reflux in people, cases of heart rhythm disorders and deaths were reported to the FDA. These cardiac problems in people were highly associated with concurrent drug therapy or specific underlying conditions. In veterinary medicine, adverse reactions to clinical use of cisapride have not been reported. Cisapride for animals can only be obtained through compounding veterinary pharmacies.

Domperidone is a peripheral dopamine receptor antagonist that has been marketed outside the USA since 1978. It is available in Canada as a 10-mg tablet. Currently, it is available in the USA only as an investigational new drug (1% oral domperidone gel) to treat agalactia in mares due to fescue toxicosis. Domperidone regulates the motility of gastric and small-intestinal smooth muscle and has some effect on esophageal motility. It appears to have very little physiologic effect in the colon. It has antiemetic activity from dopaminergic blockade in the CRTZ. But because very little domperidone crosses the blood-brain barrier, reports of extrapyramidal reactions are rare; however, if a reaction occurs, the treatment is the same as for reactions to metoclopramide. Domperidone failed to enhance gastric emptying in healthy dogs in one study. In other studies, however, domperidone was superior to metoclopramide in stimulating antral contractions in dogs but not cats, and it improved antroduodenal coordination in dogs. Because of its favorable safety profile, domperidone appears to be an attractive alternative to metoclopramide.

Macrolide antibiotics, including erythromycin and clarithromycin, are motilin receptor agonists. They also appear to stimulate cholinergic and noncholinergic neuronal pathways to stimulate motility. At microbially ineffective doses, some macrolide antibiotics stimulate migrating motility complexes and antegrade peristalsis in the proximal GI tract. Erythromycin has been effective in the treatment of gastroparesis in human patients in whom metoclopramide or domperidone was ineffective. Erythromycin increases the gastric emptying rate in healthy dogs, but large food chunks may enter the small intestine and be inadequately digested. Erythromycin induces contractions from the stomach to the terminal ileum and proximal colon, but the colon contractions do not appear to result in propulsive motility. Therefore, erythromycin is unlikely to benefit patients with colonic motility disorders.

Human pharmacokinetic studies indicate that erythromycin suspension is the ideal dosage form for administration of erythromycin as a prokinetic agent. Other macrolide antibiotics have prokinetic activity with fewer adverse effects than erythromycin and may be suitable for use in small animals. Both erythromycin and clarithromycin are metabolized by the hepatic cytochrome P450 enzyme system and inhibit the hepatic metabolism of other drugs, including theophylline, cyclosporine, and cisapride. Nonantibiotic derivatives of erythromycin are being developed as prokinetic agents.

Ranitidine and **nizatidine** are histamine H_2 -receptor antagonists that are prokinetics in addition to inhibiting gastric acid secretion in dogs and rats. Their prokinetic activity is due to acetylcholinesterase inhibition, with the greatest activity in the proximal GI tract. Cimetidine and famotidine are not acetylcholinesterase inhibitors and do not have prokinetic effects. Ranitidine and nizatidine stimulate GI motility by increasing the amount of acetylcholinesterase available to bind smooth muscle muscarinic cholinergic receptors. They also stimulate colonic smooth muscle contraction in cats through a cholinergic mechanism.

Ranitidine causes less interference with cytochrome P450 metabolism of other drugs than does cimetidine, and nizatidine does not affect hepatic microsomal enzyme activity, so both drugs have a wide margin of safety.

IV lidocaine is used in the treatment of postoperative ileus in people and has been

shown to be useful in treating ileus and proximal duodenitis/jejunitis in horses. It is thought to suppress firing of primary afferent neurons, as well as to have anti-inflammatory properties and direct stimulatory effects on smooth muscle. It is also thought to suppress the primary afferent neurons from firing, as well as have anti-inflammatory properties and direct stimulatory effects on smooth muscle. Most horses respond within 12 hr of starting an infusion.

CATHARTIC AND LAXATIVE DRUGS

Cathartics and laxatives increase the motility of the intestine or increase the bulk of feces. The dosages for all of these drugs are highly empirical and usually extracted from human dosages (see TABLE 9). Clinically, these drugs are administered to increase passage of gut contents associated with intestinal impaction, to cleanse the bowel before radiography or endoscopy, to eliminate toxins from the GI tract, and to soften feces after intestinal or anal surgery.

Stimulant Cathartics: Stimulant (irritant) cathartics appear to stimulate intestinal motility via an irritant effect on the mucosa or stimulation of intramural

nerve plexi. They also activate secretory mechanisms, provoking fluid accumulation in the GI lumen. These drugs can have potent effects, and excessive fluid and electrolyte loss can result. They act directly or indirectly (if a metabolic conversion is necessary before the compound is active).

Emodin is an irritant glycoside that is an active ingredient in several products. Its action is limited to the large intestine, and it may take 4–6 hr for an effect to be seen. Repeat doses should be avoided in horses because of the long latent period and risk of severe superpurgation. The naturally occurring emodins (eg, senna) are found in human formulations.

Vegetable oils are indirect-acting cathartics. They are hydrolyzed by pancreatic lipase in the small intestine to irritating fatty acids. Castor oil is a potent cathartic. It is hydrolyzed to release ricinoleic acid, which causes increased water secretion in the small intestine. Raw linseed oil (cooked linseed oil is toxic) is hydrolyzed to release linoleates, which are less irritating than ricinoleic acid. In smaller daily doses, linseed oil is a mild lubricant laxative and a source of fatty acids for horses.

Senna and bisacodyl are stimulant cathartics that affect the large intestine and are found in many over-the-counter human laxative formulations.

TABLE 9 CATHARTIC AND LAXATIVE DRUGS

Drug	Dosage
Castor oil	Dogs: 5–25 mL, PO Foals: 25–50 mL, PO
Bisacodyl	Dogs: 5–20 mg, PO, once to twice daily Cats: 2.5–5 mg, PO, once to twice daily
Magnesium sulfate (Epsom salts)	Dogs: 5–25 g, PO Cats: 2–5 g, PO Horses: 30–100 g, PO
Magnesium hydroxide (milk of magnesia)	Dogs: 5–10 mL, PO Cats: 2–6 mL, PO Horses: 1–4 L, PO
Lactulose	Dogs: 5–15 mL, PO, tid Cats: 2–3 mL, PO, tid
Docusate sodium, docusate calcium, docusate potassium	Dogs and cats: 2 mg/kg/day, PO Horses: 10–20 mg/kg in 2 L water

Hyperosmotic Cathartics: These drugs are poorly absorbed from the GI tract and draw fluid into the intestine by osmosis. The fluid content of the feces increases, which causes intestinal distention and promotes peristalsis. Although hyperosmotic cathartics are relatively safe, overdoses can cause excessive fluid loss and dehydration, so adequate water intake must be assured. Examples of hyperosmotic cathartics include magnesium salts, sodium salts, and sugar alcohols.

Magnesium salts are frequently used PO as saline purgatives. Normally, only 20% of the magnesium is systemically absorbed and eliminated by the kidneys. If absorption is excessive or renal elimination is impaired, then severe hypermagnesemia and metabolic alkalosis may develop.

Sodium salts can be given PO as saline cathartics but are more commonly administered as sodium biphosphate or sodium phosphate enemas. These should not be used in cats because fatal hyperphosphatemia, hypocalcemia, and hypernatremia may result.

Sugar alcohols, such as mannitol and sorbitol, are poorly absorbed and fermented in the terminal ileum and large intestine. Lactulose is a synthetic disaccharide fermented in the large intestine to produce acetic, lactic, and other organic acids that have an osmotic effect. Lactulose is used to treat chronic constipation in cats with megacolon. It is also used in the management of hepatic encephalopathy, in which acidification of the large intestine promotes formation of nonabsorbable ammonium ions and quaternary amines, thereby reducing the need for detoxification by the liver.

Polyethylene glycol (PEG3350) is a large molecular weight, water-soluble polymer used widely in people as a bulking and softening agent for treatment of constipation. It is not metabolized by the intestinal bacterial flora and is minimally absorbed by the intestines. It forms hydrogen bonds with 100 molecules of water per molecule, creating high osmotic pressures within the bowel lumen. The osmotic pressure prevents absorption of water out of the lumen. It is relatively free of adverse effects. PEG3350 is readily available in a powder form, which can be added to a dog or cat's regular food. It can also be administered as a solution via nasogastric tube. Unlike fiber laxatives, it does not cause bloating or gas.

Hydrophilic Colloids ("Bulk Laxatives"):

The bulk laxatives use fiber to draw water in to the bowel. Fiber is made up of several different compounds, all of which are

carbohydrates. The term "fiber" is used to describe the "insoluble carbohydrates" that resist enzymatic digestion in the small intestine. Found in the cell walls of plants and grains, the most common fibers are cellulose, hemicellulose, pectin, gums, and resistant starches. Almost all carbohydrate sources contain some fiber. Some of the most common sources of fiber in pet foods include rice hulls, corn and corn byproducts, soybean hulls, beet pulp, bran, peanut hulls, and pectin. Adding fiber to a diet improves colon health, helps with weight management, and helps with diarrhea, constipation, and diabetes mellitus. Many commercial brands of pet food are available in a high-fiber formula. Bulk laxatives may cause bloating and flatulence. Contrary to popular belief, bran mashes do not cause a laxative effect in horses. In cats with megacolon, high-fiber diets are used initially to help manage constipation when there is still some normal colonic motility. But once the colonic innervation has deteriorated, the diet may need to be switched to a low-residue diet with aggressive laxative treatment.

Lubricant Laxatives: These act by coating the surface of the feces with a water-immiscible film and by increasing the water content of the feces to provide a lubricant action. Lubricant laxatives usually contain mineral oil or white petroleum. Chronic use may reduce intestinal absorption of fat-soluble vitamins and cause a granulomatous enteritis. Mineral oil is very commonly used in horses and cattle, and commercial products are available to promote passage of hairballs in cats.

Fecal Softeners (Surfactants):

Docusate sodium, docusate calcium, and docusate potassium are salts that decrease surface tension and allow water to accumulate in the feces. Docusate also increases cAMP in colonic mucosal cells, which increases ion secretion and fluid permeability. Usually considered very safe, concentrations of dioctyl sodium sulfosuccinate (DSS) ranging from 3–5 times the recommended dosage produced severe diarrhea, rapid dehydration, and death in horses. DSS should not be administered concurrently with mineral oil; soaps are formed and oil absorption is increased.

DRUGS AFFECTING DIGESTIVE FUNCTIONS

Pancrealipase contains the pancreatic enzymes lipase, amylase, and protease. It is derived from the pancreatic tissues of

swine. These enzymes help digest and absorb fats, proteins, and carbohydrates. Pancrealipase is used to treat dogs and cats with exocrine pancreatic insufficiency. Several formulations are available, including oral capsules, tablets, and delayed-release capsules and tablets. The powdered forms can be added to food, and the dosage adjusted to maintain normal feces. Antacids may diminish the efficacy of pancrealipase, whereas H_2 -receptor antagonists may increase the amount of pancrealipase that reaches the duodenum.

Ursodiol, also known as ursodeoxycholic acid, is a naturally occurring bile acid. It suppresses hepatic synthesis and secretion of cholesterol and decreases intestinal absorption of cholesterol. Reducing cholesterol saturation allows solubilization of cholesterol-containing gallstones. Ursodiol also increases bile flow and reduces the hepatotoxic effect of bile salts by decreasing their detergent action. In small animals, ursodiol may be useful in treatment of cholesterol-containing gallstones, idiopathic hepatic lipidosis, and chronic active hepatitis. The dosage in dogs and cats is 15 mg/kg/day, PO.

S-Adenosylmethionine (S-AdoMet) is an endogenous molecule synthesized by cells throughout the body. Formed from the amino acid methionine and ATP, S-AdoMet is an essential part of three major biochemical pathways: transmethylation, transsulfuration, and aminopropylation. Deficiency of S-AdoMet is associated with cellular derangements in hepatocytes, and there is evidence that a S-AdoMet deficiency may contribute to abnormalities of cellular structure and function in many body tissues, including the liver. Exogenous administration of S-AdoMet appears to improve hepatocellular function in vivo and in vitro studies without cytotoxicity or significant adverse effects. S-AdoMet increases hepatic glutathione levels in cats and dogs. Glutathione is a potent antioxidant that protects hepatic cells from toxins and death. The daily dosage is 18 mg/kg, rounded to the nearest size of enteric-coated tablet, and given on an empty stomach.

Milk thistle is used as a natural remedy for diseases of the liver and biliary tract. Silymarin is the active extract and contains flavonignans that reportedly act as antioxidants, scavenging free radicals and inhibiting lipid peroxidation. Several controlled clinical trials have demonstrated the benefits of milk thistle in human patients with acute or chronic liver disease. A veterinary formulation has been approved in the USA for dogs and cats.

THE RUMINANT DIGESTIVE SYSTEM

Other than the forestomachs (rumen, reticulum, omasum), the components of the ruminant GI tract are similar to those of monogastric mammals, and the use of pharmacologic agents to treat diseases of the glandular stomach (abomasum) and intestine follows principles common to both monogastric and ruminant species. Ruminants differ significantly from other mammals in that much of their feed undergoes microbial predigestion in the forestomachs, chiefly in the rumen and reticulum. There is also postgastric fermentation in the cecum and colon, but this is much less important than in some other herbivores, eg, horses.

Ruminoreticular motility or fermentation is depressed in many conditions, including improper feeding (overload or deficiency of specific nutrients), lack of water, infectious diseases, intoxications, lesions of any part of the upper GI tract, metabolic states (eg, hypocalcemia), or reduced flow of alkaline saliva that allows pH to fall and the microbial population to be altered to an extent that is harmful to the animal. (See *also* DISEASES OF THE RUMINANT FORESTOMACH, p 221 et seq.)

The primary objectives of pharmacotherapy are to remove the cause and to promote the return of normal digestive function by meeting or reestablishing the requirements for optimal ruminoreticular function as quickly as possible. This may include any of the following: 1) ensuring an appropriate substrate for microbial fermentation; 2) providing any cofactors (eg, phosphorus, sulfur) necessary for microbial fermentative processes; 3) removing any soluble end-products, undigested solid residues, and gas; 4) maintaining continual flow culture of ruminal microorganisms; 5) ensuring that the contents of the ruminoreticulum are fluid; 6) maintaining optimal intraruminal pH (generally between 6 and 7); and 7) promoting active ruminoreticular activity.

DRUGS FOR SPECIFIC PURPOSES

Esophageal Obstruction: Esophageal obstruction due to a foreign body (see p 215) leads to severe discomfort and acute free-gas bloat. Physical removal of the object may be hampered by marked spasm of the surrounding muscle. Specific spasmolytic drugs such as acepromazine may be used (0.05–0.1 mg/kg, IV, IM, or SC in cattle). Alternatively, the moderate sedative

and muscle relaxant effects of a low dose of xylazine (0.05 mg/kg, IM in cattle) or detomidine (0.02–0.05 mg/kg, IM in cattle) may aid removal of obstructions. None of these compounds has been approved by the FDA for use in cattle.

Ruminotorics: Agents and mixtures that promote forestomach function (fermentation and motility) are known as ruminotorics. Formulations that contain glucogenic substrates, minerals, cofactors, and bitters (eg, nux vomica) have limited application in current therapy of ruminoreticular indigestion. Generally, restoration of the normal ruminoreticular environment using a physiologic approach is much more satisfactory.

Oral administration of specific alkalinizing or acidifying agents should not be routinely undertaken in cases of indigestion. Magnesium oxide or magnesium hydroxide are strongly alkalinizing agents able to substantially increase rumen pH and thus create a hostile environment for rumen protozoa. These compounds, when given at label dose to dairy cattle, result in significant decrease in rumen fermentation and a decrease in number of rumen protozoa. Therefore, these compounds should only be administered to cattle with a confirmed diagnosis of grain overload.

Mineral oil (1–2 L) or dioctyl sodium sulfosuccinate (DSS, 90–120 mL in 1–2 L of water) administered PO or via nasogastric tube followed by gentle ruminal massage can help promote the dissolution and passage of impacted fibrous ruminal omasal or abomasal contents. DSS can markedly depress rumen protozoa; thus, ruminal transfaunation should follow use of this agent if ruminal hypomotility continues.

Ruminal Fluid Transfer: Fresh ruminal fluid is considered to be the best available “ruminotoric,” because it contains viable ruminal bacteria (1×10^8 – 10^{11} /mL) and protozoa (1×10^5 – 10^6 /mL) as well as many useful fermentation factors (volatile fatty acids, microbial protein, minerals, vitamins, buffers). Strained fresh ruminal juice (at least 3 L, but 8–16 L is ideal in cattle; sheep require ~1 L) given PO or by tube is indicated in cases of ruminoreticular stasis. Ruminal fluid can be aspirated through a stomach tube from the ruminoreticulum of healthy animals using an extractor pump or by siphoning, or it can be collected at slaughterhouses. A rumen-cannulated donor animal is particularly convenient. It is best for the donor to be on a ration similar to that of the recipient, because the ruminal

microflora will then be more appropriately adapted. Provided the initiating condition or lesion is responding favorably, improvement almost invariably follows the reestablishment of normal ruminal microflora, with consequent normalization of the fermentation process and ruminoreticular motility. When the ruminoreticular contents are putrified, ingesta must first be removed before transfer of fresh ruminal fluid. This can be accomplished using a large-bore stomach tube or by performing a rumenotomy. Acetic acid (vinegar, 4–10 L, PO) can be administered to cattle with putrefaction of the rumen associated with high rumen pH.

Antifoaming Agents: Therapeutic approaches to the control of acute frothy bloat involve administration of antifoaming agents to reduce foam stability and to promote release of free gas, which is then promptly eructated. (*See also* BLOAT IN RUMINANTS, p 227.)

Acute frothy bloat in cattle should be treated with poloxalene, which may be administered as a drench or by stomach tube (25–50 g). Frothy bloat can be prevented by administering poloxalene as a top dressing to feed (1 g/45 kg body wt/day) or in a molasses block (1.5 g/45 kg body wt/day). Polymerized methyl silicone (3.3% emulsion [cattle: 30–60 mL; sheep: 7–15 mL]) may be used in a similar manner as poloxalene, although direct intraruminal injection via a needle or cannula may be more satisfactory in this case. Administration of docosate sodium in emulsified soybean oil (6–12 fl oz containing 240 mg/mL) or administration of vegetable oils alone, such as peanut oil, sunflower oil, or soybean oil (cattle: 60 mL; sheep: 10–15 mL), also relieves acute frothy bloat when given PO. The incidence of frothy bloat in feedlot cattle may be reduced by including ionophores (such as monensin) either in the ration or administering as controlled-release capsules.

Ruminoreticular Antacids: Ruminal alkalinizing agents are principally used to treat ruminal lactic acidosis (pH <5.5) due to grain engorgement or soluble carbohydrate overload. (*See also* GRAIN OVERLOAD IN RUMINANTS, p 222.) The resultant systemic dehydration and acidosis necessitate immediate correction of fluid and electrolyte balance and restoration of a viable microbial population. Often, the latter involves removal of ruminoreticular contents and replacement with fresh ruminoreticular fluid. Antacids that may be given PO, bid-tid, include magnesium hydroxide (cattle:

100–300 g; sheep: 10–30 g) and magnesium carbonate (cattle: 10–80 g; sheep: 1–8 g). Antacids should be mixed in ~10 L of warm water to ensure adequate dispersion through the ruminoreticular contents. Administration PO of activated charcoal (2 g/kg) is believed to protect the ruminoreticular mucosa from further injury by inactivating toxins. Oral administration of sodium bicarbonate (baking soda), either as powder dissolved in water or commercially available solutions prepared for IV infusion, rapidly neutralize the rumen pH but are accompanied by rapid release of large amounts of CO₂. Because of decreased rumen motility in ruminants with acute rumen acidosis, these animals are at increased risk of developing potentially life-threatening free gas bloat.

Ruminoreticular Acidifying Agents:

Ruminal acidifying agents are used to treat ruminal stasis or simple indigestion as well as acute ammonia poisoning. In ruminal stasis, the intraruminal pH often increases to >7.5 because of the constant inflow of bicarbonate-rich saliva in the absence of active ruminal fermentation and formation of volatile fatty acids. In acute ammonia intoxication, the increased intraruminal pH increases the activity of urease and facilitates the absorption of free ammonia (pK_a of ammonium is 9.1). Administration of weak acids in cold water returns the pH of ruminoreticular content toward physiologic levels, promotes the uptake of volatile fatty acids, depresses the absorption of ammonia, and inhibits excessive urease activity. Acetic acid (4%–5%) or vinegar (cattle: 4–8 L; sheep: 250–500 mL) is the most common acidifying agent used.

Modulators of Ruminoreticular

Motility: The use of motility modifiers in cattle is controversial, because evidence-based data demonstrating clinical efficacy are scarce. Several diseases, including paralytic ileus, cecal dilatation, and abomasal displacement, are accompanied by GI tract motility disorders. Pharmacologic motility modification may hasten recovery in some cases. However, in most instances, the most effective strategy to reestablish motility is correction of the underlying disorder (hypocalcemia, endotoxemia, alkalemia, obstruction, or organ displacement) followed by restoration of the normal ruminoreticular environment through transfaunation. Furthermore, conditioned responses to the presence of feed and feeding itself are physiologic means by which ruminoreticular motility can be notably enhanced.

Motility modifiers are categorized based on their mechanism of action. These can be cholinergics (parasympathomimetics), adrenergics, antidopaminergics, serotonergics, motilin agonists, opioid receptor blockers, or sodium channel blockers (lidocaine).

The use of parasympathomimetic agents (eg, neostigmine, physostigmine, bethanechol) is seldom appropriate. These drugs have cholinergic effects, which are potentially hazardous. Neostigmine (cattle: 0.02 mg/kg, SC; sheep: 0.01–0.02 mg/kg, SC) generally produces the fewest adverse effects but tends to increase frequency, rather than strength, of ruminoreticular contractions. Neostigmine given as a constant-rate IV infusion (87.5 mg in 10 L of sodium-glucose infusion at 2 drops/sec) has been used to treat cecal dilatation/dislocation. However, the stimulatory effect of neostigmine is not always reliable, and some inhibition of motility can be seen. This may be due to the adrenergic component associated with ganglion stimulation by cholinergic agents.

Bethanechol (0.07 mg/kg, SC, tid for 2 days) has been used to treat spontaneous cecal dilatation without torsion. Potential adverse effects include salivation and diarrhea. Recommendations involving neostigmine and bethanechol have not been confirmed in randomized, controlled experiments. Neither compound has been approved by the FDA for use in cattle. Parasympathomimetics are sometimes used in practice to conservatively treat left displaced abomasum in cows, although the literature indicates that use of these compounds is of no value for this purpose.

N-butylscopolammonium bromide (nonlactating adult cattle: 0.2 mg/kg, IM or IV; calves: 0.4 mg/kg, IM or IV) is a parasympatholytic agent approved for the control of diarrhea in cattle in some European countries. The commercial formulation is combined with an NSAID, metamizole (nonlactating adult cattle: 25 mg/kg, IM or IV; calves: 50 mg/kg, IM or IV). Administration of N-butylscopolammonium bromide (80 mg/cow) in combination with dipyrone has been proposed as a conservative treatment of spontaneously occurring right-side displacement of the abomasum in cattle. However, this has not been demonstrated in randomized, controlled studies. N-butylscopolammonium bromide is not approved by the FDA, and the use of dipyrone in food animals in the USA is prohibited.

Atropine (0.04 mg/kg, IV) has been found to mitigate abomasal contractions for 1–3 hr.

Atropine sulfate (0.5 mg/kg, IV) administered 5 min before placement of a reticular magnet is suggested to prevent magnet loss into the cranial sac of the rumen. Atropine (40 mg/cow as a 1% solution, SC) is also used to determine disruption of forestomach motility in cattle suspected to have vagal indigestion. An increase of >16% in heart rate 15 min after atropine administration is considered indicative of severe disruption of forestomach motility.

Xylazine hydrochloride (0.2 mg/kg, IV) administered 5 min before placement of a reticular magnet may prevent loss into the cranial sac of the rumen but will also result in deep sedation of the animal and thus is unlikely to be of any practical use. Xylazine-induced atony of the reticulorumen may be reversed by pretreatment with tolazoline (0.5 mg/kg, IV), atipamezole hydrochloride (0.08 mg/kg), or yohimbine (0.2 mg/kg, IV). Adverse effects of xylazine in cattle include bradycardia, hypothermia, salivation, diuresis, ruminal bloat, and aspiration pneumonia. Neither xylazine nor its antidotes have been approved by the FDA for use in cattle.

Metoclopramide (cattle: 0.15 mg/kg, IM; sheep: 0.023–0.045 mg/kg) has cholinergic and antidopaminergic effects but does not appear to increase the myoelectric activity of the pyloric antrum in either species. However, metoclopramide at 0.5 mg/kg given IM or IV to goats has been shown to increase myoelectric activity of the pyloric antrum but not the body of the abomasum. Because metoclopramide can cross the blood-brain barrier, restlessness and excitement are potential adverse effects. Metoclopramide has not been approved by the FDA for use in cattle.

Erythromycin lactobionate is a macrolide antimicrobial that increases gut myoelectric activity by binding to motilin receptors in intestinal smooth muscle cells. In cows, erythromycin (0.1 mg/kg, IV, or 1 mg/kg, IM) was found to increase myoelectric activity in the abomasum and duodenum for >2 hr. This effect was increased to 6–8 hr when erythromycin was administered in polyethylene glycol at 10 mg/kg, IM. Erythromycin is approved by the FDA only for treatment of shipping fever, pneumonia, footrot, and metritis at 2.2 mg/kg, IM. Deep IM injection in muscles of the neck is recommended because of the risk of pain, swelling, and tissue blemishes at the injection site.

The prokinetic serotonergic drug cisapride (cattle: 0.08 mg/kg) is widely used in equine medicine, yet significant prokinetic effects have not been conclusively demonstrated in ruminants. Furthermore, definitive clinical and experimental data to

support the use of opioids or lidocaine in ruminants have not been published.

DRUG DISPOSITION IN THE RUMINORETICULUM

Morphologic and functional characteristics of the ruminoreticulum that make it suitable for fermentative digestion of plant material also affect the activity, distribution, and absorption of many drugs, particularly when given PO. The anaerobic and reductive environment of the ruminoreticulum and the presence of many microbial enzymes result in inactivation of drugs such as trimethoprim and cardiac glycosides. Slow and inefficient mixing of drugs in the large volume of the ruminoreticular fluid delays attainment of uniform concentrations throughout the multiphasic ingesta and retards absorption from the ruminoreticulum. Absorption is also affected by the polarity and ionization status of the drug, which is determined by the pK_a of the drug and the pH of the ruminoreticular fluid. The latter depends on the diet and the relative contributions of alkaline saliva and acidic ruminoreticular fluid. Aside from the many effects that the ruminoreticular environment can have on the activity and disposition of drugs, the drugs themselves may have unintended effects on ruminoreticular function. In particular, broad-spectrum antibacterial agents and antiprotozoal agents can disrupt the normal balance of microflora in the ruminoreticulum.

These factors affecting the activity and disposition of drugs in the ruminoreticulum, together with the possible effects of drugs on ruminoreticular function, complicate oral administration of drugs to ruminants. In young animals, these undesirable effects can be avoided by making use of the esophageal groove reflex. This reflex, which is elicited by receptors in the mouth and pharynx, is well developed in suckling neonates but becomes less reliable in older animals. After ~24 mo in cattle and ~18 mo in sheep, provoked reticular groove closure is often irregular, incomplete, or absent.

Ruminoreticular morphology and function has less influence on drug disposition in neonatal ruminants than in adults. At birth, the forestomachs are underdeveloped, and the newborn ruminant is essentially monogastric. Drugs that are usually destroyed in the ruminoreticulum of adults (eg, trimethoprim) may be well absorbed during the first 2–3 wk of life. This developmental pattern depends on the period between birth and initiation of a roughage diet and exposure to microbes in the environment.

SYSTEMIC PHARMACOTHERAPEUTICS OF THE EYE

See also OPHTHALMOLOGY, p 488.

The anatomy of the eye presents unique opportunities for topical and/or systemic medical treatment of neural tissue. Like the brain, the eye has protective barriers from the vascular system. The blood-ocular barriers (ie, the blood-aqueous and blood-retinal barriers) allow the eye to control entry of inflammatory cells, protein, and low-molecular-weight compounds from the systemic circulation.

The **blood-aqueous barrier** is a function of the iris and ciliary body epithelium. In the iris, the capillary endothelium is not fenestrated, but there are tight junctions. In the ciliary body, there are tight connections between the apical ends of the nonpigmented epithelial cells. Breakdown of this barrier results in entry of protein and cells into the anterior chamber and is seen as aqueous flare or plasmoid aqueous. The **blood-retinal barrier** is composed of two layers: an endothelial and epithelial portion. The endothelial part is composed of the endothelium of the retinal capillaries, which are also nonfenestrated. The epithelial portion is the retinal pigment epithelium. When treating the eye via the systemic circulation, these barriers can limit the entry and amount of medications into the eye, especially highly water-soluble compounds. They are less effective in the face of inflammation, and many drugs gain increased access to the intraocular structures when the eye is inflamed. The time required for drugs to reach their peak concentrations in the eye depends highly on the physicochemical properties of the particular drug.

The presence of barriers such as the iris, ciliary body, and lens, as well as normal movement of aqueous humor through the pupil and out the trabecular and uveoscleral meshwork can further limit the distribution of drugs. Several enzymes are present in the cornea and ciliary body. These can metabolize drugs to inactive metabolites before and after the compound reaches the anterior chamber. Drugs predominantly leave the anterior chamber with the aqueous humor via the corneal trabecular and/or uveoscleral meshwork, although small amounts may move posteriorly into the vitreous.

ROUTES OF ADMINISTRATION

The three primary methods of delivery of ocular medications to the eye are topical, local ocular (ie, subconjunctival, intravitreal, retrobulbar, intracameral), and systemic. The most appropriate method of administration depends on the area of the eye to be medicated. The conjunctiva, cornea, anterior chamber, and iris usually respond well to topical therapy. The eyelids can be treated with topical therapy but more frequently require systemic therapy. The posterior segment always requires systemic therapy, because most topical medications do not penetrate to the posterior segment. Retrobulbar and orbital tissues are treated systemically.

Subconjunctival or sub-Tenon's therapy, although not a true form of systemic medication administration, has the potential to increase both drug absorption and contact time. Medications both leak onto the cornea from the entry hole of injection and diffuse through the sclera into the globe. Drugs with low solubility such as corticosteroids may provide a repository of drug lasting days to weeks. Appropriate amounts of medication must be used. Large amounts, especially of long-acting salts, can cause a significant inflammatory reaction. For sub-Tenon's injections, 0.5 mL per site is usually safe and effective in small animals, and ≤ 1 mL can be used in large animals such as horses and cows.

Retrobulbar medications are used infrequently for therapeutics. In cattle, the retrobulbar tissues can be anesthetized with local anesthetic (lidocaine/bupivacaine) for enucleation using either a Peterson block (15–20 mL) or a 4-point block of the orbit (5–10 mL/site). Whenever any medication is placed into the orbit, extreme care must be taken to ensure that the medication is not inadvertently injected into a blood vessel, the optic nerve, or one of the orbital foramen. Retrobulbar injection has a high risk of adverse effects and should not be used unless the clinician is experienced and the animal is appropriately restrained.

Systemic medication is required for posterior segment therapy and to complement topical therapy for the anterior segment. The blood-ocular barriers can

limit absorption of less lipophilic drugs, but inflammation will initially allow greater drug concentrations to reach the site. As the eye starts to heal, these barriers will again become more effective and can limit further drug penetration. This should be considered when treating posterior segment disease, eg, blastomycosis in small animals with hydrophilic drugs such as itraconazole.

After topical administration, up to 80% of the applied drug(s) is absorbed systemically across the highly vascularized nasopharyngeal mucosa. Because absorption via this route bypasses the liver, there is not the large first-pass metabolism seen after oral administration. Depending on the drugs used, this can result in systemic adverse effects. Topically applied β -blockers used in the treatment of glaucoma can cause heart block, atrial tachycardia, congestive heart failure, bronchospasm, dyspnea, and decreased exercise tolerance. These drugs should be used very carefully in older animals or in animals with cardiac or respiratory disease. Cushing syndrome can be easily induced in small or medium-sized dogs with chronic use of potent topical steroids.

LOCAL ANESTHETICS

Parenterally, local nerve blocks are an excellent aid for routine ocular evaluation and diagnostic procedures in horses. The auriculopalpebral block is the most helpful block to limit blepharospasm during examination. This procedure blocks some of the motor nerves of the upper eyelid and enables the examiner to control the horse's upper eyelid. The auriculopalpebral nerve is a branch of the facial nerve and can be palpated as it runs across the superior margin of the zygomatic arch. To block sensory input, a supraorbital nerve block or a ring block is used. The supraorbital nerve is a branch of the frontal nerve that traverses the supraorbital foramen of the upper orbit. If placed correctly, a dose of 1–2 mL of lidocaine is usually sufficient to block either the auriculopalpebral or supraorbital nerve. The block is usually effective within 3–5 min and can last up to 2–3 hr.

The same principles are used in food animals, such as cattle, in which both a retrobulbar and ring block may be used. A correctly placed retrobulbar block will block cranial nerves II, III, IV, the ophthalmic branch of V, and VI. The ring block is needed to inhibit sensory input from the skin around the eye.

TREATMENT OF INFECTIOUS DISEASE

Feline Herpesvirus Keratitis and Conjunctivitis:

Systemic antiviral drugs to treat feline ocular herpesvirus are needed only in circumstances when topical antiviral therapy is not effective. Fanciclovir (the prodrug of penciclovir) at 15–30 mg/kg, PO, bid-tid for 10–14 days (or empirically at 31.25 mg/kitten or small cat, or 62.5 mg/cat, bid for 2 wk) is the drug of choice for treatment and longterm management. Acyclovir has also been used at 200 mg, PO, bid-tid, although repeated dosing can cause systemic toxicity and is not recommended as first-line treatment. Previously, lifelong oral L-lysine (250–500 mg/day) was recommended to help prevent or reduce the severity of recurrent feline herpesvirus infections. However, recent work has shown that oral L-lysine can actually exacerbate feline herpesvirus infections. Recombinant human α -interferon (5–25 U/day, PO and topically) has also been recommended and may work by inhibiting replication of herpesvirus and enhancing macrophage activation and lymphocyte-mediated cytotoxicity.

Feline Chlamydial Conjunctivitis:

Feline conjunctivitis caused by *Chlamydia felis* (see p 506) that is nonresponsive to topical tetracycline therapy can be treated with oral doxycycline (10 mg/kg/day, or 5 mg/kg, bid). To avoid esophageal strictures, animals should be treated with 3–5 mL of oral fluid after dosing to ensure the tablets pass into the stomach. All cats in the household should be treated for at least 4 wk, or for 2 wk after clinical signs have resolved. To avoid issues associated with tetracycline use in pregnant queens or young cats, systemic macrolides such as erythromycin (15–25 mg/kg, PO, bid, or 10–15 mg/kg, PO, tid for 3–4 wk) or azithromycin (10–15 mg/kg/day, PO, for 3–5 days then twice weekly for 3 wk) are also effective. Alternatively, potentiated amoxicillin (12.5–25 mg/kg, bid for 3 wk) can be used. If signs recur after treatment ceases, therapy should be continued for an additional 4–5 wk.

Feline Toxoplasmosis:

Many cases of feline anterior uveitis with increasing *Toxoplasma gondii* titers, as shown by serology and anterior chamber centesis, remain undiagnosed. Chorioretinitis is often the most common presentation. Treatment is clindamycin at 8–17 mg/kg, PO, tid, or 10–12.5 mg/kg, PO, bid for 3–4 wk, in association with topical corticosteroids

(0.5%–1% prednisolone acetate or 0.01% dexamethasone alcohol tid-qid) and topical atropine for mydriasis. Adverse effects of clindamycin include anorexia, vomiting, and diarrhea, mainly at the higher doses. Other systemic antibiotics less frequently used include the synergistic combination of sulfonamides (sulfadiazine, sulfamethazine, sulfamerazine, 100 mg/kg/day, PO) and pyrimethamine (2 mg/kg/day, PO) for 1–2 wk. Adverse effects include gastric upsets and bone marrow suppression. Frequent hematologic monitoring is recommended if therapy is to last >2 wk.

Feline and Canine Rickettsial

Infection: Anterior and posterior uveitis and chorioretinitis secondary to infection with *Ehrlichia* or *Rickettsia* spp (see p 803) is common. Tetracyclines (doxycycline at 5–10 mg/kg, once to twice daily for dogs, and 10 mg/kg, bid, for cats, for 14–21 days) are the drugs of choice and have excellent intraocular penetration. In a dog from an area associated with rickettsial disease, it is rational to empirically treat uveitis with doxycycline pending serology. Enrofloxacin (3 mg/kg, PO, bid for 7 days) can also be used, although care should be taken not to exceed the dosage associated with retinal toxicity in cats (>5 mg/kg/day). Chloramphenicol is not recommended, because it directly interferes with heme and bone marrow synthesis. Appropriate topical and systemic NSAID therapy is also recommended to control ocular inflammation. When the intraocular inflammation is severe or there is a serous retinal detachment, short-term (2–7 days) corticosteroids (0.25–0.5 mg/kg, PO, once to twice daily) may be used concurrently 24–48 hr after the start of oral antibiotic therapy. Animals can regain some vision after reattachment of the retina; the amount depends on the duration of the detachment and degree of inflammation.

Canine and Feline Ocular Mycoses:

Dogs and cats diagnosed with ocular mycoses require systemic treatment. Along with systemic antifungals, topical and systemic anti-inflammatories and topical mydriatics/cycloplegics are needed to control the secondary and potentially blinding intraocular inflammation.

Blastomycosis (see p 634) is more common in dogs than cats. Up to 40% have ocular signs, usually anterior uveitis. Treatment options include parenteral amphotericin B deoxycholate or PO or IV triazoles. In dogs, itraconazole is used at 5 mg/kg, PO, bid for 5 days, then continued at 5 mg/kg/day, PO, for a minimum of 60 days

or 1 mo after all signs of the disease have resolved. Adverse effects include anorexia, which is associated with liver toxicity. Cats can be treated with 10 mg/kg/day or 5 mg/kg, bid; however, there are few published cases of successful treatment in cats. Ketoconazole may also be used to treat blastomycosis, but because the onset of effect is so slow, other triazoles should be used initially. Amphotericin B deoxycholate is also effective but is nephrotoxic. The dosage (dogs: 0.5 mg/kg, IV; cats: 0.25 mg/kg, IV) is given three times weekly until the animal becomes azotemic or a cumulative dose of 4–6 mg/kg in dogs or 4 mg/kg in cats is reached. Amphotericin B lipid complex used at the same or a slightly higher dosage is less nephrotoxic.

The predominant lesion of histoplasmosis (see p 639) is granulomatous chorioiditis, but anterior uveitis, retinal detachment, and optic neuritis can be present. Treatment options are itraconazole (10 mg/kg, PO) or fluconazole (2.5–5 mg/kg, PO) once to twice daily for 4–6 mo, or amphotericin B deoxycholate (0.25–0.5 mg/kg, IV, every 48 hr) until a cumulative dose of 5–10 mg/kg (dogs) or 4–8 mg/kg (cats) is reached. Because of its lipophilic nature and ability to cross the blood-ocular barriers, fluconazole is recommended for use in ocular disease, although animals have also had complete resolution when treated with the more hydrophilic triazole itraconazole.

Ocular signs are present in 15% of cryptococcosis (see p 637) cases and are more common in cats than in dogs. Treatment can be with amphotericin B deoxycholate (0.1–0.5 mg/kg, IV, three times per wk) alone or in combination with flucytosine (30–75 mg/kg, bid-qid for up to 9 mo). Ketoconazole, itraconazole, and fluconazole are also effective. In cats, ketoconazole is administered PO at either 5–10 mg/kg, bid, or 10–20 mg/kg/day for 6–10 mo. If toxicity occurs, the dosage can be changed to 50 mg/kg/cat, PO, every other day. In dogs, dosages are either 5–15 mg/kg, PO, bid, or 30 mg/kg/day, PO, for 6–10 mo. Systemic absorption from the GI tract is significantly enhanced by food. Adverse effects of ketoconazole include anorexia, diarrhea, vomiting, and increased liver enzymes. Because of poor CNS penetration, ketoconazole is not recommended for use as the sole agent in ocular cryptococcosis. Itraconazole (cats: 5–10 mg/kg, PO, bid, or 20 mg/kg/day, PO) is less likely to cause adverse effects than ketoconazole, and its GI tract bioavailability is enhanced by fatty food. Like ketoconazole, its hydrophilic nature leads to poor distribution into the

CNS, but it has been successful in treating CNS and ocular cryptococcosis. Adverse effects are mainly associated with the GI tract (anorexia and vomiting), but liver disease can also develop. Liver enzymes (ALT) should be monitored every 2 wk for the first month of treatment and monthly thereafter. Fluconazole is more lipophilic and has better bioavailability than itraconazole. It also penetrates the CNS better (60%–80% of serum levels) and causes fewer adverse effects than itraconazole. The dosage for cats and dogs is 5–15 mg/kg, PO, once to twice daily for 6–10 mo.

Ocular coccidioidomycosis (see p 637) is more common in dogs than in cats. Ocular involvement requires systemic treatment with ketoconazole (dogs: 15–20 mg/kg, PO, bid; cats: 15–20 mg/kg, PO, once to twice daily), although there is poor CNS and ocular penetration. Ketoconazole can be toxic in cats, so itraconazole (5–10 mg/kg/day, PO) would be a safer choice. Treatment is for 3–6 mo or longer, and relapses are common. Amphotericin B deoxycholate can also be used (0.4–0.5 mg/kg, IV, every 48–72 hr) until a cumulative dose of 8–11 mg/kg is reached.

Over the past 10 yr, a number of newer triazoles (voriconazole, ravuconazole [both fluconazole derivatives], and posaconazole [an itraconazole derivative]) with broader spectrum of activity against systemic mycoses (including those resistant to other azoles) have become available. Information on their clinical usage is limited and mostly published as pharmacokinetic studies or individual case reports. Doses have been extrapolated from their use and preclinical toxicology trials in people, and using these doses must be done carefully. Because posaconazole is primarily metabolized in most species by glucuronidation, care needs to be taken with the dose and duration, especially in cats. Voriconazole is predominantly hepatically metabolized, and in toxicology trials, chronic usage at 12 mg/kg for 6–12 months caused hepatotoxicosis. Very limited information is available on the use of ravuconazole in dogs and cats. The current literature should be reviewed before using any of these compounds.

Infectious Keratoconjunctivitis: Treatment of infectious keratoconjunctivitis (see p 512) associated with *Moraxella bovis* in cattle is improved with use of systemic antibiotics. Oxytetracycline and florfenicol are the two most commonly used. Two doses of parenteral long-acting oxytetracycline (20 mg/kg, IM or SC) 48–72 hr apart is effective, although care should be taken using tetracyclines in endemic anaplasmosis areas.

Florfenicol, at a single dose of 40 mg/kg, SC, or two doses of 20 mg/kg, IM, 48 hr apart, is also effective. The organism is also sensitive to trimethoprim-sulfonamide (15–30 mg/kg, IM or IV, once to twice daily) or a single SC dose of tilmosin (5–10 mg/kg), ceftiofur (6.6 mg/kg), or tulathromycin (2.5 mg/kg). *M. bovis* is resistant to systemic macrolides, lincosamides, and often penicillins.

Chlamydial keratoconjunctivitis in sheep and goats and nonchlamydial keratoconjunctivitis caused by *Mycoplasma* spp in goats can be treated with systemic antibiotics in addition to topical therapy. These include oxytetracycline (6–11 mg/kg, IV or IM), florfenicol (20 mg/kg, IM or SC), tylosin (10 mg/kg, IM), erythromycin base (2.2–15 mg/kg, IM, once to twice daily), or tilmosin (10 mg/kg, IM). Most animals are treated with a single dose because of management issues involved in treating flock outbreaks.

Penetrating Trauma: All penetrating wounds of the eye should be considered infected, and animals should be treated promptly with systemic broad-spectrum bactericidal antibiotics. For dogs and cats, oral amoxicillin-clavulanic acid (10–20 mg/kg, bid) is appropriate. When feasible, culture and sensitivity and cytology performed on anterior chamber centesis samples best guide appropriate antibiotic selection. Treatment should continue for a minimum of 14–21 days. In horses, the combination of systemic penicillin G procaine (22,000–44,000 U/kg, IM, bid) and gentamicin (6.6 mg/kg/day, IM or IV) is an appropriate choice.

In all cases, intensive systemic NSAIDs (flunixin 0.5–1 mg/kg, IV or PO, once to twice daily; ketoprofen 1.1–2.2 mg/kg/day, PO or IV) are warranted to control the severe inflammation usually associated with these injuries. Because treatment duration in these cases extends beyond label recommendations of 5 days, an appropriate H₂-blocker (ranitidine, famotidine) or proton pump inhibitor (omeprazole) should be used prophylactically to prevent gastric ulceration. When inflammation is also associated with leakage of lens material into the anterior chamber, the only treatment to control the inflammation is removal of the lens.

TREATMENT OF INTRAOCULAR INFLAMMATION

Many infectious and noninfectious diseases cause intraocular inflammation. Unless inflammation is controlled early, irreversible damage and blindness may result.

Topical and systemic corticosteroids and NSAIDs are used to control inflammation, depending on the cause. Care should be taken when using longterm treatment. Adrenocortical suppression can develop, and animals must be weaned off treatment slowly after the inflammation has resolved. In all species, control of noninfectious intraocular inflammation involves use of high initial doses of systemic corticosteroids (prednisone 1–2 mg/kg) in combination with topical corticosteroids (0.5% or 1% prednisolone acetate or 0.1% dexamethasone alcohol, tid–qid). Some cases of infectious disease (eg, rickettsial infections) can be treated with low doses of systemic corticosteroids but only after antibiotic therapy has been started for 24–48 hr. Topical steroids can be started at the same time as systemic antibiotic therapy. If the cause of intraocular inflammation is unknown, a combination of topical corticosteroids and systemic NSAIDs is also appropriate. Use of H₂-blockers or proton pump inhibitors should be considered when starting therapy; GI, liver, and renal parameters should be routinely monitored.

Canine Immune-mediated Disease:

Immune-mediated ocular disease is not uncommon in dogs. This can include episcleritis, nodular granulomatous episclerokeratitis (often seen in Collies as a raised granulomatous lesion involving the episclera and third eyelid and infiltrating into the cornea), and extraocular muscle myositis. In addition to infectious anterior and posterior uveitis, immune-mediated uveitis (uveodermatologic syndrome) associated with an immune reaction to melanin is seen in a number of breeds, more commonly those of Arctic origin.

These diseases can be treated with either combined topical and oral corticosteroids (prednisone, 0.5–1 mg/kg, bid) or a lower corticosteroid dose in combination with another immunosuppressive drug. This could be oral azathioprine (1.5–2 mg/kg/day, reducing the dose after 3–5 days), mycophenolate mofetil (7–20 mg/kg, bid for 3–4 wk, then reducing the dose to 10 mg/kg/day), or cyclosporine (5 mg/kg, bid for 2 wk, decreasing to daily if clinical improvement). An alternative treatment for episcleritis in dogs >10 kg is niacinamide (500 mg, PO) and tetracycline (500 mg, PO), tid, decreasing to once to twice daily once improvement occurs.

Many cases of immune-mediated ocular disease can be kept in remission with either azathioprine, 1–2 mg/kg, PO, every 3–7 days for 1–8 mo; mycophenolate mofetil, 10 mg/kg

every day or every other day; or cyclosporine 5 mg/kg daily, every other day, or once weekly with or without concurrent low-dose prednisone or prednisolone. Adverse effects of azathioprine include pancreatitis, liver disease, and bone marrow suppression. Frequent hematology and serum biochemistry monitoring is recommended. There are fewer adverse effects with mycophenolate and cyclosporine. These are mainly related to the GI tract and include anorexia, vomiting, and diarrhea. In uveodermatologic syndrome, recurrence is common and prognosis for longterm control is only fair. Many animals become blind from secondary glaucoma associated with the chronic uveitis and/or retinal detachment and degeneration.

Canine Optic Neuritis: Inflammation of the optic nerve is more common in dogs than in other species. It can be caused by infection (eg, distemper, systemic mycoses), neoplasia, contiguous inflammation, or granulomatous infiltration (reticulosis/granulomatous encephalomyelitis). Systemic corticosteroids (prednisone, 1–2 mg/kg, PO) for extended periods (often weeks) are used in an attempt to retain vision. Granulomatous encephalomyelitis is responsive to early treatment with systemic corticosteroids.

Damage to the optic nerve as a result of trauma is treated with systemic corticosteroids at similar dose rates as above. Prognosis depends on the degree of damage.

Equine Uveitis: The principles of anti-inflammatory treatment for equine uveitis (see p 508) are very similar regardless of the initiating cause. In acute uveitis, systemic NSAIDs (flunixin meglumine, 0.25–1 mg/kg, IV or PO, bid) are used in conjunction with topical and/or subconjunctival corticosteroids to control the intraocular inflammation. Phenylbutazone does not seem to be as effective in the initial treatment of equine uveitis. Horses are often treated with high doses of NSAIDs for longer than label recommendations (often 7–10 days); once the uveitis is controlled, the dose is slowly tapered over 2–3 wk. Concurrent gastric protection with either an H₂-blocker (ranitidine, 6.6 mg/kg, PO, tid, or 1 mg/kg, IV, tid; or famotidine, 0.23–0.35 mg/kg, IV, bid–tid, or 1.88–2.8 mg/kg, PO, bid–tid) or a proton pump inhibitor (omeprazole, 4 mg/kg/day, PO) is recommended. Renal function should be monitored, and extreme care taken if the horse is also being treated with gentamicin. Oral aspirin (25 mg/kg/day) has been used longterm to help prevent

recurrence in horses diagnosed with equine recurrent uveitis. Suprachoroidal cyclosporine implants are now more commonly used for longterm management (up to 3 yr).

Equine Optic Neuritis: Trauma to the poll in horses associated with rearing and hitting objects or falling over backward can result in sudden blindness. This is associated with overextension or shearing of the optic nerve within the optic canal secondary to movement of the brain in the skull. Treatment is systemic antiinflammatory agents, usually NSAIDs at higher dosages (flunixin meglumine, 0.5–1.1 mg/kg, IV or PO) and for longer than label recommendations. Prophylactic use of H_2 -blockers or a proton pump inhibitor is recommended. In addition, dimethyl sulfoxide (DMSO; 1 g/kg, IV as a 20% solution in saline or 5% dextrose in water given daily for 3 days, then every other day for 6 days) can be used. When given IV, DMSO can cause hemolysis and hemoglobinuria. Prognosis is poor for any return of vision if there has been no improvement after 72 hr.

TREATMENT OF MISCELLANEOUS FELINE CONDITIONS

Feline Eosinophilic Keratitis: Eosinophilic keratitis is associated with infiltration of eosinophils into the feline cornea. It may be an unusual immune response to latent feline herpesvirus. Treatment with topical steroids usually is sufficient, but some cases do not respond. Oral megestrol acetate (0.5 mg/kg/day until a response is noted, then 1.25 mg, PO, 2–3 times weekly as required) helps to improve or resolve the corneal inflammation via an unknown mechanism. However, its use is associated with adverse effects such as diabetes mellitus, adrenocortical suppression, and uterine hyperplasia, and this drug should be used with extreme caution. Megestrol acetate can also be dangerous to women handling the pills.

Feline Hypertensive Retinopathy: Older cats can present with sudden blindness due to serous retinal detachments secondary to systemic hypertension, or less commonly hyperthyroidism. Treatment is with the calcium channel blocker amlodipine (0.625 mg/cat once to twice daily; some cats may require 1.25 mg/cat, bid) and systemic corticosteroids (prednisone, 0.5–1 mg/kg, PO) to help control the posterior inflammation. Retinas can reattach once blood pressure returns to the normal range. At least 50% of cats will regain some clinical vision if treated early. Cats

should be rechecked 1 wk after starting therapy, and blood pressure regularly monitored. Adverse effects of amlodipine are uncommon but include azotemia, lethargy, hypokalemia, and tachycardia.

TREATMENT OF GLAUCOMA

Topical medications, such as prostaglandins, miotics, β -blocking adrenergics, and topical carbonic anhydrase inhibitors, are the primary drugs for treatment of glaucoma (see p 497), but these are often supplemented with systemic drugs.

Osmotic Diuretics: In the emergency treatment of acute glaucoma, intraocular pressure must be reduced urgently. This is done pharmacologically using osmotic diuretics such as mannitol or glycerol in combination with other topical and systemic drugs. Osmotic diuretics are large-molecular-weight molecules that increase the osmotic pressure of plasma relative to the aqueous and vitreous. Most of the water in the eye is in the vitreous. Dehydration of the vitreous allows the lens and iris to move posteriorly, opening the iridocorneal angle. The other effect is to decrease formation of aqueous humor. Mannitol is given (1–1.5 g/kg, IV over 20–30 min), with the effect peaking in 2–3 hr and lasting up to 5 hr. Mannitol is not metabolized and thus can be used in diabetic animals. Glycerol (1–2 g/kg, PO) can be used but is unpalatable, and most dogs vomit. With both drugs, water should be withheld for 3–5 hr, and the animal should be given regular opportunities to urinate. Kidney and cardiac function should be checked before treatment, and cardiac function monitored during treatment. Mannitol can be used again within 8–12 hr if initial control of intraocular pressure is not maintained; longterm control is unlikely if intraocular pressures do not stay within the normal range after two treatments.

Carbonic Anhydrase Inhibitors: Oral carbonic anhydrase inhibitors are also used to treat and manage acute glaucoma. These inhibit the enzyme carbonic anhydrase in the nonpigmented ciliary epithelium responsible for catalyzing the following reaction: $CO_2 + H_2O \rightleftharpoons \text{carbonic anhydrase} \rightarrow H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$

The bicarbonate and sodium ions are actively transported into the anterior chamber, leading to passive movement of water. This mechanism produces 40%–60% of aqueous humor. Drugs used include methazolamide (2–4 mg/kg, PO, bid-tid), acetazolamide (5–8 mg/kg, PO, bid-tid), and

dichlorphenamide (2–4 mg/kg, PO, bid-tid). Methazolamide is the drug of choice.

Maximal effect occurs 3–6 hr after administration. The most common adverse effect is a metabolic acidosis that causes panting. Other effects can include vomiting, diarrhea, and hypokalemia. Acetazolamide commonly causes anorexia.

Potassium supplementation can be given with potassium bicarbonate or citrate (1–2 g/day) added to the food. Cats are more sensitive than dogs to the adverse effects of these drugs and need careful monitoring. In general, systemic carbonic anhydrase inhibitors are not recommended for use in cats.

SYSTEMIC PHARMACOTHERAPEUTICS OF THE INTEGUMENTARY SYSTEM

See also PRINCIPLES OF TOPICAL THERAPY, p 844.

Drugs that may be used in the integumentary system fall into several therapeutic categories: antimicrobials (antibacterials, antifungals), antiparasitics, NSAIDs, immunomodulators, hormones, psychotropic agents, and vitamin and mineral supplements.

Several factors may contribute to the development of the particular clinical presentation. Each factor should be identified and treated for therapy to succeed. For example, recurrent otitis may have a primary underlying skin disease but be complicated by both predisposing and perpetuating factors. Further, successful treatment of skin disease may require longterm or lifelong therapy and is frequently a matter of successful control rather than “cure.”

ANTIBACTERIALS

Most canine skin infections are caused by coagulase-positive *Staphylococcus pseudintermedius* (formerly *S. intermedius*), which commonly produce β -lactamase. Other staphylococcal species have been described, including *S. aureus*, *S. schleiferi*, and *S. hyicus*. There does not appear to be any difference in the disease patterns or clinical signs produced by the different species, although species-specific differences in antimicrobial resistance profiles have been seen in North America, with *S. pseudintermedius* and *S. aureus* showing more resistance than *S. schleiferi* *coagulans*. Species identification requires molecular techniques such as PCR detection of species-specific thermonuclease genes (*nuc*) or 16S rDNA sequencing, because phenotypic differentiation is unreliable.

Occasionally, *Proteus* spp, *Pseudomonas* spp, and *Escherichia coli* are secondary invaders of the dermis. *Pasteurella multocida* and β -hemolytic streptococci

are the most common bacteria isolated from the epidermis of cats. *Actinomyces* and mycobacteria are rare opportunistic invaders in dogs and cats. Bactericidal drugs expected to be effective against these bacteria should be used when treating the first occurrence of pyoderma in an animal.

Bacterial skin disease in large animals may be caused by *Dermatophilus congolensis*, staphylococci, *Corynebacterium* spp, *Actinomyces*, and rarely *Bacillus* spp or *Pseudomonas* spp. Draining tracts or abscesses in the skin of sheep or goats may be caused by *Corynebacterium pseudotuberculosis*. *Fusobacterium* spp and *Bacteroides* spp are the primary invaders in interdigital necrobacillosis (footrot). The spirochete *Borrelia suilla* is a secondary invader of skin lesions caused by sarcoptic mange or ear biting in swine. Clostridial diseases in cattle and erysipelas in swine are disorders that involve the integumentary system and cause serious economic losses.

Methicillin resistance (a marker for resistance to all β -lactam antibiotics, including penicillins, cephalosporins, and carbapenems) is the most important mechanism of resistance in staphylococci; the reported incidence of antimicrobial-resistant bacteria has increased markedly over the past 5–10 yr, although this varies depending on the geographic location. For example, a 2010 Japanese study reported the incidence of methicillin-resistant *S. pseudintermedius* (MRSP) at 66.7%. Many methicillin-resistant isolates are also multidrug resistant (resistant to more than three classes of antibiotics), which makes clinical management, particularly empirical therapy, more difficult. Before the increase in incidence of resistant strains, if the exudative cytology showed the presence of an active infection with coccoid organisms, empirical antibiotic treatment could begin. The rise of antimicro-

bial resistance has led to the development of guidelines by several organizations (British Veterinary Association [www.bva.co.uk], Federation of European Companion Animal Veterinary Associations [www.fecava.org], International Society for Companion Animal Infectious Disease [www.iscaid.org]) on the appropriate use of antibiotics for case management. (See TABLE 10.)

Empiric therapy may still be appropriate in the case of first-time or previously untreated superficial infections in which positive exudative cytology (with coccoid bacteria) has been established. The following may be used as first-line antimicrobials: cephalexin, cephadroxil, amoxicillin-clavulanate, trimethoprim-sulfas, lincosamides, and cefovecin (if owner compliance is consid-

TABLE 10 DOSAGES OF ANTISTAPHYLOCOCCAL ANTIBIOTICS

Drug	Dosage
CEPHALOSPORINS	
Cephalexin	20–30 mg/kg, bid, PO
Cephadroxil	Dogs: 20 mg/kg, bid, PO Cats: 20 mg/kg/day, PO
Cefaclor	10–25 mg/kg, bid, PO
Cefovecin	8 mg/kg, SC, every 14 days
Cefpodoxime	5–10 mg/kg/day, PO
PENICILLINS	
Amoxicillin-clavulanate	13.75 mg/kg, bid, PO
Oxacillin	22 mg/kg, tid, PO
FLUOROQUINOLONES	
Enrofloxacin	5 mg/kg/day, PO
Marbofloxacin	2 mg/kg/day, PO
Orbifloxacin	2.5 mg/kg/day, PO
Difloxacin	5 mg/kg/day, PO
Pradofloxacin	3 mg/kg/day, PO
SULFONAMIDES	
Trimethoprim-sulfadiazine	15–30 mg/kg, bid, PO
Trimethoprim-sulfamethoxazole	15–30 mg/kg, bid, PO
MACROLIDES	
Erythromycin	15–30 mg/kg, tid, PO
Clindamycin	Dogs: 10–20 mg/kg, bid, PO Cats: 12.5–25 mg/kg, bid, PO
Azithromycin	10 mg/kg/day, PO
OTHERS	
Lincomycin	10–20 mg/kg, bid, PO
Chloramphenicol	50 mg/kg, tid, PO
Rifampin	5–10 mg/kg, once or twice daily, PO

ered an issue). Culture and sensitivity testing should be performed in any of the following circumstances: infections that have not responded to appropriate empiric therapy, presence of deep infections (nodules, hemorrhagic bullae, draining tracts), rod-shaped or unusual organisms on cytology, recurrent or relapsing infection, history of previous courses (particularly multiple) of antibiotic therapy, nonhealing wounds, recent potential exposure of owner or affected animal to methicillin-resistant staphylococci in health care environments, or history of prior MRSP infections. Second-line antimicrobials should be used only if there is no sensitivity to first-line antimicrobials on culture and sensitivity testing. These antibiotics are not appropriate for empiric therapy and include cefovecin (except when owner compliance is an issue), cefpodoxime, and fluoroquinolones (difloxacin, enrofloxacin, marbofloxacin, orbifloxacin, pradofloxacin). Third-line antimicrobials should be used only in cases in which there is evidence of sensitivity, no sensitivity to first or second-line antimicrobials, and topical antiseptics are not feasible or effective. Third-line antimicrobials include aminoglycosides, azithromycin, chloramphenicol, clarithromycin, imipenem, rifampin, and ticarcillin. With the increase in methicillin- and multidrug-resistant strains of staphylococci, the use of topical antiseptics has increased. They can be used as sole therapy for mild to moderate superficial infections and can reduce the treatment duration in more severe infections. There is little evidence that even multidrug-resistant staphylococci are not susceptible to topical antiseptics.

Duration of therapy varies with the type of infection present but should continue until the clinical lesions have resolved and cytology is normal. In general, superficial infections should be treated for 7 days beyond surface healing (commonly 3–4 wk); deep infections should be treated 7–21 days beyond resolution, which may require treatment durations of 8–12 wk if continued improvement is seen. Clinical resolution of MRSP infections may take longer than methicillin-susceptible *S. pseudintermedius* infections, but this is most likely due to infection chronicity and secondary changes of the skin rather than to any inherent virulence of the bacterial strain.

The potential for serious adverse effects when using either chloramphenicol or rifampin should be understood. Chloramphenicol can cause a dose-dependent bone marrow suppression (cats more sensitive), although GI irritation, inappetence, and weight loss are the most common.

Rifampin may cause hepatic enzyme induction and increase in hepatic enzyme activity, particularly alkaline phosphatase. Some dogs may develop a fatal hepatotoxicity. Other adverse effects include GI upset, hemolytic anemia, thrombocytopenia, and orange discoloration of body fluids. Liver enzymes should be monitored at least every 2 wk for the duration of therapy.

ANTIFUNGALS

The antifungal drugs used most commonly to treat integumentary diseases are listed in TABLE 11.

Griseofulvin: Griseofulvin has a very low solubility in water; GI absorption is variable and incomplete with the micronized form. Absorption may be enhanced by administration with a fat-containing meal or by formulations using polyethylene glycol or very small particles (micronization). The ultramicronized form is nearly 100% absorbed.

Griseofulvin is concentrated in skin (the highest concentration is in the stratum corneum), hair, nails, fat, skeletal muscle, and liver and can be found in the stratum corneum within 4 hr of dosing. It is also secreted in sweat and is deposited in keratinocytes and remains tightly bound during differentiation, so new skin growth is the first to be clear of infection. It is effective only against dermatophytes, eg, *Microsporum*, *Trichophyton*, and *Epidermophyton*.

In dogs, adverse effects (eg, vomiting, diarrhea) and increased liver enzymes predominate. In cats, anemia, leukopenia, vomiting, diarrhea, depression, pruritus, fever, and ataxia have been described. Bone marrow suppression (usually manifest as neutropenia) may occur idiosyncratically, especially in feline immunodeficiency virus (FIV)-positive cats and in kittens. FIV status should be determined before use, and griseofulvin avoided in kittens <8 wk old. The reactions may be more common and severe in Persian, Himalayan, Siamese, and Abyssinian cats. Teratogenicity is a major problem in all species.

Hemograms should be collected every 2 wk and close observation maintained. Leukopenia is more common in FIV-positive cats, so screening should be done before initiating treatment.

Ketoconazole: Ketoconazole is a synthetic, broad-spectrum antifungal drug belonging to the imidazole family. It is a potent inhibitor of ergosterol (a main membrane lipid of fungi) synthesis. Fungal

TABLE 11 DOSAGES OF ANTIFUNGAL MEDICATIONS

Drug	Dosage
Griseofulvin	
Microsize	25–60 mg/kg, PO, bid
Ultramicrosize	2.5–15 mg/kg, PO, bid
Ketoconazole	10 mg/kg/day, PO; 20 mg/kg, PO, every 48 hr
Itraconazole	5–10 mg/kg/day, PO
Fluconazole	10–20 mg/kg, PO, bid
Amphotericin B	Dogs: 0.25–0.75 mg/kg, IV, 3 times/wk to total cumulative dose of 4–8 mg/kg or until azotemia develops Cats: 0.1–0.25 mg/kg, IV, 3 times/wk to cumulative dose of 4–6 mg/kg
Flucytosine	25–50 mg/kg, PO, tid-qid
Terbinafine	10–30 mg/kg/day, PO
Potassium iodine	Dogs: 40 mg/kg, PO, once or twice daily with food Cats: 20 mg/kg, PO, once or twice daily with food

cells are thus unable to maintain the integrity of plasma membranes, which leads to cell wall rupture. Because the therapeutic effect of ketoconazole is delayed, amphotericin B is often used in combination for cases of serious systemic disease.

For dermatophytosis, ketoconazole is active against *Trichophyton verrucosum*, *T. equinum*, *T. mentagrophytes*, *Microsporum canis*, and *M. nanum*. It is also active against the yeast *Malassezia pachydermatis* and *Cryptococcus neoformans* and is normally used at 10 mg/kg/day, PO. For candidiasis, the dosage is 10 mg/kg/day, PO, for 6–8 wk. In some chronic cases, a maintenance dosage of 2.5–5 mg/kg can be used. Coccidioidomycosis responds better to ketoconazole than to amphotericin B in many instances, with a minimal treatment period of 12 mo in animals with disseminated disease. Blastomycosis, histoplasmosis, and cryptococcosis may be treated with a combination of ketoconazole and amphotericin B (the combination is not more effective than the latter alone, but there are fewer nephrotoxic signs). For blastomycosis, a 4–6 mg/kg total dose of amphotericin B is combined with ketoconazole (20 mg/kg/day in dogs, and 10 mg/kg/day in cats). For histoplasmosis, amphotericin B (2–4 mg/kg total dose) is combined with ketoconazole (20 mg/kg/day in dogs, and 10 mg/kg/day in cats).

Ketoconazole inhibits cortisol synthesis and has been used to treat canine hyperadrenocorticism at 10 mg/kg/day. If the cortisol level is still above resting levels

after 10 days, the dosage may be increased to 15 mg/kg/day.

Ketoconazole requires an acidic environment for optimal absorption, so H_2 -blockers or antacids should not be administered concurrently.

In dogs, the most common adverse effects are inappetence, vomiting, pruritus, alopecia, and reversible lightening of the hair coat. Anorexia may be reduced by administering the dose with food. Cats appear to be more sensitive to ketoconazole. Clinical signs of toxicity include anorexia, fever, depression, diarrhea, and increased liver enzymes. Dosages >10 mg/kg/day are rarely given. Hepatotoxicity (cholangiohepatitis and increased liver enzymes) has also been reported.

Itraconazole: The primary antifungal mechanism of action of itraconazole seems to be the same as that of ketoconazole; however, it has a greater potency, decreased toxicity, and a wider spectrum of activity. Even at high dosages, it does not alter hormone levels in rats, dogs, or people. Itraconazole should be administered with food; the concurrent administration of antacids, H_2 -blockers, and cholinergics is contraindicated.

Itraconazole is effective against dermatophytes, *Candida*, *Cryptococcus*, *Histoplasma*, *Blastomyces*, and *Sporothrix* spp, and the protozoans *Leishmania* and *Trypanosoma*. For dermatophytosis in dogs, the dosage is 5 mg/kg/day. For systemic mycoses, the dosage is 5–10 mg/kg/day, but the addition of

amphotericin should be considered in rapidly progressing infections. For treatment of dermatophytosis and systemic mycoses in cats, the dosage is 10 mg/kg/day.

A severe, dose-related ulcerative dermatitis (due to vasculitis) has been seen in 5%–10% of dogs given itraconazole in doses of 10 mg/kg. If the condition is identified early, drug withdrawal leads to resolution; if not recognized early, severe, extensive necrosis and sloughing can develop.

Fluconazole: Fluconazole is a fungistatic triazole compound with a mode of action similar to that of ketoconazole. However, it does not affect mammalian hormone synthesis. Because of its small molecular size and low lipophilicity, it may be more useful in treating CNS mycoses.

Fluconazole is effective against superficial dermatophytes and *Candida*, *Cryptococcus*, *Histoplasma*, and *Blastomyces* spp. The dosage is 2.5–10 mg/kg/day in dogs. Cats with cryptococcosis can be given 2.5–10 mg/kg, bid.

Fluconazole has had limited use in small animals. In people, it can cause occasional GI adverse effects (eg, vomiting, diarrhea, anorexia, nausea).

Amphotericin B: Amphotericin is a lipophilic polyene from *Streptomyces nodosus* that binds to sterols (especially ergosterol), causing increased permeability and leakage of nutrients and electrolytes. It is poorly absorbed from the GI tract and must be given parenterally. IV administration gives good penetration, except into muscle, bone, eye, or synovial fluid.

Amphotericin B is used in progressive or disseminated deep mycosis. It may be combined with flucytosine or minocycline for treatment of *Candida* and *Cryptococcus*. Rifampin potentiates the effect of amphotericin on *Aspergillus* (which is usually resistant against amphotericin alone), *Candida*, and *Histoplasma*.

Amphotericin B is insoluble in water and is prepared as an IV solution by forming a colloidal dispersion with sodium deoxycholate. Because it is inactivated by sunlight, it should be stored in the dark. Dilution with large volumes of 5% glucose (10 mg amphotericin B/100 mL fluid) is recommended to reduce nephrotoxicity. The dilution should be given over 2–6 hr. If a bolus is given in 10–60 mL of dextrose (via a butterfly catheter), supplemental fluid diuresis is helpful. Amphotericin B is given at 0.15–0.5 mg/kg every 48 hr until a total cumulative dose of 4–12 mg/kg is reached. Renal toxic effects are monitored

by electrolytes or urinalysis at least weekly (urinalysis detects toxicity earlier than biochemistry); BUN, creatinine, PCV, and total plasma proteins should be checked before the administration of each dose. Monthly maintenance therapy is recommended to avoid relapses.

The major adverse effect seen with amphotericin B is nephrotoxicity—most dogs incur some kidney damage. The damage is not correlated with either total dose or duration of therapy. The causes of toxicity include vasoconstriction, impaired acid excretion, and direct tubular injury. Cats are more sensitive, so lower doses are recommended. Adverse effects such as fever, nausea, and vomiting are less severe if diphenhydramine (0.5 mg/kg, IV), aspirin (10 mg/kg, PO), or hydrocortisone sodium succinate (0.5 mg/kg, IV) is given before administration of amphotericin B.

Flucytosine: This fluorinated pyrimidine was developed as an antineoplastic agent. It interferes with RNA metabolism and protein synthesis in fungal cells. It is well absorbed and enters the CNS in high concentrations. Most of the drug is excreted unchanged in the urine.

Flucytosine is effective against *Cryptococcus neoformans*, *Candida*, and other yeasts but has little or no effect on other fungi. Resistance develops frequently; thus, it is given in combination with amphotericin B. It is used almost exclusively for treatment of cryptococcosis. The dosage in dogs and cats is 25–50 mg/kg, tid-qid.

GI tract disturbances (vomiting, diarrhea, anorexia), bone marrow suppression (anemia, leukopenia, thrombocytopenia), and cutaneous eruption (depigmentation, ulceration, exudation, and crust formation) are the most common adverse effects.

Terbinafine: Terbinafine is an allylamine compound that interferes with fungal sterol biosynthesis at an early stage, causing deficiency of ergosterol, intracellular accumulation of squalene, and fungal cell death. It achieves high concentrations in hair follicles, hair, sebum-rich skin, nail plates, and nails. In people, levels exceeding the minimum inhibitory concentration may be found for up to 3 wk after treatment has ended. There are anecdotal reports of its use against *Trichophyton*, *Microsporum*, and *Epidermophyton*, as well as *Malassezia* dermatitis. The dosage in cats is 10–30 mg/kg/day. In people, rare cases of hepatic toxicity are seen, along with GI tract signs (eg, nausea, vomiting, diarrhea) and skin signs (eg, urticaria, itch, erythema).

Systemic Iodine: The mechanism of action of systemic iodine is unknown; no fungicidal effects are seen *in vitro*. It is used in small animals for sporotrichosis; in cattle for actinomycosis and actinobacillosis; and in horses for mycetomas, zygomycosis, and *Sporothrix schenckii*. Dogs are treated with potassium iodide 40 mg/kg, PO, bid; cats with potassium iodide 20 mg/kg, PO, once to twice daily; cattle with sodium iodide 60 mg/kg, IV, weekly; and horses (sporotrichosis) with sodium iodide, 40 mg/kg/day, IV, for 2–5 days, followed by potassium iodide, 2 mg/kg/day, PO, for 60 days.

In small animals, vomiting, diarrhea, depression, and inappetence (especially in cats) may develop. Ocular and nasal discharge, scaling, and a dry hair coat also may be seen in dogs. In large animals, seromucoid discharge, lacrimation, cough, variable appetite, joint pain, and seborrhea sicca with partial alopecia may develop. Systemic iodine may also cause abortion and should not be used in pregnant or lactating animals.

ANTIPARASITICS

Ivermectin: Ivermectin is an avermectin and a fermentation product of *Streptomyces avermitilis* (see also MACROCYCLIC LACTONES, p 2647). It acts as a GABA agonist, causing paralysis in susceptible arthropods and nematodes. It is used in small animals for treatment of *Sarcoptes scabiei*, *Otodectes cynotis*, *Cheyletiella blakei*, *C. yasguri*, and *Demodex canis*; in cattle for psoroptic mange, lice, and *Hypoderma* larvae; in horses for equine filarial dermatitis from *Onchocerca cervicalis*; and in swine for *Sarcoptes scabiei*.

In small animals, all use for skin conditions is extra-label in the USA. For *Demodex*, the dosage is 0.3–0.6 mg/kg/day, PO, until two negative skin scrapings 1 mo apart. For *Sarcoptes*, *Otodectes*, and *Cheyletiella*, the dosage is 0.3 mg/kg, PO, repeated in 2 wk. In cattle, 0.2 mg/kg is given as a single SC injection for *Psoroptes* and lice. In horses, 0.2 mg/kg, PO, kills microfilariae but not adult *Onchocerca cervicalis*, so relapse may be noted within 2 mo of treatment. In swine, the dosage is 0.3 mg/kg, SC, repeated in 2 wk, or 0.1–0.2 mg/kg in feed for 7 days.

In mammals, GABA is found only in the CNS and does not readily cross the blood-brain barrier. At least 10 times the normal dose of ivermectin is needed for toxic reactions. Ataxia, depression, and visual impairment develop in horses given 2 mg/kg, PO. In cattle, 4 mg/kg by drench or

8 mg/kg, SC, leads to listlessness and ataxia; 30 mg/kg induces ataxia in swine.

Some dog breeds (Collies, Shetland Sheepdogs, Old English Sheepdogs, Australian Collies, and their crosses) have an abnormality in the blood-brain barrier associated with a mutation of the multiple drug resistance gene MDR1, which allows increased ivermectin into the CNS and results in toxicity. Dogs that are homozygous for the mutation produce a severely truncated P-glycoprotein (<10% of the normal amino acid sequence) and will develop ivermectin toxicity at any of the dosages used to treat demodicosis. The critical point seems to be 120–150 mcg/kg, at which transient, nonfatal clinical signs (mydriasis, ataxia, tremors) are seen. At higher dosages, collapse, coma, and respiratory collapse may develop. Similar idiosyncratic reactions may develop in any breed, so a gradually increasing dose (daily progression of 50, 100, 150, 200, then 300 mcg/kg) should be given to identify susceptible individuals. Administration should be stopped if any adverse effects are seen. One cat treated with 4 mg of the oral paste (~70 mcg/kg) showed ataxia, blindness, tremors, and mydriasis, with retinal atrophy in one eye 10 hr later.

Milbemycin: Milbemycin is derived from fermentation products of *Streptomyces hygroscopicus* and, like ivermectin, acts as a GABA agonist but with a wider spectrum of activity against intestinal parasites. It has been used extra-label in dogs to treat nasal mites, scabies, and generalized demodicosis. No adverse effects have been seen in ivermectin-sensitive breeds. The dosage in dogs is 1–2 mg/kg every 7 days for 3–5 treatments for nasal mites and scabies and 1–2 mg/kg/day for *Demodex*.

Moxidectin: Moxidectin belongs to the milbemycin class of compounds. It is registered for heartworm control (*Dirofilaria immitis*) but has also been used extra-label for treatment of *Otodectes* and demodicosis in dogs. In cattle, it is used to treat lice (*Linognathus vituli*, *Solenopotes capillatus*, *Bovicola bovis*), mites (*Psoroptes*, *Chorioptes bovis*), ticks (*Boophilus microplus*), and fly warbles and grubs (*Hypoderma bovis*, *Hypoderma lineatum*). In sheep, it is used for *Psorobia ovis* infestation. The dosage is 0.2–0.4 mg/kg/day, PO, in dogs and 0.2 mg/kg in cattle and sheep.

Selamectin: This semisynthetic macrocyclic lactone is applied topically but acts

systemically. It is effective against *Ctenocephalides* spp (both adults and larvae), *Sarcoptes scabiei*, *Otodectes cynotis*, and *Dermacentor variabilis*. The dosage in dogs and cats is 6 mg/kg, applied topically.

Lufenuron: Lufenuron is an insect growth regulator that inhibits the synthesis of chitin, a critical component of insect exoskeletons. It is taken up by adult fleas while feeding. While it has no effect on adult fleas, it prevents development of the intermediate stages of the flea life cycle (ie, eggs, larvae, pupae). It is effective against *Ctenocephalides* spp in dogs and cats at a dosage of 10 mg/kg, PO, once a month. Chitin is also a component in the fungal cell wall of dermatophytes. An initial study showed efficacy of lufenuron in treating small animal dermatophytosis; however, additional studies have failed to show efficacy.

Nitenpyram: Nitenpyram inhibits the nicotinic acetylcholine receptor. It is used to treat *Ctenocephalides* spp in dogs and cats at a dosage of 1 mg/kg, PO. Nitenpyram has a short half-life and kills fleas on the animal within 30 min of administration. It is toxic to fleas for only 24–48 hr and is normally used in combination with an insect growth regulator to provide continuous flea control.

Spinosad: Spinosad stimulates the nicotinic acetylcholine receptor, which causes activation of motor neurons and results in involuntary muscle contractions and tremors, leading to paralysis and death of the insect. It is used to treat *Ctenocephalides* spp in dogs at a dosage of 31–70 mg/kg monthly and in cats at a dosage of 50–90 mg/kg monthly. It may trigger severe signs of ivermectin toxicity if administered concurrently with extra-label, high-dose ivermectin.

Indoxacarb: Indoxacarb blocks sodium channels in the insect to cause paralysis and death. It is effective against *Ctenocephalides* spp, both adults and larvae, and is applied as a spot-on topically, once a month.

Cythioate: Cythioate is an organophosphate that kills via anticholinesterase activity. It is indicated for *Ctenocephalides* spp infestations at a dosage of 3 mg/kg, PO, twice weekly (dogs) or 1.5 mg/kg, PO, twice weekly (cats). Although effective blood levels are maintained for <12 hr, serum cholinesterase activity may be decreased for >1 mo after dosing.

Sodium Stibogluconate: Sodium stibogluconate is used for treatment of cutaneous leishmaniasis, either as a sole therapy or in combination with allopurinol, paromomycin, or pentamidine. The exact mode of action is unknown, but it is believed to interfere with energy metabolism in *Leishmania* amastigotes. Dosage in dogs is 30–50 mg/kg/day, IV or SC, for 3–4 wk. If adverse effects occur (musculoskeletal pain, increase in liver transaminases, pancreatitis, myocardial injury, hemolytic anemia, leukopenia, renal dysfunction), the dose may be administered every other day for longer periods. Note that IV administration should be over 5 min to minimize cardiotoxicity.

ANTIHISTAMINES

Antihistamines block either H_1 or H_2 receptors. H_1 receptors are responsible for pruritus, increased vascular permeability, release of inflammatory mediators, and attraction of inflammatory cells. H_1 blockers act by competing with histamine for H_1 -receptor sites on effector cells (they do not block release of histamine but can antagonize its effects). They also have anticholinergic, sedative, and local anesthetic effects and vary greatly in their potency, dosage, incidence of adverse effects, and cost.

Second-generation H_1 blockers (eg, terfenadine, cetirizine, loratadine, astemizole) are less likely to cross the blood-brain barrier, or they have a low affinity for brain compared with peripheral H_1 receptors. They have not proved useful to date in controlling pruritus in small animals. Responses to antihistamines vary considerably, and several trials may be necessary to find one effective for an animal (see TABLE 12). Antihistamines may act synergistically with NSAIDs, glucocorticoids, or fatty acid supplements and may allow dosages of these agents to be reduced in some cases.

First-generation antihistamines may cause drowsiness or GI signs (eg, vomiting, diarrhea). Overdoses may cause CNS hyperexcitability and may be fatal. Anticholinergic properties lead to hypertension (and thus contraindicated in cardiac patients), dry mouth, blurred vision (contraindicated in glaucoma), and urinary retention. Hydroxyzine is teratogenic. They may also stimulate appetite (particularly cyproheptadine).

Second-generation antihistamines are cardiotoxic at high doses. High doses of terfenadine and astemizole lead to

TABLE 12 ANTIHISTAMINE DOSAGES

Drug	Dosage
Diphenhydramine	2–4 mg/kg, bid-tid
Hydroxyzine	0.5–2 mg/kg, tid-qid
Chlorpheniramine	Cats: 2–4 mg, bid Dogs <20 kg: 4 mg, tid Dogs >20 kg: 8 mg, tid; 0.25–0.5 mg/kg, tid
Cyproheptadine	0.25–0.5 mg/kg, tid; 1.1 mg/kg, bid
Terfenadine	5 mg/kg, bid
Clemastine	Cats: 0.05 mg/kg, bid Dogs: 0.1 mg/kg, bid
Trimeprazine	1 mg/kg, bid
Cetirizine	Dogs: 1 mg/kg or 10–20 mg per dog, once or twice daily Cats: 1 mg/kg or 5 mg per cat, once or twice daily
Fexofenadine	Dogs: 2–5 mg/kg, once or twice daily Cats: 10–15 mg per cat, once or twice daily

prolonged QT intervals and arrhythmias (eg, ventricular tachycardia, cardiac arrest). Cardiotoxicity has been reported only as a result of overdose in animals with impaired hepatic metabolism.

ESSENTIAL FATTY ACIDS

Fatty acids are essential components of cell membranes and are an integral component of the intercellular barrier in the stratum corneum. Essential fatty acids cannot be synthesized and therefore must be supplied in the diet. The essential fatty acids most important for homeostasis of the skin in dogs and cats are linoleic acid and linolenic acid. The anti-inflammatory properties of fatty acids are thought to be due to competitive inhibition of arachidonic acid metabolism, leading to a reduction in inflammatory leukotriene and prostaglandin synthesis and activity, and to the formation of metabolic byproducts of normal fatty acid metabolism that have direct anti-inflammatory properties.

Essential fatty acids are indicated for pruritic inflammatory diseases (eg, allergies, feline eosinophilic granuloma), crusting diseases (eg, discoid lupus erythematosus), and onychodystrophy. Many commercial products are available and may be used at the manufacturers' recommended dose. Lack of response to one product does not preclude response to

another, and increasing the dose to several times the label recommendation can help in some cases. Approximately 20% of dogs and 50% of cats with allergic pruritus will show some improvement. There are few adverse effects; however, pancreatitis has rarely been reported. Large doses may also cause weight gain or diarrhea.

HORMONAL THERAPY

Glucocorticoids: Glucocorticoids have profound effects on nearly all cell types and organ systems, particularly immunologic and inflammatory activity. They may be used in either an anti-inflammatory or immunosuppressive capacity, depending on the dosage selected. Glucocorticoids are used for hypersensitivity dermatoses, contact dermatitis, immune-mediated diseases (eg, pemphigus, pemphigoid, lupus erythematosus), and neoplasia (eg, mast cell tumor, lymphoma). Glucocorticoids may be classified according to their duration of effect and relative potency (see TABLE 13). They may be administered PO, IV, IM, or SC.

The anti-inflammatory dosage of prednisolone is 0.5–1 mg/kg/day in dogs (severe cases may require 2 mg/kg/day) and 1–2 mg/kg/day in cats. This dosage is given for an induction period of 5–7 days and then reduced to the lowest possible maintenance dosage (ideally 0.25 mg/kg, every 48–72 hr

TABLE 13 GLUCOCORTICOIDS

Drug	Relative Potency	Duration of Effect
Hydrocortisone (cortisol)	1	<12 hr
Prednisolone	4	12–36 hr
Prednisone	4	12–36 hr
Methylprednisolone	5	12–36 hr
Triamcinolone	5	12–36 hr
Flumethasone	15–30	36–48 hr
Betamethasone	25	>48 hr
Dexamethasone	30	>48 hr

or lower in dogs). Maintenance doses must be given ≥ 48 hr apart to minimize adrenal suppression and chronic adverse effects. The immunosuppressive dosage of prednisolone is 2.2 mg/kg/day in dogs (up to 6.6 mg/kg/day may be required in severe disease) and 4.4 mg/kg/day in cats.

The induction period is generally longer (10–20 days) than with anti-inflammatory dosing but is then gradually tapered in a stepwise fashion to an alternate-day dosing regimen once there is evidence of disease remission. Treatment should never be stopped abruptly, because of the risk of inducing signs of hypoadrenocorticism. If relapse occurs during the tapering process, the dose is increased to at least one step above the point at which the relapse occurred and tapered again if possible. In many cases, therapy may be withdrawn entirely without relapse, whereas others require lifelong treatment.

Administration PO is preferred, because dosing can be more closely regulated and physiologic processes are disrupted less than with repositol forms. In some cases, difficulties with animal handling or owner adherence may require injectable therapy. This is normally satisfactory for acute, short-term disease that does not require repeated administration (eg, a single injection of methylprednisolone acetate alters adrenocortical function in dogs for up to 10 wk).

Adverse effects include polyuria, polydipsia, polyphagia, weight gain, increased susceptibility to infection, GI ulceration, pancreatitis, osteoporosis, hyperglycemia, steroid myopathy, and callosities cutis. The extent and severity of adverse effects are related to the dose, duration, and type of glucocorticoid used, along with individual animal sensitivity. The most commonly encountered infections are

urinary tract infections, pyoderma, and pulmonary infections. Urinary tract infections may develop in many animals on long-term glucocorticoid therapy (68% in one study), and these animals may show no clinical signs of the infection. Urine should be cultured for bacterial growth every 3–6 mo in all animals on long-term therapy.

Progressive hepatocellular swelling due to glycogen accumulation may develop during glucocorticoid therapy. Alkaline phosphatase (ALP), ALT, and γ -glutamyl transferase all show progressive increases. In dogs, the initial ALP increase is due to hepatic ALP but later is due to a cortisone isoenzyme.

Most injectable forms are labeled for IM use; however, they are commonly given SC. Local areas of alopecia, pigmentation, and epidermal and dermal atrophy may be seen with SC injection.

Thyroid Hormone: Thyroid hormones are indicated as replacement therapy for primary, secondary, and tertiary hypothyroidism. Most cases of canine hypothyroidism are primary in nature and are due to autoimmune destruction of the thyroid gland. Drug-induced low hormone levels or “euthyroid sick syndrome” are not indications for supplementation with thyroid hormones.

Synthetic levothyroxine (T_4) is the drug of choice for canine hypothyroidism. Most dogs respond clinically to a dosage of 0.02 mg/kg, bid. Insufficient serum levels after 4–6 wk of treatment or lack of a clinical response after 12 wk are indications to increase the dose. Synthetic liothyronine (T_3) may be used for those rare animals that cannot convert T_4 to T_3 . It should not be used for routine treatment of hypothyroidism, because it bypasses the normal cellular regulatory pathways and has a short

half-life. Dosage is 4–6 mcg/kg, PO, bid-tid. Crude preparations from thyroid tissue and synthetic thyroid hormone combinations that mimic the T_4 : T_3 ratio in people should not be used in animals.

Signs of thyrotoxicosis in cats and dogs are rare. They include polyuria, polydipsia, nervousness, aggressiveness, panting, diarrhea, tachycardia, pyrexia, and pruritus. Complications in dogs are usually related to concurrent cardiac or adrenal insufficiencies. In animals with a marginal cardiac reserve, T_4 medication should be initiated at one-fourth the recommended dosage and gradually increased to full dosage over a 1-mo period.

Trilostane: Trilostane is a hormonally inactive, steroid competitive inhibitor of the adrenal enzyme β -hydroxysteroid dehydrogenase. It is used in treatment of pituitary-dependent hyperadrenocorticism. It inhibits the production of progesterone and 17-hydroxyprogesterone and their end products, including adrenal, gonadal, and placental hormones. However, the inhibition of adrenal steroidogenesis occurs at lower doses than those required to inhibit steroid hormone synthesis in other organs. The recommended starting dosage for dogs is 2–10 mg/kg/day, PO, but this may be increased or decreased, based on periodic adrenocorticotrophic hormone (ACTH) stimulation test results (performed 3–8 hr after trilostane administration). If the post-ACTH plasma cortisol concentration is <20 nmol/L, trilostane administration should be stopped for 48–72 hr and the ACTH stimulation test repeated. If the post-ACTH plasma cortisol concentration is 20–200 nmol/L, the dosage should not be altered. If the post-ACTH plasma cortisol concentration is >200 nmol/L, the dosage should be increased.

Adverse effects include depression, ataxia, hypersalivation, vomiting, muscle tremors, and skin changes. Sudden death has been reported in a small number of cases. Iatrogenic hypoadrenocorticism can occur but is generally reversible. Because of its inhibition of placental hormones, trilostane is contraindicated in pregnant and nursing animals and in any animals intended for breeding. Serial biochemical, electrolyte, and hematologic analyses and ACTH stimulation tests should be performed to monitor hepatic and renal function before treatment and at 10 days, 4 wk, 12 wk, and every 3–6 mo thereafter.

Mitotane (o,p'DDD): o,p'DDD is a chlorinated hydrocarbon with potent adrenocorticolytic effects causing selective necrosis of the zona fasciculata and zona

reticularis and partial or complete necrosis of the zona glomerulosa. It is used to treat pituitary-dependent hyperadrenocorticism. Before starting therapy, food intake (amount), time taken to eat, and the 24-hr water intake should be recorded to determine a baseline. Once this has been established, a loading dose is administered daily (25 mg/kg, bid) until the animal becomes lethargic, water intake drops, appetite is reduced, or the animal has other GI adverse effects (vomiting, diarrhea) or after 5 days of administration. An ACTH stimulation test should be performed to confirm whether adequate suppression of the adrenals has been achieved.

Most dogs respond to o,p'DDD therapy at the initial loading dose within 5–10 days, and the decision to change to maintenance therapy should be based on clinical signs (reduced appetite and water intake) and ACTH stimulation test results. Dogs with a post-ACTH plasma cortisol concentration <25 nmol/L should receive no medication for 2 wk and should then be treated with 25 mg/kg/wk divided into 2 or 3 doses. Dogs with a post-ACTH plasma cortisol concentration of 25–125 nmol/L should receive 25 mg/kg/wk in 2 or 3 doses, and dogs with a post-ACTH cortisol concentration >125 nmol/L should receive 50 mg/kg/wk.

During maintenance therapy, an ACTH stimulation test should be performed after 1 mo and then every 3–4 mo. If the post-ACTH plasma cortisol concentration is <25 nmol/L, the dose of o,p'DDD should be reduced; if the concentration exceeds 125 nmol/L, the dose should be increased, usually by about 20%–25% weekly. Although most dogs are stable on maintenance therapy, their adrenal reserve may not be adequate to handle major stress (physiologic or psychologic). In these cases, o,p'DDD administration should be discontinued and replaced with glucocorticoids (0.2 mg/kg/day, PO, tapered) during this period.

Adverse effects are relatively common, particularly in cases of o,p'DDD overdose. These include signs of hypoadrenocorticism, eg, weakness, ataxia, depression, vomiting, diarrhea, and inappetence. Biochemical and hematologic analysis may be unremarkable despite systemic illness. Treatment includes lowering the dose or ceasing administration of o,p'DDD and supplementing with glucocorticoids. Clinical improvement is usually seen within 1–6 hr. Iatrogenic hypoadrenocorticism is the most serious adverse effect and may develop at any time during maintenance treatment. Administration of o,p'DDD should be stopped and appropriate supplementation with glucocorticoids and

mineralocorticoids started. Other rare CNS adverse effects include ataxia, apparent blindness, circling, and head pressing.

Progestones: The two most commonly used forms of progesterone are megestrol acetate and medroxyprogesterone acetate. Megestrol acetate has a quick onset of action and potent glucocorticoid and slight mineralocorticoid activity, and it may be given PO. Medroxyprogesterone acetate is antiestrogenic and has significant glucocorticoid activity. Neutered male and female cats with bilateral alopecia suspected to be caused by sex hormone imbalances may respond to treatment. The dosage of megestrol acetate is 2.5–5 mg/cat, PO, every 48 hr, decreasing to every 1–2 wk for maintenance. Medroxyprogesterone acetate is given at a dosage of 50–100 mg/cat, IM, and may be repeated in 3–6 mo.

Progestagens should be avoided whenever possible because of adverse effects; severe, prolonged adrenocortical suppression is seen even with low doses. Diabetes mellitus has been reported in cats treated with megestrol acetate. Decreased spermatogenesis, pyometra, increased levels of growth hormone with acromegaly, mammary gland hyperplasia and tumors, and behavioral changes may be seen.

Growth Hormone: Growth hormone (somatotropin) is a polypeptide produced by the anterior pituitary that acts either directly on target tissues or indirectly through insulin-like growth factors (somatomedins) produced by the liver (see also THE PITUITARY GLAND, p 542). It is necessary for hair growth and for development of elastin fibers in the skin. It is used to treat growth hormone-responsive alopecia in dogs. Either bovine, porcine, or human growth hormone (0.1 IU/kg, 3 times/wk for 4–6 wk) is effective. Hair usually regrows in 2–3 mo, and remission may last from 6 mo to 3 yr. Growth hormone is diabetogenic, and dogs can develop transient or permanent diabetes mellitus during therapy. Weekly monitoring of blood glucose before and during therapy is recommended.

Sex Hormones: Several syndromes in dogs and cats have been attributed to imbalances of sex hormones; however, the etiopathogenesis of these disorders is generally poorly documented. Hypoestrogenism in spayed female dogs, hypoandrogenism in male dogs, and feline acquired symmetric alopecia may respond to sex-hormone therapy. Dosages for sex-hormone replacement therapy are

empirical. Hypoestrogenism in spayed female dogs may be treated with diethylstilbestrol (0.02 mg/kg/day for 3 wk of every month until hair regrows or for a maximum total dose of 1 mg/dog). After hair regrows, the maintenance dosage should be given 1–2 times/wk. An alternative protocol is to treat every other day or twice weekly until a response is seen. Hair regrowth should be evident in 3–4 wk, with a complete response within 4 mo. Exogenous estrogen can cause bone marrow hypoplasia, so a CBC and platelet count should be performed weekly during therapy. Other potential adverse effects include induction of estrus, hepatotoxicity, nymphomania, abortion, pyometra, or prostatic hyperplasia. Cats are highly sensitive to estrogens, and a total dose of 10 mg of diethylstilbestrol can be lethal.

Hypoandrogenism of male dogs may be treated with methyltestosterone, 0.5–1 mg/kg, PO, up to a total maximal dose of 30 mg every 48 hr. Alternatively, testosterone propionate can be given IM once weekly at dosages of 0.5–1 mg/kg, or every 4–16 wk at 2 mg/kg. Complications include aggressive behavior, greasy hair coat, prostatic hypertrophy, and hepatotoxicity. Liver function should be evaluated before treatment and monthly during therapy.

Repositol testosterone, 12 mg/cat, IM, may be given once for treatment of feline acquired symmetric alopecia or may be combined with a low dose of diethylstilbestrol, 0.625 mg/cat, IM, or with a low dose of estradiol, 0.5 mg/cat, IM. Hepatobiliary disease has been reported in cats given testosterone.

Melatonin: Melatonin is produced in the pineal gland and is involved in the control of photoperiod-dependent molting of some mammals. Secretion is inversely related to daylight length and is highest during the winter. Various canine hair-growth disorders including recurrent flank alopecia, pattern baldness, and excessive tricholemmal keratinization have improved with melatonin supplementation. Recurrent flank alopecia may be treated with 36-mg SC implants. Oral melatonin is also available; an empirical dosage of 3–6 mg/dog, tid-qid, has been used successfully.

IMMUNOMODULATORS

Immunostimulants

Immunostimulation is used to enhance a deficient immunologic response; however, animals that appear to benefit from these

agents are not severely immunosuppressed. The most common use of immunostimulants in dogs is for chronic, recurrent staphylococcal pyoderma. For primary therapy, immunomodulatory bacterins should not be substituted for antibiotics; they should be used concurrently with an appropriate antibiotic until the infection has been resolved. The immunomodulator is then continued and success judged on the time to and severity of any infection relapse. They are clearly helpful as adjunct agents or for maintenance therapy for some dogs with recurrent pyoderma but have no benefit in other cases.

Staphage lysate is a preparation of *Staphylococcus aureus* and polyvalent staphylococcus bacteriophage. When given concurrently with antibiotics, staphage lysate (0.5 mL, SC, twice weekly, or 1 mL, SC, weekly) has improved the response of dogs with superficial staphylococcal pyoderma compared with antibiotics alone. The mechanism of action is believed to be stimulation of T lymphocytes and activation of phagocytic cells. Deficient IgM levels—but not IgA or IgG levels—may be normalized with treatment.

S aureus bacterin-toxoid, used for prevention of staphylococcal mastitis in cattle, has been used with some success in cases of canine bacterial hypersensitivity. Various treatment protocols have been advocated. One schedule consists of 0.1 mL, intradermally, daily for 5 days, then weekly for 1 mo, then at monthly intervals. At corresponding times, doses given SC increase from 0.15 mL to 1.9 mL. Local swelling at the injection site, fever, and malaise are common adverse effects in dogs.

Propionibacterium acnes bacterin is labeled for use in dogs (0.25–2 mL, IV, 1–2 times/wk) and appears to have some benefit as adjunct treatment for recurrent pyoderma.

Many other immunostimulants have been described for use; however, responses in dermatologic disorders have been equivocal.

Immunosuppressants

Glucocorticoids: Glucocorticoids are the immunosuppressive agents most commonly used to treat immune-mediated skin disease (see p 827). A range of other immunosuppressants may be used either concurrently with glucocorticoids or alone for the treatment of various immune-mediated dermatoses, including systemic lupus erythematosus (SLE), pemphigus complex, bullous pemphigoid, and vasculitis.

Azathioprine: Azathioprine is converted to 6-mercaptopurine in the liver. It competes with purines in the synthesis of nucleic acids and prevents proliferation of rapidly dividing cells. It is used for treatment of pemphigus disorders, bullous pemphigoid and SLE in dogs, ocular inflammation in the uveodermatologic syndrome, and histiocytomas. There is a 3- to 5-wk lag period before its effects are evident, so it is often initially combined with glucocorticoids. The dosage is 2.2 mg/kg (50 mg/m²), daily for 2 wk, and then reduced to every 48 hr. In dogs, it may be used in combination with metronidazole (10 mg/kg/day) for perianal furunculosis, although surgery may be necessary to remove residual scarring.

GI adverse effects (vomiting, diarrhea) may be avoided by administering with food or lowering the dose. Bone marrow suppression may also develop. All three cell lines can be affected, but leukopenia is the most common. The CBC should be monitored every 2 wk during induction and at least every 4 mo during maintenance therapy. Acute pancreatitis and hepatotoxicity has been reported in dogs. Azathioprine is contraindicated in cats because of rapid, lethal bone marrow suppression.

Cyclophosphamide: Cyclophosphamide is an alkylating agent used to treat a wide variety of cancers, especially lymphoreticular neoplasms, and is usually given in combination with other drugs. It may also be used short-term in severe cases of SLE, rheumatoid arthritis, pemphigus complex, and vasculitis. The dosage for immunosuppression is 1.5–2.5 mg/kg, every 48 hr. The dose should be given in the morning so that it does not remain in the bladder overnight. Because most animals treated with cyclophosphamide also receive corticosteroids, polyuria induced by the steroids may be somewhat protective. The potential for hemorrhagic cystitis and bladder fibrosis limits the use of cyclophosphamide to no more than 3–4 mo. GI tract toxicity, bone marrow suppression, alopecia, infertility, and teratogenic effects may also be seen.

Chlorambucil: Chlorambucil is an alkylating agent similar to cyclophosphamide. However, it is slower acting and the least toxic of the group. It may be used for treatment of immune complex diseases in which azathioprine or cyclophosphamide are not tolerated, and it may be given to cats. The dosage is 0.1–0.2 mg/kg/day, reduced to every other day once a response is seen. It is mostly used in combination with glucocorticoids but can be used with

azathioprine in dogs only in particularly refractory cases. It may also be used to replace cyclophosphamide if hemorrhagic cystitis develops. Adverse effects are rare and include bone marrow suppression (which generally develops within 7–14 days of starting treatment and resolves in 7–14 days), GI irritation, and seizures. Delayed hair regrowth has been reported in shaved dogs.

Crysotherapy: Gold salts have anti-inflammatory, antirheumatic, immunomodulating, and antimicrobial (in vitro) effects. Parenteral and oral forms are available. Aurothiomalate is given parenterally. It is absorbed rapidly and reaches peak levels in 4–6 hr. Rising serum values are noted for 5–10 wk. Beneficial effects are seen 6–12 wk after the start of treatment. The oral form is auranofin. Only 25% is absorbed, and lower and more predictable plasma concentrations are found. The half-life is ~21 days, but the retention and tissue accumulation are only 1% (parenteral gold 30%). Results with this compound are equivocal in dogs. Gold salts are indicated for canine and feline pemphigus unresponsive to glucocorticoids and feline plasma cell pododermatitis.

Routine protocols start with a test dose IM (1 mg if <10 kg body wt, 5 mg if >10 kg body wt). The next week a second test dose is given IM (2 or 10 mg), and if no adverse reactions are seen, treatment continues at 1 mg/kg, IM, weekly until remission. Once in remission, the dose is given every 2 wk and may later be reduced to monthly injections. Occasionally, a higher dosage (1.5–2 mg/kg) may be required to induce remission. Treatment effects are not seen for 6–12 wk, so other medications (commonly glucocorticoids) must be given at therapeutic doses during this time. Gold salts should not be administered with other cytotoxic drugs because of the increased risk of toxic reactions. Adverse effects include allergic reactions (skin eruption, oral reactions), nephrotoxicity, and bone marrow suppression. Toxic epidermal necrolysis has been reported in dogs starting gold therapy immediately after azathioprine, so a 4-wk washout period is recommended in these cases.

Cyclosporine: Cyclosporine impairs the proliferation of activated T cells by inhibiting transcription of interleukin-2, gene activation, and RNA transcription. This early inhibition of T cells also leads to reduced production of other cytokines, mast cells, and eosinophils, and inhibition of mononu-

clear cells, antigen presentation, histamine release from mast cells, neutrophil adherence, natural killer cell activity, and B-cell growth and differentiation.

Cyclosporine is used for treatment of atopic dermatitis and anal furunculosis. Extra-label use for the treatment of immune-mediated disorders (pemphigus, SLE) and epitheliotropic lymphoma has been less successful. Response has been good when used for sebaceous adenitis. The dosage for atopic dermatitis in dogs is 5 mg/kg/day for 30 days, after which the dose may be reduced to alternate-day or even third-day dosing in some animals. The dosage for anal furunculosis is 7.5 mg/kg/day. The dosage for feline atopic dermatitis is 7 mg/kg/day for 30 days and then reduced to 7 mg/kg alternate-day dosing.

Adverse effects include GI signs (nausea, vomiting, soft feces, diarrhea), gingival hypertrophy, hirsutism, and papillomatosis (which generally decreases when the dose is decreased). Drugs that inhibit cytochrome P450 (eg, ketoconazole) potentiate cyclosporine toxicity significantly. If ketoconazole (10 mg/kg, bid) is also administered to animals with anal furunculosis, the dosage of cyclosporine can be reduced to 1 mg/kg, bid. This induction dose is maintained for 4 wk and then reduced if the response is adequate or adverse effects (vomiting, lethargy) develop.

Oclacitinib: Oclacitinib is a Janus kinase (JAK) inhibitor and exerts its action through the inhibition of a variety of pruritogenic cytokines (eg, IL-31) and pro-inflammatory cytokines dependent on JAK 1 or JAK 3 enzyme activity. However, it may also exert effects on other cytokines (eg, involved in host defense or hematopoiesis) with the potential for adverse effects.

It is rapidly absorbed and reaches peak plasma concentrations within 1 hr, leading to rapid onset of clinical effect. It is indicated for the treatment of pruritus associated with allergic dermatitis in dogs at a dosage of 0.4–0.6 mg/kg, bid, for 2 wk and then reduced to once daily administration for maintenance therapy. In a double-blind, placebo-controlled study for treatment of atopic dermatitis, the treatment success was 66% in reducing pruritus and 49% for Canine Atopic Dermatitis Extent and Severity Index (CADESI) scores.

Sulfones: Dapsone is an anti-inflammatory, antibacterial sulfone that inhibits

neutrophil chemotaxis and adhesion to basement membrane zone antibodies, degranulation of mast cells, action of lysosomal enzymes, and activation of the alternative complement pathway. Dapsone also inhibits synthesis of IgG, IgA, and prostaglandins, as well as T-cell responses. Although it is used for a variety of diseases characterized by accumulation of neutrophils in people, the results are more equivocal in dogs. However, it has been used for pemphigus foliaceus and erythematous, subcorneal pustular dermatosis, leukocytoclastic vasculitis, and IgA dermatosis. The dosage is 1 mg/kg, tid (dogs only) for 2–4 wk or until a response is seen, then every 24–48 hr. Longterm therapy is not recommended. Mild anemia or severe leukopenia, blood dyscrasias, hepatotoxicity, or skin reactions may develop. Animals should be monitored by CBC, urinalysis, BUN, and ALT every 2 wk during induction. Cats are particularly sensitive to toxicity, and a dosage of 1 mg/kg/day is recommended. Concurrent use may allow the dosage of glucocorticoids to be reduced.

Tetracycline and Niacinamide:

Although the precise mechanism of action is unknown, tetracyclines may inhibit in vitro lymphocyte blastogenic transformation and antibody production, activation of complement (component C3), prostaglandin synthesis, lipases and collagenases, and suppress leukocyte chemotaxis in vitro and in vivo. Niacinamide blocks IgE-induced histamine release, inhibits phosphodiesterases, and decreases protease release by leukocytes. The combination is indicated for discoid lupus erythematosus and pemphigus erythematosus. These diseases are characterized by leukocyte chemotaxis secondary to complement activation by antigen-antibody complexes and by release of proteases. Dogs weighing >10 kg are given 500 mg of each drug tid. If a clinical response is seen, the frequency may be decreased to once or twice daily. Vomiting, diarrhea, and anorexia are the most common adverse effects.

Pentoxifylline: Pentoxifylline results in a range of immunologic and rheologic effects, including increases in RBC and WBC deformability; decreases in RBC and platelet aggregation, leukocyte endothelial adherence, natural killer cell activity, neutrophil degranulation, and production of monocyte TNF- α , IL-1, IL-4, and IL-12; and inhibition of T- and B-cell activation. It has

been used in limited numbers of animals for a variety of conditions, including vasculitis, canine familial dermatomyositis, ulcerative dermatitis of Shetland Sheepdogs and Collies, rabies vaccine-induced ischemic alopecia, ear margin dermatosis, contact allergy, and atopic dermatitis. The dosage is 10 mg/kg, bid-tid. Once a response is seen, the dosage may be tapered to once or twice daily. GI-related adverse effects have been reported (eg, nausea, vomiting).

PSYCHOTROPIC AGENTS

Psychotropic drugs have been used extra-label for treatment of feline psychogenic alopecia and canine acral lick dermatitis, syndromes characterized by excessive self-licking (*see also* ABNORMAL REPETITIVE BEHAVIORS IN DOGS, p 1561, and FELINE COMPULSIVE DISORDERS, p 1574). Classes of drugs used include antidepressants, antipsychotics, opiate antagonists, anxiolytics, and mood stabilizers (*see* table 14).

Sedation is the most common adverse effect of diazepam. It is also an appetite stimulant in cats. Idiosyncratic fatal hepatic necrosis has been reported in several cats treated for as little as 8–14 days. Tricyclic antidepressants are potent H₁ blockers in addition to inhibiting uptake of serotonin and norepinephrine. These drugs can induce cardiac arrhythmias and lower the seizure threshold. Other adverse effects include dry mouth, hypersalivation, vomiting, constipation, urinary retention, ataxia, disorientation, depression, and anorexia. Tricyclic antidepressants should not be used concurrently with monoamine oxidase inhibitors, including amitraz dips for demodicosis. Dosages should be tapered slowly when discontinued.

VITAMINS AND MINERALS

Retinoids: Naturally occurring and synthetic compounds with vitamin A activity include retinol, retinoic acid, and retinol derivatives or analogues. At the molecular level, retinoids are important in regulation of proliferation, growth, differentiation, and maintenance of epithelial tissues. Retinoids also affect proteases, biosynthesis of mucopolysaccharides, prostaglandins, cellular adhesion, cellular communication, and immunity. They prevent tumor promotion by inhibition of ornithine decarboxylase, a key enzyme for cell proliferation and differentiation. Vitamin A (1,000 IU/kg) has been used for follicular keratosis in cats. However, the

TABLE 14 PSYCHOTROPIC DRUGS USED FOR SKIN DISORDERS

Drug	Dosage
ANTIDEPRESSANTS	
Clomipramine	Dogs: 1–3 mg/kg, bid Cats: 0.5–1.5 mg/kg/day
Amitriptyline	1–3 mg/kg, bid
Doxepin	0.5–2 mg/kg, bid
Fluoxetine	1 mg/kg/day
ANXIOLYTICS	
Diazepam	1–2 mg/kg, bid
Phenobarbital	0.5–2.2 mg/kg, bid; 15 mg/cat, twice weekly
Hydroxyzine	2.2 mg/kg, tid
OPIATE ANTAGONISTS	
Naltrexone	2.2 mg/kg/day

retinoids used most commonly are isotretinoin (13-cis-retinoic acid) and etretinate (no longer available but replaced with acitretin, a metabolically active metabolite of etretinate).

Isotretinoin is indicated for Schnauzer comedone syndrome, ichthyosis, feline acne, sebaceous adenitis, epitheliotropic lymphoma, keratoacanthoma, and sebaceous gland hyperplasias and adenomas. The dosage is 1–3 mg/kg/day. Adverse effects include conjunctivitis, mucocutaneous drying, alopecia, pruritus, hyperactivity, vomiting, and diarrhea. In dogs, blood chemistry increases not normally associated with clinical disease include plasma cholesterol, triglycerides, ALT, AST, and alkaline phosphatase. Rarely, keratoconjunctivitis sicca may develop in dogs. Conjunctivitis, anorexia, diarrhea, and vomiting are the major adverse effects in cats. All retinoids are potent teratogens, and teratogenicity may persist for up to 2 yr after treatment with etretinate because the half-life is ~100 days. Skeletal abnormalities that may be seen with longterm therapy, including premature closure of the epiphyses in growing animals, cortical hyperostosis, periosteal calcification, and long-bone demineralization, are less common with etretinate than with isotretinoin. Monitoring during longterm therapy should include complete physical examinations and serum chemistry profiles at monthly intervals for the first 3–4 mo and then every 4–6 mo.

Zinc: Zinc is an important factor of many enzyme systems and is necessary for maintenance of growth, metabolism, normal reproduction, and hormonal regulation. It is essential for keratinization and immune function. Zinc supplementation is given in cases of insufficient intestinal absorption, including deficiency syndrome I (Siberian Huskies, Alaskan Malamutes) and syndrome II (rapidly growing dogs on zinc-deficient diets). Dietary deficiency may be either absolute or relative—diets high in phytates or minerals may inhibit zinc absorption. For syndrome I, zinc supplementation is given as elemental zinc 1 mg/kg/day, PO (zinc sulfate 10 mg/kg, zinc gluconate 5 mg/kg, or zinc methionine 1.7 mg/kg). Supplementation is typically lifelong. If the response is insufficient after 4 wk, the dose should be increased by 50%. Low-dose corticosteroids may also enhance zinc absorption through induction of metallothionein in some nonresponsive cases. Animals with syndrome II normally respond to correction of the diet with resolution within 2–6 wk, although supplementation speeds this process.

Hereditary zinc deficiency associated with deficient intestinal absorption has also been reported in Friesian, Danish Black Pied, and Shorthorn cattle. There is a rapid response to zinc oxide given at 0.5 g/day, PO, or zinc sulfate at 2 g, PO, given weekly. Response to zinc supplementation is usually rapid (a few days) except for cases of achromotrichia, which requires several weeks for resolution.

SYSTEMIC PHARMACOTHERAPEUTICS OF THE MUSCULAR SYSTEM

Drugs that affect skeletal muscle function fall into several therapeutic categories. Some are used during surgical procedures to produce paralysis (neuromuscular blocking agents); others reduce spasticity (skeletal muscle relaxants) associated with various neurologic and musculoskeletal conditions. In addition, several therapeutic agents influence metabolic and other processes in skeletal muscle, including the nutrients required for normal muscle function used to prevent or mitigate degenerative muscular conditions. For example, selenium and vitamin E are used to prevent or treat muscular dystrophies such as white muscle disease (*see* p 1172). The steroidal, nonsteroidal, and various other anti-inflammatory agents (eg, dimethyl sulfoxide) are also commonly used to treat acute and chronic inflammatory conditions involving skeletal muscle. Anabolic steroids promote muscle growth and development and are administered in selected cases in which serious muscle deterioration has developed as a complication of a primary disease syndrome.

The clinical pharmacology of the neuromuscular blocking agents, skeletal muscle relaxants, and anabolic steroids are discussed below. (For anti-inflammatory agents, *see* p 2707.)

NEUROMUSCULAR BLOCKING AGENTS

The peripherally acting skeletal muscle relaxants characteristically interfere with the transmission of impulses from motor nerves to skeletal muscle fibers at the neuromuscular junction, thus reducing or abolishing motor activity. The skeletal muscle paralysis that ensues is not associated with depression of the CNS. Animals are fully conscious throughout the period of immobilization unless an anesthetic or hypnotic agent is administered concurrently.

Neuromuscular transmission can be modified either at the axonal membrane (prejunctional blockade) or at the cholinergic receptors in the sarcolemma (postjunctional blockade).

There are no clinically useful drugs that act prejunctionally, but a number of important substances can impair the synthesis, storage, and release of acetylcholine, thus resulting in prejunctional blockade at the motor endplate

and consequently paralysis. Examples of prejunctional blocking agents include biotoxins, electrolytes, local anesthetics or other drugs, and antibiotics. **Biotoxins** include black widow spider venom, which depletes acetylcholine stores; botulinum toxin, which decreases acetylcholine release; tetrodotoxin from the puffer fish and saxitoxin from shellfish, which block Na^+ -conducting channels; and grayanotoxin found in rhododendrons, which facilitates excessive Na^+ entry through the sarcolemma, leading to constant depolarization of the membrane. **Electrolytes** include excess Mg^{2+} , which inhibits release of acetylcholine from the axon and uncouples the excitation-contraction process by competing with Ca^{2+} ; and depleted Ca^{2+} levels, which decrease release of acetylcholine and impairment of excitation-contraction coupling. **Local anesthetics** in high concentration can stabilize membranes by blocking both Na^+ and K^+ channels; **hemicholinium** can inhibit synthesis of acetylcholine by blocking choline uptake into the nerve. **Antibiotics**, such as the aminoglycosides, polymyxins, tetracyclines, and lincosamides, appear to act by decreasing the availability of Ca^{2+} at membrane-binding sites on the axonal terminal and perhaps by reducing the sensitivity of the nicotinic receptors to acetylcholine.

Postjunctional blocking agents are used clinically and act either by blocking the nicotinic receptors in a competitive fashion (nondepolarizing agents) or by interacting with these receptors in a manner that does not allow the membrane to repolarize so that paralysis results (depolarizing agents). The mechanisms involved in the latter case are not fully understood. All of the neuromuscular blocking agents are structurally similar to acetylcholine (actually two molecules linked end-to-end). The depolarizing agents are usually simple linear structures, and the nondepolarizing agents are more complex bulky molecules. With a single exception (vecuronium), all have a quaternary nitrogen in their structure, which makes these drugs poorly lipid soluble.

Competitive Nondepolarizing Agents:

The members of this group of peripherally acting skeletal muscle relaxants are often referred to as curarizing agents because of their relationships with

the curare alkaloids that were first used clinically. The currently available drugs, which interact with nicotinic cholinergic receptors on skeletal muscle cells and render them inaccessible to the transmitter function of acetylcholine (and thus produce a flaccid paralysis) include tubocurarine, metocurine (dimethyltubocurarine), gallamine, pancuronium, alcuronium, atracurium, vecuronium, and fazadinium.

In general, nondepolarizing muscle relaxants are not absorbed from the GI tract and must be administered parenterally, usually IV. Plasma protein binding is insignificant, and there is rapid equilibration but only within the extracellular fluid. The blood-brain and blood-placental barriers are rarely crossed. Tubocurarine, metocurine, and gallamine are not biotransformed to any extent and are excreted unchanged, principally in the urine but sometimes in bile. The other members of the group undergo metabolic transformation to some degree, and the metabolites are excreted by both renal and biliary routes in most instances. The elimination half-lives at standard dosages are 60–100 min, and the duration of paralysis is 30–60 min, except in the case of atracurium and vecuronium, which have shorter actions of ~20–30 min.

After IV administration of these agents, the skeletal muscles become totally flaccid and nonresponsive to neuronal stimulation. Muscles capable of rapid movement, such as those of the eye, are paralyzed before the larger muscles of the head and neck, which are followed by those of the limbs and body. Lastly, the diaphragm becomes paralyzed, and respiration ceases. If ventilation is controlled (tracheal intubation and positive-pressure ventilation), there are no adverse effects, and full recovery ensues in reverse order, with the diaphragm regaining function first. All of the currently used nondepolarizing muscle relaxants have cardiovascular effects, many of which are mediated by autonomic and histamine receptors. Tubocurarine and, to a much lesser extent, metocurine result in hypotension, which probably results from the liberation of histamine and, in larger doses, from ganglionic blockade. Premedication with an antihistamine reduces tubocurarine-induced hypotension. Pancuronium causes a moderate increase in heart rate and, to a lesser degree, cardiac output. Gallamine increases heart rate by both a vagolytic action and sympathetic stimulation.

A number of agents can potentiate the activity of neuromuscular blockers. These include other peripherally acting skeletal muscle relaxants, inhalant anesthetics (halothane, methoxyflurane), antibiotics

(aminoglycosides, polymyxins, tetracyclines, and lincosamides), and various other drugs (quinidine, procaine, lidocaine, diazepam, and barbiturates). Several states, such as hyper- and hypomagnesemia, hypokalemia, acidosis, and hypothermia, also prolong the action of this group of drugs. Animals with myasthenia gravis are much more susceptible to the action of muscle relaxants.

Indications for the use of nondepolarizing neuromuscular blocking agents include muscle relaxation of the operative field, hypoxemic animals resisting mechanical ventilation, tracheal intubation, animals with unstable cardiovascular function that require anesthesia but cannot tolerate cardiac depression, cesarean section in toxic or high-risk animals, epileptiform convulsions not controllable with usual anticonvulsant agents, tetanus, strychnine poisoning, shivering animals in which the metabolic demand for oxygen should be reduced, and capture of certain exotic species (eg, gallamine used for immobilization of crocodiles). Animals should always be carefully monitored when under the influence of neuromuscular blocking drugs, and support of ventilation is essential.

The action of the competitive relaxants can be reversed by anticholinesterase drugs, especially neostigmine, after the administration of atropine, which eliminates excessive muscarinic responses. This attribute is a great advantage for this group of peripherally acting muscle relaxants.

The selection of dose rates (see TABLE 15) serves only as general guidelines for the use of competitive blocking agents.

Depolarizing Agents: Succinylcholine (suxamethonium) is the only commonly used, peripherally acting muscle relaxant that is a depolarizing agent. Decamethonium, the other member of the group, is rarely used clinically.

Depolarizing blocking drugs occupy the postjunctional cholinergic receptors and, by mechanisms that remain obscure, elicit prolonged depolarization of the endplate region. This prevents the synaptic membrane from completely repolarizing, thus rendering the motor endplate unresponsive to the normal action of acetylcholine. Characteristically, succinylcholine elicits transient muscle fasciculations before causing neuromuscular paralysis. The onset of action of succinylcholine is rapid after IV injection (20–50 sec), and the duration of the effect is usually 5–10 min in most species. Succinylcholine is rapidly hydrolyzed by pseudocholinesterases in the plasma and liver in most species, but substantial genetic differences exist.

TABLE 15 COMPETITIVE NONDEPOLARIZING AGENTS AND ANTAGONISTS

Drug	Dosage
NONDEPOLARIZING AGENTS	
Tubocurarine chloride	Horses: ≤ 0.22 – 0.25 mg/kg, IV Dogs, cats: ≤ 0.4 mg/kg, IV
Gallamine triethiodide	All species (except pigs): 0.8 – 1 mg/kg, IV
Pancuronium bromide	Dogs, cats: 0.6 mg/kg, IV
Alcuronium chloride	Dogs, cats: 0.1 mg/kg, IV
Atracurium besylate	Dogs, cats: 0.5 mg/kg, IV
ANTAGONISTS	
Neostigmine	0.04 mg/kg, with atropine at 0.04 mg/kg, IV
Pyridostigmine	0.2 – 0.25 mg/kg, with atropine at 0.04 mg/kg, IV
Edrophonium	0.125 mg/kg, IV

Other pharmacologic effects are associated with the depolarizing muscle relaxants. After IV administration of succinylcholine, transient muscle fasciculations are usually evident, although general anesthesia tends to attenuate them. Succinylcholine-induced cardiac arrhythmias are many and varied. Succinylcholine stimulates all autonomic cholinergic receptors—both nicotinic and muscarinic. Sudden hyperkalemia may be precipitated by succinylcholine, and muscle pain is seen with the use of succinylcholine in the absence of anesthesia. After recovery from succinylcholine-induced muscle paralysis, muscle damage and even myoglobinuria can develop. Malignant hyperthermia (*see* p 1027) or clinical signs related to this syndrome may also follow the use of succinylcholine in susceptible animals.

Factors that can alter the activity of competitive blocking agents (*see* p 2586) can also affect the action of succinylcholine. In addition, previous (within 1 mo) or concurrent use of organophosphate anthelmintics or external parasiticides can have a significant impact on the recovery time from succinylcholine immobilization because of prolonged inhibition of the pseudocholinesterase enzyme systems. A genetically mediated deficiency of pseudocholinesterases also has been identified in certain strains of sheep. Cattle are much more susceptible to the effects of succinylcholine than other species.

The indications for the clinical use of succinylcholine are similar to those for the nondepolarizing agents. However, it must be emphasized that succinylcholine should *never* be used as an agent for euthanasia or

for immobilization for castration without local or general analgesia. The use of succinylcholine for game-cropping procedures is also highly undesirable.

No antagonists are available to reverse the action of the depolarizing muscle relaxants. Continued positive-pressure ventilation until recovery occurs is the only therapy in cases of overdosage.

The IV dose rates for succinylcholine by species are as follows: horses: 0.125 – 0.20 mg/kg (~ 8 min recumbency); cattle: 0.012 – 0.02 mg/kg (~ 15 min recumbency); dogs: 0.22 – 1.1 mg/kg (~ 15 – 20 min paralysis); and cats: 0.22 – 1.1 mg/kg (~ 3 – 5 min paralysis).

SKELETAL MUSCLE RELAXANTS

Muscle spasticity is a characteristic of many clinical conditions, including trauma, myositis, muscular and ligamentous sprains and strains, intervertebral disc disease, tetanus, strychnine poisoning, neurologic disorders, and exertional rhabdomyolysis. An increase in tonic stretch reflexes originates from the CNS with involvement of descending pathways and results in hyperexcitability of motor neurons in the spinal cord. Drug therapy (*see* TABLE 16) alleviates muscle spasms by modifying the stretch reflex arc or by interfering with the excitatory coupling process in the muscle itself. Centrally acting muscle relaxants block interneuronal pathways in the spinal cord and in the midbrain reticular activating system. Some drugs also have sedative effects, which are beneficial to animals that are anxious or in pain. The hydantoin derivatives have a direct action on muscle.

Methocarbamol is a centrally acting muscle relaxant chemically related to guaifenesin. Its exact mechanism of action is unknown, and it has no direct relaxant effect on striated muscle, nerve fibers, or the motor endplate. It also has a sedative effect. In dogs, cats, and horses, methocarbamol is indicated as adjunct therapy of acute inflammatory and traumatic conditions of skeletal muscle and to reduce muscle spasms. Because methocarbamol is a CNS depressant, it should not be given with other drugs that depress the CNS. Overdosage is generally characterized by CNS depression, but emesis (small animals), salivation, weakness, and ataxia may be seen.

Guaifenesin (glyceryl guaicolate) is a centrally acting muscle relaxant believed to depress or block nerve impulse transmission at the internuncial neuron level of the subcortical areas of the brain, brain stem, and spinal cord. It also has mild analgesic and sedative actions. Guaifenesin is given IV to induce muscle relaxation as an adjunct to anesthesia for short procedures. It relaxes both laryngeal and pharyngeal muscles, allowing easier intubation, but has little effect on diaphragm and respiratory function. It may cause transient increases in cardiac rate and decreases in blood pressure. It is also used in treatment of horses with exertional rhabdomyolysis and in dogs with strychnine intoxication. Overdose results in apneustic breathing, nystagmus, hypotension, and contradictory muscle rigidity. Treatment of overdose is supportive until the drug is cleared to nontoxic levels.

Benzodiazepines, such as diazepam, affect polysynaptic reflexes at the supraspinal level,

act as a spinal cord depressant at the interneuronal level, and inhibit presynaptic acetylcholine release. Clinically, diazepam is used as an adjunct to anesthesia, in management of clinical signs of tetanus, and in treatment of functional urethral obstruction and urethral sphincter hypertonus in cats.

Dantrolene, a hydantoin derivative, is structurally and pharmacologically different from other skeletal muscle relaxants. Dantrolene has a direct action on muscle, probably by interfering with the release of calcium from the sarcoplasmic reticulum. It has no discernible effects on respiratory and cardiac function but can cause dizziness and sedation. In veterinary medicine, dantrolene is used to treat malignant hyperthermia in various species, porcine stress syndrome, equine postanesthetic myositis, and equine exertional rhabdomyolysis (*see* p 1027 and p 1202).

Phenytoin is a hydantoin derivative, primarily used as an anticonvulsant in people. Phenytoin has shown efficacy in some horses susceptible to exertional rhabdomyolysis. Phenytoin may alter the function of neurotransmitters at the neuromuscular junction, the release of calcium from the sarcoplasmic reticulum, and sodium flux at the sarcolemma. Dosages are adjusted in horses to maintain serum concentrations of 5–10 mcg/mL.

Baclofen is a centrally acting skeletal muscle relaxant used to control spasticity and pain in people with multiple sclerosis and spinal disorders. Baclofen is structurally similar to the inhibitory neurotransmitter gamma-aminobutyric acid (GABA). It acts as a GABA receptor B agonist to reduce calcium

TABLE 16 SKELETAL MUSCLE RELAXANTS

Drug	Dosage
Methocarbamol	Dogs, cats: 44 mg/kg, IV, up to 330 mg/kg/day for tetanus or strychnine poisoning; 132 mg/kg/day, PO, divided bid-tid Horses: 4.4–5.5 mg/kg, IV
Guaifenesin	Dogs: 44–88 mg/kg, IV Horses, ruminants: 66–132 mg/kg, IV
Diazepam	Cats: 2–5 mg, PO, tid, for urethral obstruction
Dantrolene	Horses: 15–25 mg/kg, slow IV, qid; 2 mg/kg/day, PO, for prevention of exertional rhabdomyolysis Swine: 3.5 mg/kg, IV
Phenytoin	Horses: 6–8 mg/kg/day, PO, increase by 1 mg/kg every 3 days until rhabdomyolysis is prevented or the horse appears sedated
Baclofen	Dogs: 12 mg/kg, PO, tid

influx into presynaptic nerve terminals, thereby decreasing the amount of excitatory neurotransmitters released by primary afferent neurons in the spinal cord and brain. This results in reduced muscle tone as well as pain associated with spasticity. Because of a very narrow safety margin, baclofen has limited use in veterinary medicine. It has been used to treat dogs with tetanus and to reduce urethral resistance in treatment of urinary retention. Baclofen transiently inhibits lower esophageal sphincter relaxation in dogs and theoretically is of benefit in the treatment of gastroesophageal reflux disease. Baclofen is not recommended for use in cats. Even at therapeutic doses, dogs may show clinical signs of vomiting, depression, and vocalization. With overdose, the severity of CNS signs can be substantial and may include dysphoria, lateral recumbency, or coma. Treatment of baclofen toxicity should include rapid and aggressive decontamination, along with intensive supportive treatment. Management of affected dogs may require positive-pressure ventilation as a result of severe obtundation, respiratory depression, and respiratory arrest or hypoventilation. Cyproheptadine, a serotonin antagonist, may be given orally or rectally as needed to reduce vocalization or disorientation. IV lipid emulsion has been useful to treat some dogs with baclofen toxicity.

ANABOLIC STEROIDS

Anabolic steroids are synthetic derivatives of testosterone with enhanced anabolic activity and reduced androgenic activity. Testosterone or its derivatives diffuse through cell membranes of target organs and combine with specific receptor proteins in the cytoplasm. The receptor hormone migrates into the cell nucleus and binds

to nuclear chromatin, stimulating the production of specific messenger RNA. The messenger RNA then regulates the enzyme synthesis responsible for the physiologic activity of the anabolic steroid.

Anabolic steroids stimulate and maintain a positive nitrogen balance by reducing renal elimination of nitrogen, sodium, potassium, chloride, and calcium. Production of myosin, sarcoplasm, and myofibrillar protein is enhanced. Anabolic steroids promote appetite, weight gain, and improved mental attitude, so they are used to reverse debilitation associated with surgery, trauma, illness, glucocorticoid-induced catabolism, and aging. In all cases, improved well-being depends on adequate intake of protein and calories and on treatment of the underlying disease.

Anabolic steroids have a variety of undesirable effects. They induce androgenic effects, such as increased libido in males and abnormal sexual behavior in females, along with adverse reproductive effects, including azoospermia, anestrus, testicular atrophy, and clitoral hypertrophy. They promote edema formation due to sodium and water retention. Icterus can develop due to intrahepatic cholestasis. Anabolic steroids can induce epiphyseal plate closure, thereby retarding growth. Anabolic steroids are used in treatment of debilitated animals; however, they are often misused to gain a competitive advantage in performance animals. Approved veterinary formulations are no longer marketed in North America. Currently, any anabolic product for veterinary use (aside from bovine ear implants) can be obtained only from a compounding pharmacy. Use of anabolic steroids in performance horses is prohibited by most equine sport organizations, and drug detection times can be >2 mo.

SYSTEMIC PHARMACOTHERAPEUTICS OF THE NERVOUS SYSTEM

Drugs used to modify or treat disorders of the nervous system fall into several categories: anticonvulsants or antiepileptic drugs (AEDs), tranquilizers, sedatives, analgesics, and psychotropic agents. *See also* PRINCIPLES OF THERAPY OF NEUROLOGIC DISEASE, p 1220, ANALGESIC PHARMACOLOGY, p 2107, and PRINCIPLES OF PHARMACOLOGIC AND

NATURAL TREATMENT FOR BEHAVIORAL PROBLEMS, p 1543.

ANTICONVULSANTS OR ANTIEPILEPTIC DRUGS

Anticonvulsants or antiepileptic drugs (AEDs) are used to stop an ongoing seizure

or to decrease the frequency or severity of anticipated future seizures. During a seizure episode or status epilepticus, the route of administration for AEDs is IV (see TABLE 17). For longterm maintenance, the oral route is preferred, although absorption may be limited or variable depending on the drug used (see TABLE 18). SC or IM injections are seldom used because of the variability in drug absorption.

ANTIEPILEPTIC DRUGS USED TO STOP ONGOING SEIZURE ACTIVITY

In status epilepticus, treatment is essential to prevent death from hyperthermia, acidosis, hypoperfusion, and hypoxia. Because diazepam has a rapid onset of action that prevents the spread of the seizure, it is usually the drug of choice to control status epilepticus and stop seizures in small and large animals.

Foals and Horses

Diazepam in horses has a long elimination half-life (7–22 hr). In foals, the dosage is 0.05–0.4 mg/kg, slowly IV (or about 5–20 mg/dose); higher doses can be fatal to neonates. For seizures in adult horses, diazepam can be given at 25–50 mg/horse, IV. To prevent further seizures after initial diazepam injection, IV phenobarbital may be started as a follow up at 12–20 mg/kg, IV over 20 min, and then maintained at a dosage of 6.65–9 mg/kg over 20 min, bid or tid. If sedation occurs, the dose should be reduced. Alternatively, treatment of seizures in foals can be initiated with phenytoin at 5–10 mg/kg, IV or PO, with subsequent treatments of 1–5 mg/kg, IV, IM, or PO, every 2–4 hr for 12 hr and later maintained with oral phenytoin at 2.83–16.43 mg/kg, tid, although erratic plasma concentrations may limit usefulness. The dose may need to be reduced if sedation occurs.

TABLE 17 DRUGS USED FOR TREATMENT OF STATUS EPILEPTICUS

Drug	Species and Dosage
Diazepam	Dogs, cats: 0.5–2 mg/kg, IV bolus; can be repeated 2–3 times at intervals of 5–10 min; CRI* 0.5–2 mg/kg/hr Foals: 0.05–0.4 mg/kg, IV slowly Adult horses: 25–50 mg/horse, IV Ruminants: 0.5–1.5 mg/kg, IV or IM
Midazolam	Dogs, cats: 0.2 mg/kg, IV bolus; can be repeated 2–3 times at intervals of 5–10 min; CRI 0.05–0.5 mg/kg/hr
Phenobarbital	Dogs, cats: For those not already on maintenance phenobarbital, loading dose of 15 mg/kg, slowly IV. Alternatively, 3–6 mg/kg, IV or IM, every 15–30 min until a total dosage of 20 mg/kg is reached. In an animal already receiving maintenance phenobarbital, a single 3 mg/kg bolus, IV or IM, CRI 3–10 mg/hr to effect. Foals, adult horses: loading dose of 12–20 mg/kg, IV over 20 min, then 6.65–9 mg/kg, IV over 20 min every 8–12 hr
Sodium pentobarbital	Dogs, cats: 2–15 mg/kg, IV, to effect to stop motor activity Foals, adult horses: 2–4 mg/kg, IV to effect
Levetiracetam	Dogs: 20–60 mg/kg, IV; can be repeated at 8-hr intervals
Propofol	Dogs, cats: 2.5–4 mg/kg, IV, to effect to stop motor activity; CRI 0.1–0.3 mg/kg/min to effect
Phenytoin	Dogs: 2–5 mg/kg as slow IV infusion Foals, adult horses: 5–10 mg/kg, IV followed by 1–5 mg/kg, IV, IM, or PO, every 2–4 hr until seizures stop and maintenance dose started

* CRI = constant-rate infusion

TABLE 18 ANTIEPILEPTIC DRUGS

Drug	Dosage and Frequency	Half-life
FIRST-LINE MAINTENANCE ANTIEPILEPTIC DRUGS		
Phenobarbital	Dogs: 2–4 mg/kg, PO, bid (starting dose); up to 10 mg/kg, bid	40–90 hr (Beagles 25–38 hr)
	Cats: 2–4 mg/kg, PO, bid (starting dose)	34–43 hr
	Horses: 3–5 mg/kg/day, PO, as a starting dose; up to 11 mg/kg/day, PO	18 hr
	Foals: as above	13 hr
	Ruminants: 11 mg/kg/day, PO	
Bromide (potassium salt)	Dogs, cats: 20–40 mg/kg, PO, once daily or divided bid if GI upset. Caution using bromide in cats (see comments). Dogs: loading dose 400–600 mg/kg, PO divided into 4 doses, given over 1–4 days Horses: 90 mg/kg/day, PO	Dogs: 20–46 days Cats: 10 days Horses: 5 days
Bromide (sodium salt)	17–30 mg/kg, PO, once daily or divided bid if GI upset. The dose of sodium bromide is less than that of potassium bromide to account for the higher bromide content.	
Diazepam	Cats: 0.25–0.5 mg/kg, PO, bid-tid	Cats: 15–20 hr
SECOND-LINE (ADD-ON) ANTIEPILEPTIC DRUGS FOR DOGS		
Clonazepam	Dogs: 0.1–0.5 mg/kg, PO, bid-tid	1.5–3 hr
Clorazepate	Dogs: 0.5–1 mg/kg, PO, tid	5–6 hr
Felbamate	Dogs: 15 mg/kg, PO, tid; increase by 15 mg/kg biweekly until seizures controlled; maximal (toxic) dosage 300 mg/kg	5–6 hr

TABLE 18 ANTIEPILEPTIC DRUGS (*continued*)

Time to Steady State	Therapeutic Level	Adverse Effects/Comments
FIRST-LINE MAINTENANCE ANTIEPILEPTIC DRUGS		
10–24 days	15–45 mcg/mL (66–200 μ mol/L), preferably keep values within 20–35 mcg/mL (85–150 μ mol/L)	Adjust dosage in all species by monitoring serum levels and seizure diary.
	10–30 mcg/mL	Sedation, polydipsia, induces P450 system, increase in alkaline phosphatase common; liver failure is possible but uncommon.
	10–40 mcg/mL (43–175 μ mol/L)	Liver enzymes do not typically increase in cats.
Dogs: 100–200 days Cats: 6 wk	Bromide alone: 1–3 mg/mL (15–20 μ mol/L) Bromide/phenobarbital combined: 1–2 mg/mL	Sedation, weakness, polydipsia, vomiting, polyphagia, skin rash. Reduce dose with renal insufficiency. High chloride intake increases bromide elimination. Chloride content of diet should be stable. Use with extreme caution in cats and monitor with thoracic radiographs because bronchial/asthmatic signs may be fatal in cats. See potassium bromide comments.
		While oral diazepam is not effective as maintenance AED in dogs, it can be used in cats as a maintenance AED. Sedation and liver failure are potential problems in cats.
SECOND-LINE (ADD-ON) ANTIEPILEPTIC DRUGS FOR DOGS		
	22–77 ng/mL	Extremely potent benzodiazepine; sedation; withdrawal signs if drug stopped abruptly.
1–2 days	20–75 mcg/L	15 times less potent than clonazepam; sedation; withdrawal seizures. Can increase phenobarbital concentration.
1 day	125–250 μ mol/L ^a	Nervousness, keratoconjunctivitis sicca, mild thrombocytopenia, leukopenia; induces P450 system; liver disease. Use with care with other potentially hepatotoxic drugs.

(*continued*)

TABLE 18 ANTIEPILEPTIC DRUGS (*continued*)

Drug	Dosage and Frequency	Half-life
Gabapentin	Dogs: 10 mg/kg, PO, tid; up to 30–60 mg/kg, tid	3–4 hr
Levetiracetam	Dogs: 20 mg/kg, PO, tid	4–10 hr
Topiramate	Dogs: 5–10 mg/kg/day, PO, bid	2–4 hr
Valproic acid	Dogs: 10–60 mg/kg, PO, tid	90–120 min
Zonisamide	Dogs: 5 mg/kg/day, PO, bid, if phenobarbital is not concurrently given; 10 mg/kg, PO, bid if phenobarbital is concurrently administered.	15–20 hr

^a Therapeutic range established for people

Other ways to control ongoing seizure activity include sodium pentobarbital (2–4 mg/kg, IV to effect), a mixture of 12% chloral hydrate and 6% magnesium sulfate at a rate not exceeding 30 mL/min to avoid excessive depression, or a mixture of 44–88 mg/kg of 5% guaifenesin and 2.2–6.6 mg/kg thiamylal, given IV to effect. Horses with seizures induced by toxins or adverse drug effect (eg, xylazine) can be treated with diazepam (0.1–0.15 mg/kg, IV). If cerebral edema is suspected, see PRINCIPLES OF THERAPY OF THE NERVOUS SYSTEM, p 1220.

Ruminants

Diazepam has been used at 0.5–1.5 mg/kg, IM or IV. In sheep and goats, pentobarbital at 20–30 mg/kg can be used IV to effect to induce anesthesia. The duration of effect is 5–30 min.

Dogs and Cats

A variety of drugs can be used to stop seizures in dogs and cats.

Benzodiazepines: Diazepam is the most common benzodiazepine used in dogs and cats to reduce motor activity and permit placement of an IV catheter. When used as an IV bolus (0.5–2 mg/kg), the dose may

be repeated up to three times at intervals of 5–10 min. However if seizures occur after the second or third bolus, a constant-rate infusion (CRI) of diazepam at 0.5–2 mg/kg/hr may be more effective (especially if titrated based on seizure control and sedation level), and IV phenobarbital should be started as a preventive (see p 2595). When diazepam is used as a CRI, it should be mixed with 5% dextrose or 0.9% saline. It should not be mixed with lactated Ringer's solution, because the calcium may cause precipitation of the diazepam. Because plastic will absorb diazepam, it should not be left in plastic syringes or IV sets for prolonged intervals. When diazepam is administered as a CRI, it is thought that the initial pass-through in the IV set saturates the surface of the tubing such that there is no further absorption. If IV access is not possible in dogs, diazepam can be administered rectally at 0.5–2 mg/kg (2 mg/kg if the dog is receiving phenobarbital) or intranasally at 0.5 mg/kg. Rectal diazepam has been recommended as an at-home emergency treatment for some dogs that have clusters of seizures; it can be administered up to three times in a 24-hr period by owners.

Other benzodiazepines that can be used in dogs to stop seizure activity are

TABLE 18 ANTIEPILEPTIC DRUGS (*continued*)

Time to Steady State	Therapeutic Level	Adverse Effects/Comments
<24 hr	4–16 mg/L ^a (70–120 µmol/L)	Sedation, dizziness, ataxia, fatigue, diarrhea; reduce dose with renal dysfunction.
2–3 days	35–120 µmol/L ^a	Restlessness, vomiting, ataxia at dosages >400 mg/kg/day
3–5 days	2–25 mg/L (15–60 µmol/L) ^a	GI upset, irritability
<24 hr		Probably ineffective due to very short half-life; liver, alopecia, and pancreatitis; vomiting usually avoided by giving drug with food.
3–4 days	10–40 mg/L (45–180 µmol/L)	Sedation, ataxia, loss of appetite. Potential adverse effects (eg, keratoconjunctivitis sicca, bone marrow dyscrasia, hepatopathy, vasculitis, and metabolic acidosis) could occur because of sulfonamide base.

clonazepam (0.05–0.2 mg/kg, IV; the IV form of the drug may not be available in the USA), lorazepam (0.2 mg/kg, every 4–6 hr), and midazolam (0.2 mg/kg, IV or IM; CRI dose 0.05–0.5 mg/kg/hr).

Barbiturates: Phenobarbital is often used in status epilepticus cases to prevent further seizure activity. For animals not already on maintenance phenobarbital, a loading dose of 15 mg/kg, slow IV or IM, can be used. Alternatively, 3–6 mg/kg, IV or IM, can be administered every 15–30 min to attain the desired serum concentration; serum level increases by ~5 mcg/mL for every 3 mg/kg dose of phenobarbital. It is usually not necessary to exceed a total dose of 20 mg/kg. If injectable phenobarbital is effective in preventing or controlling seizures, an oral maintenance dose may be initiated, with the plan to decrease or stop injectable anticonvulsant infusions within the following 24 hr. Caution is necessary when administering both diazepam and phenobarbital, because a potentiation of their effects increases the risk of respiratory and cardiovascular collapse.

Propofol is a short-acting IV hypnotic anesthetic agent that may have anticonvulsant activity because it is GABA-mimetic, stabilizing GABA-inhibitory neurotransmit-

ter sites. After IV administration, propofol rapidly crosses the blood-brain barrier and usually has an onset of action of <1 min. However, the duration of action after a single bolus is only ~2–5 min. When used as a single dose (2.5–4 mg/kg, IV) in dogs and cats, ~25% of the calculated dose is administered every 30 sec until the desired effect is reached. If seizures recur after 1–2 injections, a propofol CRI (0.05–0.2 up to 0.4 mg/kg/min) can be used if definitive airway control and hemodynamic support are available and if the animal can be closely monitored. During IV injection, seizure-like signs of excitement, paddling, nystagmus, muscle twitching, and opisthotonos may sometimes be seen.

Sodium pentobarbital is generally reserved for treatment of uncontrollable status epilepticus in dogs and cats, especially when diazepam and phenobarbital have failed (*see* TABLE 17). In these species, it is administered at 2–15 mg/kg to effect for anesthesia. Pentobarbital is a respiratory depressant, so respiratory assistance must be readily available. The drug is irritating if administered perivascularly or subcutaneously. As the animal recovers from the drug's effects, excitement may occur, which can be mistaken for seizure activity.

Inhalation Anesthesia: In some cases, inhalation anesthesia is necessary to control or stop seizure activity. This requires constant monitoring and mechanical ventilation.

Alternative Methods to Stop a Seizure

Seizure: Phenytoin at 2–5 mg/kg has been used as a slow IV infusion in dogs to stop a seizure. Ocular compression (application of digital pressure to one or both eyes) may be beneficial via stimulation of the vagus nerve. An implantable pacemaker device that delivers repetitive stimulation to the left cervical vagus nerve has been investigated in dogs and may be of benefit in some epileptic animals. Acupuncture points KID 1 and/or GV 26 might also be of benefit.

MAINTENANCE ANTICONVULSANT OR ANTIEPILEPTIC THERAPY

The decision to start maintenance anticonvulsant or antiepileptic therapy should be based on the frequency and severity of the seizures, the age of onset, the likely cause(s) of the seizures, and the results of diagnostic testing. In general, a maintenance antiepileptic drug (AED) should be considered in animals that have had more than one or two seizures within a 6-mo period (assuming these seizures were not caused by repeated toxin exposure) or in animals that have had more than one seizure of unknown cause on any particular day. A maintenance AED should also be considered if the first seizure episode is protracted or severe, or during an episode of status epilepticus (as a followup to emergency treatment, *see p 2591*).

Treatment should begin with a single drug at the minimal required level for effect. Owners should keep a calendar to document the frequency and pattern of seizures as a guide for treatment strategy. This calendar, in conjunction with serum AED levels, can be used as a guide for dosage and drug treatment changes. If seizure control is unsatisfactory, the drug level should be checked. If the level is not within the middle of the therapeutic range, the dose should be increased before adding or switching to a new drug. Doses may be doubled in early stages and increased by 25%–50% in later stages. Monotherapy is preferred, but if the drug level is well into the middle or high therapeutic range, it may be necessary to consider the addition of another AED. To discontinue any AED, except bromide, the dose of the drug should

be tapered gradually over a few weeks to avoid precipitating a seizure. Tapering phenobarbital is crucial, because it is addictive and can result in withdrawal seizures if stopped abruptly.

Maintenance Antiepileptic Drugs (Anticonvulsants)

In dogs, phenobarbital and bromide are considered first-line maintenance AEDs, but levetiracetam and zonisamide are often used as well. In cats, phenobarbital is the usual first choice, but levetiracetam and zonisamide are becoming more acceptable; diazepam is an alternative choice. In ruminants, phenobarbital is the first choice; in horses, both bromide and phenobarbital have been used.

Phenobarbital: Phenobarbital has a long record of safety, efficacy, low cost, and convenience in regard to monitoring serum concentrations. For longterm maintenance in cats and dogs, phenobarbital may be given at 2–4 mg/kg/day, PO, bid. In all species, it takes ~2 wk to approach a steady-state plasma concentration, because oral absorption is extremely variable and the half-life is long. Drug levels are monitored 2 wk after initiation of therapy, 2 wk after any dosage change, and usually every 6–12 mo once seizure control is achieved. Serum therapeutic concentrations are 15–45 mcg/mL. The dosage should be adjusted on the basis of serum level and the history of seizure control. Tolerance to phenobarbital therapy may develop in dogs treated continually for months to years and may result in decreased seizure control; however, an increase (25%) in the dose usually will result in improved seizure control.

Phenobarbital causes physical dependence, and thus abrupt withdrawal may cause “barbiturate withdrawal” seizures. Hepatotoxicity and liver failure in dogs have been associated with high serum concentrations (>35 mcg/mL), necessitating the serum level checks every 6–12 mo. Adverse effects such as sedation, polydipsia, polyuria, and polyphagia are common but may decrease within the first few weeks. Other, less common adverse effects are idiosyncratic hyperexcitability, dermatitis, anemia, neutropenia, thrombocytopenia, gingival hyperplasia, and osteomalacia. Phenobarbital has also been used to treat episodic dyscontrol syndrome (rage) in dogs when seizure activity is demonstrable via electroencephalogram recordings.

Oral phenobarbital has been used in ruminants at 11 mg/kg/day and in horses at 3–11 mg/kg/day. Serum concentrations should be checked periodically.

Bromide: Bromide appears to stabilize neuronal cell membranes by interfering with chloride transport across cell membranes and by potentiating the effect of GABA via hyperpolarizing membranes. Bromide (potassium or sodium salt) can be used as a first-choice AED in dogs with epilepsy, as an adjunctive AED in dogs with refractory seizure disorders, or for dogs that have unacceptable adverse effects related to phenobarbital or other AEDs. In countries where bromide is not available as a pharmaceutical formulation (USA), an analytical grade may be obtained from a chemical supply company, although caution is recommended in handling and packaging. Bromide can be formulated into a solution of various concentrations (100 mg/mL, 200 mg/mL, 250 mg/mL are convenient ones) or into tablets or capsules.

The elimination half-life is extremely long (24 days) in dogs; therefore, it takes ~4 mo to achieve steady state kinetics. Bromide is renally eliminated and thus should not be used in dogs with renal dysfunction without careful monitoring. If azotemia is present, a different AED can be used, or the initial bromide dose can be reduced by half and serum concentrations monitored. Because it does not undergo hepatic metabolism, bromide is useful in dogs with liver disease.

As adjunct therapy with phenobarbital, potassium bromide can be administered at 20–40 mg/kg/day, PO, either as one dose or divided into two or more doses; the sodium bromide dosage is slightly lower at 17–30 mg/kg/day, PO. When bromide is used as the sole treatment for epilepsy in dogs, higher dosages (50–80 mg/kg/day) may be necessary. Dogs on a high salt diet may require dosages of 50–80 mg/kg/day to maintain adequate serum concentrations, because high chloride intake increases bromide loss in the urine and lowers serum bromide concentrations. Many laboratory assays cannot distinguish between serum bromide and chloride ions, so serum chloride values may be reported as falsely high.

Because a daily maintenance dose may take 4 mo to reach steady state serum concentration, there are situations (eg, severe seizures, seizures that occur on a monthly basis, the need to rapidly switch from phenobarbital to bromide because of phenobarbital toxicity) when a loading dose of bromide should be administered. An oral

loading dosage of 400–600 mg/kg of bromide is divided into four doses and given with food over a 1- to 4-day period. Smaller doses, such as 50 mg/kg, bid for 4–6 days, may reduce adverse effects (eg, nausea and vomiting) caused by rapid increase in serum bromide concentrations. The regular maintenance dose can be started at the same time as the loading dose or immediately afterward. The loading dose regimen can be discontinued if the dog becomes too sedated, or smaller divided daily doses can be tried. A serum sample can be submitted within 2 wk after loading to determine whether a therapeutic level has been reached. (If cost is an issue, however, a sample is best checked in 4 mo when steady-state concentrations have been reached.) The therapeutic range for bromide is 1–2 mg/mL (10–20 mmol/L) with concurrent phenobarbital treatment, or 1–3 mg/mL (10–30 mmol/L) for bromide as a monotherapy. However, the dosing regimen needs to be tailored for each animal; the upper end of the therapeutic range is only limited by adverse effects of bromide.

Bromide is generally well tolerated by dogs, but potential adverse effects include bitter taste, gastric irritation, nausea (particularly with the potassium form), polyuria, polydipsia, polyphagia, sedation, ataxia, and pancreatitis. It should be administered with food; the amount and type of food given should be kept constant, because variable dietary salt content will affect the elimination of bromide via the kidneys. Bromide therapy must be titrated to the individual animal based on careful therapeutic drug monitoring and careful monitoring by the owner for early signs of toxicity. Reports of hindlimb weakness should be investigated as potential bromide toxicosis by measuring serum bromide concentration and discontinuing bromide for several days to see whether the weakness improves. Severe bromide toxicosis (bromism) is characterized by lethargy, disorientation, delirium, and ataxia progressing to quadriplegia and coma. Bromide toxicity can be seen at any concentration in an unusually sensitive dog, but it is rare when bromide is used alone and when serum concentrations are <1.5 mg/mL (15 mmol/L). When used in combination with phenobarbital, bromide toxicity can be seen at concentrations of 2–3 mg/mL (20–30 mmol/L). Severe signs of toxicity are easily treated by IV administration of 0.9% sodium chloride, which promotes renal excretion of the bromide ion.

Bromide is an effective maintenance AED in cats, but the incidence of adverse effects

does not warrant its routine use unless there is no other choice. Approximately 25%–50% of cats administered bromide developed signs of bronchial disease characterized by a cough and marked pulmonary infiltrates seen on radiographs. In some cases, the asthmatic changes were fatal, but in most cases the signs resolved after discontinuation of bromide.

Bromide has been used in horses as a maintenance AED, but there are no published studies on its clinical efficacy. Pharmacokinetic studies have suggested that a loading dose of potassium bromide of 120 mg/kg/day over 5 days and maintenance dosages of ~90–100 mg/kg/day will likely result in effective serum bromide concentrations.

Primidone: Primidone is a barbiturate that has three metabolites: phenobarbital, primidone, and phenylethylmalonamide. The phenobarbital metabolite is likely the major functional one, and there may not be an advantage to using primidone over phenobarbital. Nevertheless, one report indicated that dogs with seizures that are not well controlled with phenobarbital may respond better to primidone (eg, psychomotor seizures). The initial dosage (dogs only) is 5–15 mg/kg/day in three divided doses, increased over time to a maximum of 35 mg/kg/day. Effective serum levels are determined by the serum level of phenobarbital (15–45 mcg/mL). If primidone is switched to phenobarbital, one grain of phenobarbital can be substituted for 250 mg primidone.

Primidone may be more likely to cause hepatotoxicity than phenobarbital, and it has been associated with hepatic necrosis and lipidosis and bile canaliculi obstruction. ALT, serum alkaline phosphatase, and/or bile acids should be monitored. Other adverse effects and signs of overdose are similar to those of phenobarbital.

Primidone is not recommended for use in cats because of toxicity concerns. However, preliminary studies suggest primidone at 40 mg/kg/day for 90 days may be acceptable in cats.

Diazepam: Diazepam is not suitable for oral maintenance therapy in dogs, because it is absorbed poorly, has a short half-life of 2.5–3.2 hr, and tolerance to its anticonvulsant effects develops rapidly. However, cats not only have a longer half-life (15–20 hr) than dogs but also do not develop a tolerance to the anticonvulsant effects. Thus, diazepam can be used as a maintenance treatment in cats, with dosages ranging from 0.25–0.5 mg/kg, PO, bid-tid.

Acute hepatic failure has been reported in cats given diazepam for behavioral problems; thus, a pretreatment chemistry profile should be evaluated before using diazepam, and cats should be watched closely during the first 2 wk of use.

Newer or Adjunctive Anticonvulsants

Levetiracetam: This pyrrolidine-based anticonvulsant has an unknown mechanism of action. It has been used as an adjunct AED for dogs and cats and is occasionally used as monotherapy. In dogs, it has excellent oral bioavailability, does not appear to undergo hepatic metabolism, is primarily excreted unchanged in the urine, and has a half-life of ~4 hr. It appears very safe with no to few adverse effects (ataxia, sedation, vomiting) reported at the routine dosage ranges. Levetiracetam is initially administered at 20 mg/kg, PO, tid, in dogs; 10–20 mg/kg, PO, tid, in cats. If adverse effects occur, the dosage should be reduced to 20 mg/kg, bid, and increased to 20 mg/kg, tid, gradually. Studies suggest that 60% of dogs respond initially; however, after 4–8 mo, there is a loss of effect in ⅓ of previous responders because of development of tolerance. In dogs, the dosage can be increased every 2 wk in increments of 20 mg/kg if therapeutic benefit has not been noted. Adverse effects of salivation, restlessness, vomiting, and ataxia at dosages >400 mg/kg/day have been seen experimentally in dogs but resolved within 24 hr of discontinuing the drug. Therapeutic monitoring is generally not necessary when using this drug, and there does not appear to be a correlation between serum drug concentration and therapeutic efficacy. An IV formulation can be used in status epilepticus.

Zonisamide: This sulfonamide-based anticonvulsant restricts the propagation and spread of seizures and suppresses epileptogenic focus activity. It has been used as first-line AED as well as an adjunct AED in dogs not adequately controlled by phenobarbital and bromide. Although some of it is metabolized by the P450 enzyme system, much is excreted unchanged in the urine. Dogs receiving concurrent drug therapy known to induce hepatic microsomal enzymes (ie, phenobarbital) require nearly twice the dosage of zonisamide to achieve and maintain serum concentrations than dogs receiving zonisamide alone. Thus, the dose of zonisamide in dogs receiving phenobarbital is 10 mg/kg, PO, bid. In dogs

not on drugs that induce hepatic microsomal enzymes, the dosage is 5 mg/kg, PO, bid. The dosage in cats has varied from 5 mg/kg, PO, bid, to 5–10 mg/kg/day, PO. The recommended therapeutic range is 10–40 mg/mL; trough concentrations can be measured ~7–10 days after initiating treatment or altering the dosage. The adverse effects are usually mild, such as transient ataxia, loss of appetite, lethargy, and vomiting. Although the drug appears safe, owners should be warned that because of the sulfonamide base, potential adverse effects (eg, keratoconjunctivitis sicca, bone marrow dyscrasia, hepatopathy, vasculitis, and metabolic acidosis) could occur. A nonfatal hepatopathy in a dog was attributed to zonisamide.

Gabapentin: This synthetic analogue of the inhibitory neurotransmitter γ -aminobutyric acid (GABA) inhibits seizure activity via multiple mechanisms, including inhibition of neuronal sodium channels and potentiation of the release and action of GABA. It is well absorbed in dogs after oral administration and undergoes both hepatic and renal metabolism. In dogs, the initial dosage is 10–15 mg/kg, PO, tid. Higher dosages (30–60 mg/kg, PO, tid-qid) may be necessary but can produce sedation and ataxia. If excessive sedation occurs, a lower dose should be used initially and gradually increased. Therapeutic monitoring is not usually necessary with this drug. No drug interactions have been reported. Gabapentin has been used in cats at 5–10 mg/kg, bid-tid.

Felbamate: Felbamate is a dicarbamate AED that exerts its anticonvulsant effects through multiple mechanisms, including potentiating GABA-mediated neuronal inhibition, inhibiting voltage-sensitive neuronal calcium and sodium channels, and blocking N-methyl-D-aspartate-mediated neuronal excitation. It is primarily (70%) renally excreted in dogs, with the remainder of the drug undergoing hepatic metabolism. The recommended initial dosage is 15 mg/kg, PO, tid, but the dose can be increased every 14–21 days in increments of 15 mg/kg if therapeutic benefit has not been noted. The principle advantage of felbamate is a lack of sedation, and adverse effects are reportedly rare. Potential adverse effects are hepatotoxicity, reversible myelosuppression, generalized tremors, and possibly keratoconjunctivitis sicca; regular monitoring for anemia and liver dysfunction in dogs is recommended. In people, felbamate has been associated with aplastic

anemia and liver toxicity. There is no clinical information on use of felbamate in cats.

Valproic Acid: Valproic acid (10–60 mg/kg, tid) has been used as an adjunct to phenobarbital and primidone in dogs with refractory seizures. It has also been used to treat aggressive behavior problems (see p 2601). Common adverse effects include transient GI distress, alopecia, sedation, and vomiting. Hepatic failure is rare. Use of valproic acid in dogs is limited because of rapid metabolism.

Clonazepam: Clonazepam, unlike diazepam, can be used in dogs for oral maintenance therapy, because anticonvulsant tolerance develops less rapidly, the saturability of its metabolism reduces the elimination rate at therapeutic concentrations, and because it is more highly absorbed orally (particularly in micronized formulations). For maintenance therapy in dogs, it may be used alone at 0.5 mg/kg, tid, but it is best used as an adjunct to phenobarbital at dosages of 0.1–0.5 mg/kg/day. Diarrhea sometimes develops with clonazepam, but this may be avoided by starting with once daily dosing and increasing the frequency to three times daily over a period of several days.

Carbamazepine: Carbamazepine is not recommended for use in dogs because of a rapid induction of hepatic enzymes that eliminate the drug quickly. Although plasma concentrations declined rapidly in dogs on a 1-wk regimen of 30 mg/kg, tid, one case report described adequate seizure control despite undetectable drug concentrations in plasma, possibly due either to an active metabolite or to a highly sensitive drug reaction. Carbamazepine has been used to treat aggressive behavior problems in cats (see p 2601).

Clorazepate Dipotassium: Clorazepate dipotassium (0.5–1 g/kg, tid) has been proposed as an adjunct to phenobarbital treatment in dogs. Severe withdrawal symptoms, even lethal seizures, may appear after abrupt discontinuation of chronic clorazepate treatment, in spite of the relatively low tolerance liability of clorazepate. Administration of phenobarbital alters the deposition of clorazepate such that the amount of nordiazepam in circulation during each dose interval is significantly reduced. Adequate control of seizures in epileptic dogs, therefore, may require higher dosages of clorazepate when coadministered with

phenobarbital. However, clorazepate may increase phenobarbital concentrations, resulting in adverse effects.

Phenytoin: Phenytoin (diphenylhydantoin) is no longer recommended for maintenance use in dogs, cats, or foals because of undesirable pharmacokinetic properties. Its metabolism is too rapid in dogs, which reduces its effectiveness, and too slow in cats, which increases the risk of toxicity (salivation, vomiting, weight loss). In foals, phenytoin has erratic plasma concentrations. It may still be used in status epilepticus in dogs as a slow IV injection of 2–5 mg/kg.

Mephenytoin: Mephenytoin, although related to phenytoin, has been effective in dogs (10 mg/kg, tid) because of a slower rate of elimination. It may be combined with phenobarbital or bromide. Adverse effects consist of sedation only, but periodic hematologic monitoring is advised, because blood dyscrasia and hepatotoxicity are reported in people.

Topiramate: Topiramate is a newer AED that is well tolerated by people and increasingly used for neuropathic pain. In one report, it was listed as an adjunct AED for dogs, but its effectiveness is not yet known. Because the elimination half-life is short in dogs (2–4 hr), it is probably not an effective anticonvulsant, but a dosage of 5–10 mg/kg, bid, has been suggested. There have been no clinical studies to date, and only limited information is currently available.

TRANQUILIZERS, SEDATIVES, AND ANALGESICS

Tranquilization reduces anxiety and induces a sense of tranquility without drowsiness. Drug-induced sedation has a more profound effect and produces drowsiness and hypnosis. Analgesia is the reduction of pain, which according to a drug's effect, may be more pronounced in either the viscera or the musculoskeletal system (see p 2104). Many drugs cannot be categorized by only

TABLE 19

TRANQUILIZERS AND SEDATIVES WITHOUT ANALGESIC EFFECTS

Drug	Dosage		
	Dogs	Cats	Ferrets
BENZODIAZEPINES			
Diazepam	1 mg/kg, IV or PO	1 mg/kg, IV	2 mg/kg, IM
Midazolam	0.2–0.4 mg/kg, IV or IM	0.2–0.4 mg/kg, IV or IM	
BUTYROPHENONE			
Azaperone			
PHENOTHIAZINES			
Acepromazine maleate	0.05–0.1 mg/kg, IV, IM, or SC; 0.55–2.2 mg/kg, PO, tid-qid	0.11–0.22 mg/kg, IV, IM, or SC; 1.1–2.2 mg/kg, PO, bid-tid	0.1–0.25 mg/kg, IM or SC
Chlorpromazine hydrochloride	0.55–4.4 mg/kg, IV; 1.1–6.6 mg/kg, IM; 3.2 mg/kg, PO, tid-qid as needed	1–2 mg/kg, IV or IM, bid	
Promazine hydrochloride	2–6 mg/kg, IV, IM, or PO, tid-qid	2–4.4 mg/kg, IV, IM, or PO, tid-qid	
Triflupromazine hydrochloride	1.1–2.2 mg/kg, IV; 2.2–4.4 mg/kg, IM	4.4–8.8 mg/kg, IM	

one pharmacologic effect, ie, as tranquilizers, sedatives, or analgesics. For example, many psychotropic drugs can either tranquilize or sedate according to the dose administered, and many sedatives are also analgesics. Also, drugs classified as tranquilizers, sedatives, and/or analgesics may have additional effects (eg, behavioral modification, antiemesis).

For drugs commonly used in various species for tranquilization, sedation, or analgesia, *see* TABLES 19 and 20. Drugs that have some of these effects but are used mainly for other properties (eg, as antispasmodics, antiemetics, or preanesthetics) are not listed. Single-use doses are emphasized because many situations require only a brief duration of effect, but frequency of administration is also provided for drugs likely to be used for multiple-dose therapy. The dosages listed serve only as a general guideline and apply to the use of each drug alone, not to a combination for anesthesia or neuroleptanalgesia. No reference is made to schedule restrictions,

extra-label use, or precautions in the use of these drugs; the product label and referenced texts should be consulted for information on the pharmacology and alternative applications of each drug.

PSYCHOTROPIC AGENTS

Anxiolytics, antipsychotics, antidepressants, and mood stabilizers used to treat human behavioral disorders are being used more commonly in veterinary medicine as adjuncts to behavioral modification therapy (*see also* PRINCIPLES OF PHARMACOLOGIC AND NATURAL TREATMENT FOR BEHAVIORAL PROBLEMS, p 1543). Few veterinary clinical studies have been reported, and guidelines for veterinary use are grounded on therapeutic applications in human medicine.

Anxiolytics

Anxiolytics, including the benzodiazepines and an azapirone (buspiron), have been

Phenylbutazone	15–22 mg/kg, PO; 15 mg/kg, IV, bid-tid (maximum 0.8 g/dog/day or 44 mg/kg/day); use of phenylbutazone in dogs has decreased since the introduction of other NSAIDs with better safety margins.	15 mg/kg, IV, tid; 10–14 mg/kg, PO, bid; use of phenylbutazone in cats has decreased since the introduction of other NSAIDs with better safety margins.	

^a Recommended dosages of opiates may produce excitement in cats and horses.

used to treat generalized anxiety and panic disorder in dogs and cats, as well as urine spraying in cats. Benzodiazepines, such as diazepam, alprazolam, oxazepam, and clorazepate, act by binding to γ -amino butyric acid (GABA) receptors and enhancing GABA-mediated chloride influx. They may cause sedation and muscle relaxation; dependence and withdrawal signs also can occur.

Diazepam has been recommended to alleviate fear-related behaviors in dogs and social anxiety and urine spraying in cats. However, benzodiazepines may not alleviate fear-related aggression in certain animals but instead may cause a paradoxical increase in such behaviors. Although diazepam has been reported to diminish urine spraying in cats, most cats resume spraying when the drug is withdrawn. There have been rare reports of hepatic failure within 3–5 days of starting diazepam in cats.

Oxazepam (dogs 0.2–0.5 mg/kg, PO, once to twice daily; cats 1–2.5 mg/cat, PO, bid) and alprazolam have been used to treat fears and phobias in both dogs and cats. In addition, alprazolam has been used to treat night-time anxiety in dogs (0.01–0.1 mg/kg, PO) and refractory housesoiling in cats (0.1 mg/kg or 0.125–0.25 mg [total dose] per cat, PO, bid-tid). Clorazepate has been used to treat anxiety in cats (1.75–3.75 mg/cat, PO, once to twice daily). Diazepam, clonazepam, and clorazepate dipotassium also have anticonvulsant properties.

Buspirone differs from the benzodiazepines in pharmacologic properties (ie, it blocks serotonin pre- and postsynaptically and acts as a dopamine agonist), onset of action (delayed onset of 7–30 days), and lack of sedative effect. Buspirone appears to offer no greater control for anxiety-related behaviors than the benzodiazepines, but it helps treat urine spraying in cats at 2.5–7.5 mg/cat.

Antipsychotics

Antipsychotics are classified as low-potency agents (acepromazine, chlorpromazine, and thioridazine hydrochloride) and high-potency agents (haloperidol, fluphenazine, trifluoperazine hydrochloride, prochlorperazine, thiothixene, risperidone). Low-potency agents require larger doses and produce more sedation, more anticholinergic adverse effects, and cardiovascular effects, but they have a lower incidence of extrapyramidal adverse effects (parkinsonism, dystonia, dyskinesia, and akathisia) than the high-potency agents. All the antipsychotics are used for nonselective tranquilization and diminishing behavioral arousal. Acepromazine is commonly used for infrequent anxiety episodes, but it may induce a paradoxical hyperactivity in some dogs and cats. In one report, a dog with aberrant behavior (tail chewing, growling, snapping, barking) was controlled with thioridazine at 1.1 mg/kg.

TABLE 20 ANALGESICS (continued)

Dosage			
Rabbits	Horses	Cattle	Pigs
3 mg/kg, IM	2.2 mg/kg/day, IV	2.2 mg/kg, IV; 3 mg/kg/day, IM	
	2.2 mg/kg/day, PO		
	4.4 mg/kg, PO, bid on day 1; 2.2 mg/kg, PO, bid for 4 days; 2.2 mg/kg, PO, daily or every other day	2–5 mg/kg, IV; 4–8 mg/kg, PO	2–5 mg/kg, IV; 4–8 mg/kg, PO

Mood-stabilizing Drugs

Mood-stabilizing drugs (lithium, carbamazepine, and valproic acid) are unrelated chemical compounds used in human medicine to treat bipolar disorder, impulsivity, emotional reactivity, and aggression. Carbamazepine and valproic acid are also antiepileptic drugs. Carbamazepine has been used in cats (25 mg/cat, PO, bid) to decrease fear-related aggression against people, but it may paradoxically increase aggression against conspecifics. Lithium is excreted unmetabolized via the urine. Serum concentration monitoring is necessary because of its narrow therapeutic index (recommended range: 0.8–1.2 mEq/L). Adverse effects include polyuria, polydipsia, memory problems, weight gain, and diarrhea. In one report, lithium (75 mg total dose, bid) was used to treat owner-directed aggression and psychotic behavior (random air-snapping, pawing) in a Cocker Spaniel.

Antidepressants

Antidepressants are classified as tricyclic compounds (tertiary amines, secondary amines), selective serotonin reuptake inhibitors, and atypical antidepressants. They can be used to treat behavioral disorders, including obsessive-compulsive behaviors, stereotypies, aggression, and inappropriate elimination. The mode of action is to block reuptake of serotonin and/or norepinephrine or to reduce neurotransmitter turnover. All have a lag time until a behavioral effect is seen.

The **tricyclic antidepressants** include amitriptyline, imipramine, clomipramine, and doxepin. Case reports indicate that treatment success for behavioral disorders is highly variable among drugs within the same chemical class. The antihistaminic effect of these agents may be a useful adjunct in controlling pruritus due to atopy and food allergies. Adverse effects include vomiting, diarrhea, hyperexcitability, sedation, arrhythmias including tachycardia, orthostatic hypotension, mydriasis, reduced lacrimation and salivation, urine retention, constipation, and weight gain. Widening of the QRS complex on an ECG has been used as an early indication of toxicity. It may take 7–30 days for drugs to be effective. Amitriptyline hydrochloride has been used in dogs at 1–2 mg/kg for separation anxiety, anxiety-related aggression, urination due to submission or excitement, and allergy-related pruritus, and in cats at 0.5–1 mg/kg for urine marking and hypervocalization. Imipramine hydrochloride has been used in dogs at 2.2–4.4 mg/kg, bid-tid, for urination due to submission or excitement. Clomipramine hydrochloride has been used in dogs at 1–3 mg/kg to reduce lick behavior for canine lick granuloma and for stereotypies such as circling and tail chasing, and in cats at 0.5 mg/kg. In some countries, it is approved for treatment of separation anxiety in dogs. Doxepine has been used in dogs at 3–5 mg/kg.

Selective serotonin reuptake inhibitors, including fluoxetine, sertraline, and paroxetine, have been used to treat

psychogenic alopecia, allergy-related pruritus, owner-directed aggression, fearful behaviors, obsessive-compulsive behaviors, and urine marking. It may take 7–30 days for these drugs to be effective. The most common adverse effects are changes in appetite and GI signs, although seizures have been reported. These drugs inhibit liver P450 enzymes, so drug interactions are possible. Dosages for fluoxetine are 1 mg/kg/day, PO, for dogs, and 0.5–1 mg/kg/day, PO, for cats.

Other Agents and Hormones

Monoamine oxidase inhibitors, such as selegiline, are used for cognitive impairment in aging dogs. The use of progestin

hormones to treat behavioral problems is currently considered a “last resort” therapy because of the risk of adverse effects. In castrated and intact male dogs, megestrol acetate has been used to treat aggression, urine marking, and roaming. Likewise, in neutered male cats, megestrol acetate can reduce spraying, but potential adverse effects of inducing diabetes mellitus, mammary gland hyperplasia and adenocarcinoma, and bone marrow suppression make it risky to use. Medroxyprogesterone acetate, an injectable, long-acting progestin, has been used to treat aggression, urine marking, and roaming; however, it is rarely used because of the risk of adverse effects and availability of other, safer behavioral drugs.

SYSTEMIC PHARMACOTHERAPEUTICS OF THE REPRODUCTIVE SYSTEM

See also PRINCIPLES OF THERAPY OF THE REPRODUCTIVE SYSTEM, p 1328.

Drugs used to regulate or control the reproductive system are often naturally occurring hormones or chemical modifications of hormones. **Gonadotropin-releasing hormone** (GnRH) and its analogues are used for treatment of ovarian cysts and for control of ovarian follicular dynamics in cattle, for estrus induction (by pulsatile administration) in mares and bitches, and for stimulation of testicular function (eg, in testing for cryptorchidism). Implants of GnRH analogues (eg, deslorelin) are effective for induction of estrus and ovulation in mares and bitches and, in higher doses over a prolonged period, are useful for contraception in male and female animals (such as dogs) by mediating longterm (≥ 12 mo) reversible infertility caused by downregulation of GnRH receptors.

Follicle-stimulating hormone (FSH), usually extracted from animal pituitary glands, stimulates follicular growth and estrogen production in females and spermatogenesis in males. It is used for superovulation of several domestic species. It has also found application in induction of fertile estrus in bitches and queens. Prolonged FSH use or higher doses can cause adverse effects such as cystic endometrial hyperplasia and follicular cysts.

Human chorionic gonadotropin (hCG), which exerts mainly luteinizing hormone-

like effects in domestic animals, is used for stimulation of gonads (as a test for cryptorchidism and also for treatment of ovarian cysts in cattle or dogs). It is also used to cause ovulation of mature ovarian follicles in cows or mares in controlled-breeding programs. hCG is given parenterally; plasma levels peak in ~6 hr. It is primarily distributed to the ovaries in females and the testes in males, although some is also distributed to the renal proximal tubules.

Equine chorionic gonadotropin (eCG) has FSH activity in most species and is used to induce ovarian follicular growth, both for superovulation and for estrus induction. (*See also* HORMONAL CONTROL OF ESTRUS, p 2244, and MANAGEMENT OF REPRODUCTION: CATTLE, p 2171 et seq.)

Estradiol esters (eg, valerate, cypionate, or propionate) have a longer duration of action than the parent compound. These compounds are used in bitches, mares, and cows for induction or enhancement of fertile estrus or for induction of estrous behavior; treatment of urinary incontinence in bitches; and for antitumor activity in prostatic and perianal tumors. Availability of these compounds and restrictions on their use vary by country. Estrogenic therapy may cause bone marrow suppression and potentially fatal aplastic anemia in dogs and cats; its use is also associated with development of cystic endometrial hyperplasia in these species, and it may

have teratogenic effects in pregnant animals. Because of these potential complications, estrogens are no longer recommended for termination of pregnancy in cases of mismating.

The nonsteroidal synthetic compound **diethylstilbestrol** also has estrogenic activity; its use is prohibited in food animals in the USA. Estrogen antagonists, such as tamoxifen, have been proposed for treatment of metastatic mammary carcinoma in dogs.

Progesterone and **synthetic progestins** are used for suppression or postponement of estrus in bitches and queens. They have also been used in behavior modification and to treat dermatologic disorders. Progesterone supplementation is used to support pregnancies regarded as at risk (eg, in pregnant mares with potentially endotoxemic conditions) and in horses or dogs with demonstrated hypoluteoidism. Adverse effects of progestin administration in small animals include induction of cystic endometrial hyperplasia, adrenocortical suppression, induction or exacerbation of diabetes mellitus, and mammary gland development. Mifepristone (a progesterone-receptor antagonist) has been used experimentally as a canine abortifacient; epostane, a progesterone-synthesis inhibitor, also terminates canine pregnancy.

Testosterone is used for estrus suppression (particularly in racing Greyhounds). Mibolerone, a weak androgenic steroid, is used to prevent estrus in bitches. It should not be used in Bedlington Terriers or cats, and it may exacerbate perianal tumors. After PO administration, mibolerone is absorbed from the intestine, metabolized in the liver, and excreted in the urine and feces. Chronic administration of testosterone may cause testicular degeneration in male animals. Finasteride, a 5α -reductase inhibitor, prevents the conversion of testosterone to 5α -dihydrotestosterone, the active androgen in male accessory sex glands. It is useful in the treatment of benign prostatic hyperplasia of dogs (0.1–0.5 mg/kg/day, PO). Flutamide blocks dihydrotestosterone receptors and is used for the same purpose. Chemical modifications of testosterone potentiate its anabolic actions while minimizing virilizing effects. These compounds (eg, boldenone undecylenate, stanozolol, nandrolone decanoate) are used for their anabolic effects in convalescing or athletic animals. Protracted use may cause at least temporary infertility in both sexes.

Prostaglandin $F_2\alpha$ and its analogues are used mainly for their luteolytic effects to

induce predictable onset of estrus (or synchronization of estrus) in a variety of species. They may also be used for termination of pregnancy either alone or in combination with corticosteroids (cattle, sheep) or dopaminergic agents (dogs). These compounds also cause marked uterine contractions, which may be useful for expulsion of uterine contents in pathologic conditions (eg, pyometra).

Oxytocin is used to promote milk letdown, to treat agalactia, as an adjunctive treatment of mastitis, and to cause contraction of the uterus either to induce (or supplement) labor or to enhance postpartum uterine contraction and expulsion of uterine fluid or fetal membranes. It is administered parenterally (IV, IM, or SC). Oxytocin may be given intranasally, but absorption can be erratic. Uterine relaxation is caused by β_2 -mimetic agents, such as clenbuterol. Such agents have been used to postpone parturition (to reduce obstetrical complications in heifers) and to facilitate obstetric manipulations in large domestic animals. Clenbuterol use in food-producing animals is illegal in the USA.

Dopaminergic agents, such as bromocryptine or cabergoline, cause decreased serum prolactin concentrations. They are useful in treatment of pseudopregnancy in dogs (bromocryptine at 10 mcg/kg, PO, for 10 days, or at 30 mcg/kg for 16 days) and as an adjunct to $PGF_2\alpha$ in terminating pregnancy, although not approved in the USA for this use. Prolactin is luteotrophic in some species, including dogs.

Dopamine antagonists, such as sulpiride, have shown promise in the manipulation of seasonal breeding species—their use hastens the onset of estrous cycles in mares in the spring.

In the UK and New Zealand, **melatonin** is labeled for use in sheep (and goats in New Zealand) to improve early breeding and ovulation rates. It is available as an 18-mg SC implant; combined with exposure to rams, its use is associated with hastened onset of the breeding season and increased prolificacy.

Glucocorticoids, especially the C-16 substituted steroids dexamethasone, betamethasone, and flumethasone, are used for induction of parturition in ruminants (eg, dexamethasone 20–30 mg, IM, given within 2 wk of normal term). Their therapeutic administration may inadvertently lead to abortion. Xylazine and other α_2 -adrenergic agents cause myometrial contraction that may harm the fetus or impede obstetrical manipulations.

EFFECT OF REPRODUCTIVE THERAPY ON THE FETUS OR NEONATE

An important component of reproductive pharmacology encompasses the effect of treatment on the fetus or neonate of medication administered to pregnant or lactating dams that are nursing. Many factors influence the ability of a drug to cross the placenta, including placental architecture of the particular species, but in general, drugs that are lipid-soluble, nonionized, and of low molecular weight can be expected to cross the placenta readily. Among antimicrobials, aminoglycosides are associated with nephrotoxicity and ototoxicity in the fetus, fluoroquino-

lones may affect developing cartilage, and tetracyclines affect bone and tooth development. Teratogenicity has been associated with use of the antifungal agents griseofulvin and ketoconazole in pregnant animals. All cancer chemotherapeutic agents are potentially harmful to developing fetuses. Glucocorticoids may induce palatoschisis or other defects in puppies.

Any administration of medication to lactating animals requires consideration of the excretion of the drug or its metabolites in milk and of the effects on suckling neonates. Milk produced for human consumption must be free of potentially harmful residues, and all relevant laws and regulations regarding usage and appropriate withdrawal times should be followed.

SYSTEMIC PHARMACOTHERAPEUTICS OF THE RESPIRATORY SYSTEM

See also PRINCIPLES OF THERAPY OF RESPIRATORY DISEASE, p 1416.

Drugs used to treat respiratory tract diseases fall into several categories: antitussives, bronchodilators, anti-inflammatories, expectorants, decongestants, and respiratory stimulants. In addition, antimicrobials and antifungals are important in the therapy of many respiratory diseases.

ANTITUSSIVE DRUGS

A **cough** is a sudden, explosive exhalation of air that functions to clear material from the airways. Coughing is one way in which the lungs and airways are protected from inhaled particles. Coughing sometimes brings up sputum (also called phlegm), a mixture of mucus, debris, and cells expelled from the lungs. The cough reflex has both sensory (afferent) and motor (efferent) pathways. The internal laryngeal nerve carries the sensory information away from the area above the glottis in the trachea to the cough center located in the medulla oblongata via the vagus nerve. Stimulation of this area by dust or foreign particles produces a cough to remove the foreign material from the respiratory tract before it reaches the lungs. Mucus production in the bronchi is an airway defense mechanism, and it increases with inflammation and

infection. In dogs and cats, coughing occurs because of a primary disease process, such as *Bordetella bronchiseptica* infection ("kennel cough") or chronic bronchitis in dogs, or feline asthma or heartworm-associated respiratory disease in cats. In most cases, addressing the primary disease will resolve the cough. Antitussive therapy is symptomatic and is primarily for the comfort of the animal and the owner. Most antitussive drugs are opiates or opioids that directly suppress the cough center in the medulla oblongata (see TABLE 21). The antitussive effect does not appear to be related to the binding of traditional opiate receptors (μ and κ). For example, dextromethorphan is an opioid derivative with good antitussive activity, but it does not have activity at opiate receptors and is not analgesic or addictive.

Morphine is an effective antitussive at doses lower than those that produce analgesia and sedation. It is not commonly used for antitussive activity because of adverse effects and the potential for abuse and addiction. Morphine has poor oral bioavailability due to a significant first-pass effect by the liver.

Codeine is methylmorphine; methylation of morphine significantly improves the oral bioavailability by reducing the first-pass effect. Codeine phosphate and codeine sulfate are found in many

TABLE 21 ANTITUSSIVE DRUGS

Drug	Dosage
Codeine	Dogs: 1–2 mg/kg, PO, bid-qid
Hydrocodone	Dogs: 0.25 mg/kg, PO, bid-qid
Butorphanol	Dogs: 0.055–0.11 mg/kg, SC, bid-qid, or 0.55–1.1 mg/kg, PO, bid-qid Cats: 0.1–0.4 mg/kg, SC, bid-qid

preparations, including tablets, liquids, and syrups. Codeine has analgesic effects that are about one-tenth that of morphine, but its antitussive potency is about equal to that of morphine. The adverse effects of codeine are significantly less than those seen with morphine at antitussive doses. Toxicity (especially in cats) is exhibited as excitement, muscular spasms, convulsions, respiratory depression, sedation, and constipation. Codeine should not be used after GI tract surgery because of its effects on intestinal motility. The potential for addiction and abuse of codeine is considerably lower than that for morphine.

Hydrocodone is chemically and pharmacologically similar to codeine but more potent. It is combined with an anticholinergic drug (homatropine) to discourage abuse by people. It can be prescribed for small animals but should be used with caution in cats.

Dextromethorphan is technically not considered an opiate, because it does not bind to traditional opiate receptors and is not addictive or analgesic. It is the *D*-isomer of levorphanol. The *L*-isomer of levorphanol has addictive and analgesic properties. Although it is recommended anecdotally to treat cough, a pharmacokinetic study in dogs demonstrated a short elimination half-life, rapid clearance, and poor oral bioavailability, making its use as an orally administered cough suppressant in dogs questionable.

Butorphanol, an opioid agonist-antagonist, is used as an analgesic and antitussive in dogs. As an antitussive in dogs, butorphanol is 4 times more potent than morphine and 100 times more potent than codeine. At antitussive dosages, it may produce considerable sedation in dogs. Because butorphanol has poor bioavailability, the oral dose in dogs is 10 times the SC dose. In cats, butorphanol is primarily used as an injectable analgesic. In some cats, it may cause pain on injection, as well as mydriasis, disorientation, swallowing/licking, and sedation.

SPECIES APPROACH TO INFLAMMATORY AIRWAY DISEASE

Dogs, cats, horses, and people develop spontaneous bronchoconstriction associated with airway inflammation and characterized by chronic cough and wheeze. Attacks of airway obstruction are induced by exposure of susceptible animals to antigens (typically hay dust, molds, and pollens). Effective therapy of allergic airway disease is species dependent because of the inflammatory mediators involved in bronchoconstriction. The pathogenesis of feline asthma differs from allergic airway disease in other species in that cats are exceptionally responsive to serotonin (5-hydroxytryptamine). Serotonin, which is released from degranulating mast cells, appears to be the major mediator of allergen-induced bronchoconstriction in cats. Cats also appear to suffer from chronic bronchitis, similar in clinical presentation to feline asthma; the main feature that differentiates these two conditions is the lack of bronchoconstriction in chronic bronchitis. In dogs, chronic bronchitis is an inflammatory, chronic pulmonary disease that results in cough and can lead to exercise intolerance and respiratory distress but is typically not characterized by severe bronchoconstriction. In horses, there are two clinical syndromes of airway inflammation. Recurrent airway obstruction, or “heaves,” is an inflammatory, obstructive airway disease clinically evident in middle-aged horses. Inflammatory airway disease is a low-grade inflammation of the small airways that is a common cause of poor performance in young to middle-aged, athletic horses. Inflammatory airway disease is typically not treated in ruminants or swine.

The goals of therapy for inflammatory airway disease are to prevent recurrent exacerbations of airway obstruction and reduce emergency visits and expenses, to provide optimal chronic anti-inflammatory therapy with minimal or no adverse effects,

to maintain (near) "normal" pulmonary function, and to meet the owner's expectations of quality of life for their animal.

SYSTEMIC THERAPY OF INFLAMMATORY AIRWAY DISEASE

β-Adrenergic Receptor Agonists:

The β-adrenergic receptor agonists have beneficial effects in treatment of bronchoconstrictive respiratory tract diseases (see TABLE 22). Bronchial smooth muscle is innervated by β₂-adrenergic receptors. Stimulation of these receptors leads to increased activity of the enzyme adenylate cyclase, increased cAMP, and relaxation of bronchial smooth muscle. Stimulation of β receptors on mast cells decreases the release of inflammatory mediators from mast cells, but other inflammatory cells are not suppressed. There is some evidence that β-adrenergic receptor agonists increase mucociliary clearance in the respiratory tract. The β-adrenergic receptor agonists should be used with caution in animals with preexisting cardiac disease, diabetes mellitus, hyperthyroidism, hypertension, or seizure disorders, or that are being treated with digoxin, tricyclic antidepressants, or monoamine oxidase inhibitors.

Epinephrine (adrenaline) stimulates α and β receptors, resulting in pronounced vasopressor and cardiac effects in addition to bronchodilation. Epinephrine is reserved for emergency treatment of life-threatening bronchoconstriction (eg, anaphylaxis). The

nonspecific stimulation of other receptors and its short duration of action make it unsuitable for longterm use. Epinephrine is available as a 1 mg/mL solution. Its onset of action is immediate, and the duration of effect is 1–3 hr.

Isoproterenol is a potent β-receptor agonist. It is selective for β receptors, but cardiac (β₁) effects make it unsuitable for longterm use. It is administered by inhalation or injection and has a short duration of action (<1 hr). For emergency relief of bronchoconstriction in horses, it is given by slow IV solution at a dilution of 0.2 mg/50 mL of saline. Administration is discontinued when the heart rate doubles.

Terbutaline is a β₂-receptor agonist similar to isoproterenol but longer acting (6–8 hr). It may be available in some countries as an injectable solution, powder inhaler, or oral syrup and tablets. For cats with feline asthma that experience frequent, severe bronchoconstrictive episodes despite chronic glucocorticoid therapy, injectable terbutaline can be dispensed to owners with instructions to administer 0.01 mg/kg, SC, to treat episodes of bronchoconstriction at home. An increase in the cat's heart rate to 240 bpm and a 50% decrease in respiratory rate indicates a positive effect. Terbutaline also can be given as chronic oral therapy at 0.625 mg/cat, bid (¼ of a 2.5-mg tablet). It should not be used in cats with hypertrophic cardiomyopathy or glaucoma, in which β₂-receptor stimulation would be detrimental.

Albuterol (salbutamol) is similar to terbutaline and may be used systemically in

TABLE 22 β-ADRENERGIC RECEPTOR AGONIST DRUGS

Drug	Dosage
Epinephrine	Dogs: 0.05–0.5 mg, intratracheally or IV Cats: 0.1 mg, IV or IM Large animals: 0.1 mg/kg, IV, SC, or IM
Isoproterenol	Dogs: 0.1–0.2 mg, IM or SC, qid Cats: 4–6 mcg, IM, every 30 min as needed Horses: 0.4 mcg/kg, IV (diluted)
Terbutaline	Dogs, cats: 0.1 mg/kg, SC, every 4 hr, or 0.03 mg/kg, PO, tid Horses: 0.0033 mg/kg, IV, or 0.2–0.6 mg/kg, PO, bid
Albuterol	Dogs: 0.05 mg/kg, PO, tid Horses: 8 mcg/kg, PO, bid
Clenbuterol	Horses: 0.8–3.2 mcg/kg, PO, bid

dogs and horses. Oral syrup, oral tablets, and oral extended-release tablets are available, but albuterol is more commonly used as inhalation therapy.

Clenbuterol is used in the treatment of recurrent airway obstruction in horses; it is not used in dogs and cats. It is available as an oral syrup and may be available as an injectable solution for IV injection in some countries. Results of efficacy studies for bronchoconstriction have been conflicting, but clenbuterol appears to significantly increase mucociliary transport in horses with the disorder. The dosage is increased gradually until a satisfactory clinical response is seen. If there is no response at the highest recommended dose, the horse is considered to have irreversible bronchospasm. It should not be administered chronically to horses with recurrent airway obstruction without concurrent anti-inflammatory therapy. The most common adverse effects of clenbuterol are tachycardia and muscle tremors. Clenbuterol inhibits uterine contractions, so it should be used during late pregnancy only if this effect is desired for obstetric manipulations. Clenbuterol is also a repartitioning agent; it directs nutrients away from adipose tissue and toward muscle. The result is increased carcass weight, increased ratio of muscle to fat, and increased feed efficiency. Because there is a significant human health risk from clenbuterol residues, it is banned in food

animals in most countries and should not be used in horses that will be sent to slaughter.

Methylxanthines: The methylxanthines, particularly theophylline, are bronchodilators (see TABLE 23). Once the mainstay of human asthma therapy, theophylline has a high incidence of adverse effects, and its use has diminished with the development of metered-dose or disk inhalers for local drug delivery. The methylxanthines have a variety of pharmacologic effects on various organ systems, including bronchial smooth muscle relaxation, CNS stimulation, mild diuresis, and mild cardiac stimulation.

The respiratory effects of methylxanthines are the result of several cellular mechanisms. Antagonism of adenosine is currently thought to be the most important action. Adenosine induces bronchoconstriction in asthmatic animals and antagonizes adenylate cyclase. Adenylate cyclase is responsible for the synthesis of cAMP, which controls bronchial smooth muscle relaxation and inhibits the release of inflammatory mediators from mast cells. Methylxanthines also inhibit phosphodiesterase, which further increases intracellular cAMP. They also inhibit calcium mobilization in smooth muscle, inhibit prostaglandin production, augment the release of catecholamines from storage granules, and increase the availability of calcium to contractile proteins of the heart and

TABLE 23 METHYLXANTHINE BRONCHODILATORS

Drug	Dosage
Theophylline (parenteral)	Dogs: 10 mg/kg, IV (slow) or IM Horses: 15 mg/kg, IV (slow)
Theophylline (oral)	Dogs: 5–7 mg/kg, PO, tid Cats: 3 mg/kg, PO, bid Horses: 10–15 mg/kg, PO, bid
Theophylline (extended-release tablets)	Dogs: 20 mg/kg/day, PO Cats: 25 mg/kg/day, PO Horses: 15 mg/kg/day, PO
Aminophylline (parenteral)	Dogs: 10 mg/kg, IV (slow) Cats: 5 mg/kg, IV (slow) Horses: 5 mg/kg, IV (slow)
Aminophylline (oral)	Dogs: 10 mg/kg, PO, tid Cats: 5 mg/kg, PO, bid Horses: 15 mg/kg, PO, bid

diaphragm. In addition to promoting bronchial smooth muscle relaxation, methylxanthines decrease the release of inflammatory mediators from mast cells and increase mucociliary transport.

Theophylline is available in several formulations, including injectable, aqueous solutions, elixirs, tablets, and capsules. Theophylline base is poorly soluble in water and often results in GI irritation when administered PO. Aminophylline is a theophylline salt that is 78%–86% theophylline. It is more water soluble and results in less GI irritation. Other theophylline salts, such as oxtriphylline (a choline salt), are available, and their theophylline content must be considered when developing a drug dosage regimen.

Several sustained-release formulations of theophylline are suitable for use in dogs and cats and may be administered less frequently than the regular formulations. After oral administration, theophylline is rapidly and completely absorbed. Therapeutic plasma concentrations, extrapolated from people, are 5–20 mcg/mL. Animals are sensitive to high concentrations of theophylline, especially after rapid IV administration, and toxicity may be seen with concentrations <20 mcg/mL. Theophylline tablets may become trapped in bezoars (such as hairballs in cats), and continued absorption can result in toxicity. Cardiac arrhythmias, CNS excitement, tremors, convulsions, and GI irritation may be seen. Theophylline undergoes enterohepatic recirculation, so activated charcoal is recommended if clinical signs are present, no matter how long after the drug was administered. Theophylline metabolism is inhibited by erythromycin, cimetidine, propranolol, enrofloxacin, and marbofloxacin; concomitant therapy can result in theophylline toxicity. Theophylline metabolism is induced by rifampin and phenobarbital, which may necessitate increasing the dose of theophylline.

Theophylline is used to treat both cardiac and respiratory diseases in dogs and cats. Theophylline is also used in management of intrathoracic collapsing trachea and various forms of canine bronchitis, but it is less effective than glucocorticoids such as prednisone. Theophylline or aminophylline was used in horses in the management of recurrent airway obstruction, but efficacy was often poor and use of these drugs has been replaced by β -agonist bronchodilators delivered by metered-dose inhalers.

Anticholinergic Drugs: The anticholinergic (parasympatholytic) drugs are

effective bronchodilators that reduce the sensitivity of irritant receptors and inhibit vagally mediated cholinergic smooth muscle tone in the respiratory tract. Cholinergic stimulation causes bronchoconstriction; asthmatic individuals appear to have excessive stimulation of cholinergic receptors.

Atropine is primarily used as a preanesthetic to prevent bradycardia and reduce airway secretions, and as emergency therapy of dyspneic animals with organophosphate intoxication. Atropine is also used for bronchodilation in horses; a low IV dose (0.014 mg/kg) is more effective and less toxic than IV theophylline. A test dose of 0.022 mg/kg may also be used to determine prognosis in horses with recurrent airway obstruction; if pulmonary function does not improve with a test dose of atropine, successful management with bronchodilators is unlikely. Atropine should be used with caution, because even low doses may cause tachycardia, ileus, neurologic derangement, and blurred vision in horses.

Glycopyrrolate is twice as potent as atropine in people and does not cross the blood-brain barrier. Its onset of action is slower than atropine, but its duration of effect is longer. Information about use in horses is sparse, but doses of 2–3 mg can be given IM, bid–tid.

N-butylscopolammonium bromide is an anticholinergic drug approved to relieve spasmodic colic in horses. Unlike atropine, N-butylscopolammonium bromide does not cross the blood-brain barrier. Adverse effects are minimal and include transient tachycardia, decreased boborygmi, and transient pupillary dilatation. In horses with recurrent airway obstruction challenged with moldy hay, N-butylscopolammonium bromide was a potent bronchodilator, with maximum relief occurring 10 min after IV administration. The bronchodilatory effect is short lived, dissipating within 1 hr of drug administration.

Glucocorticoids: The glucocorticoids inhibit the release of inflammatory mediators from macrophages and eosinophils but do not inhibit the release of granules from mast cells. Glucocorticoids decrease synthesis of prostaglandins, leukotrienes, and platelet-activating factor, which play important roles in the pathophysiology of respiratory tract inflammation. Studies suggest glucocorticoids enhance the action of adrenergic agonists on α_2 -receptors in the bronchial smooth muscle. Because of immunosuppres-

sive effects, glucocorticoids are generally avoided in infectious respiratory diseases.

For severe attacks of canine bronchitis, feline asthma, or recurrent airway obstruction, parenteral injection of glucocorticoids usually provides rapid relief. For chronic therapy in dogs, oral prednisone is usually the drug of choice. Prednisone is a prodrug; it is metabolized by the liver to the active drug prednisolone. Pharmacokinetic studies have shown poor oral bioavailability of prednisone in cats and horses.

Therefore, it is preferable to administer prednisolone to these species. In dogs, a typical anti-inflammatory dosage is 0.5–1 mg/kg, with chronic therapy on an every-other-day basis. A similar dose of prednisolone can be used in cats; if prednisone is used, higher doses may be necessary. Cats are somewhat resistant to the effects of glucocorticoids, and dosages of prednisone of 1 mg/kg/day may be necessary for chronic therapy of feline asthma. Alternatively, 20 mg of methylprednisolone acetate can be administered IM to asthmatic cats every 3 wk. For emergency treatment of dyspneic cats, a shock dose of an IV glucocorticoid (prednisone sodium succinate, 5–10 mg/kg; or dexamethasone sodium phosphate, 1–2 mg/kg) should be used. It is common for clinical signs to resolve in cats with feline asthma or chronic bronchitis that are treated with oral glucocorticoids despite persistent lower airway inflammation, so therapy should be tapered very carefully. Although prednisolone can be administered to horses, the small tablet sizes available make it inconvenient, so equine formulations of oral dexamethasone (10 mg/450 kg) are recommended. The injectable formulation of dexamethasone can be given IV to horses with acute bronchoconstriction and dyspnea. Flunithasone or isoflupredone may also be used in horses. Isoflupredone is as effective as dexamethasone in the treatment of recurrent airway obstruction in horses, but in cattle, it is associated with hypokalemia.

Cyproheptadine: Because of the role of serotonin in allergen-induced bronchoconstriction in cats, the serotonin antagonist/antihistamine cyproheptadine (2 mg, PO, once to twice daily) may be used as an adjunct to glucocorticoids and bronchodilators to block bronchoconstriction in chronically asthmatic cats. In experimental models of feline asthma, cyproheptadine decreased airway hyperactivity but did not significantly decrease eosinophilic airway inflammation. However, pharma-

cokinetic studies of cyproheptadine suggest that some cats may require doses as high as 8 mg to reach therapeutic concentrations. Because of its long elimination half-life (12 hr), cyproheptadine requires several days to reach steady-state concentrations, and 4–7 days may be needed to see clinical effects. Serotonin antagonism in the appetite center stimulates appetite, so weight gain may be a problem. Lethargy, depression, and increased appetite may occur within 24 hr of initiating therapy.

Antimicrobial Therapy: Antimicrobial therapy may or may not be necessary in treatment of airway inflammatory diseases. Antimicrobial therapy should be started for cats with tracheobronchial cultures suggestive of a true bacterial infection or those positive for *Mycoplasma*. *Mycoplasma* spp can be isolated from healthy dogs but are not found in healthy cats. Doxycycline, azithromycin, and fluoroquinolones treat *Mycoplasma* infections effectively. Secondary bacterial infection from *Streptococcus zooepidemicus* may exacerbate inflammatory airway disease in horses and can easily be treated with penicillin, ceftiofur, or a trimethoprim/sulfonamide.

INHALATION THERAPY OF AIRWAY DISEASE

The current approach to management of inflammatory airway disease is through inhalation therapy with nebulizers or metered-dose inhalers (MDIs). With inhalation therapy, high drug concentrations are delivered directly to the lungs via nebulizers or MDIs, and systemic adverse effects are avoided or minimized. The onset of action for inhaled bronchodilators and anti-inflammatory drugs is substantially shorter than that of oral or parenteral formulations. Nebulizers have long been used in animals, but the overall efficiency of drug delivery is low, and the equipment is cumbersome and inconvenient for owners. Administration of medications via MDIs is commonplace in treatment of human asthma and seems to benefit management of animals as well. Human MDIs are designed to provide optimal lung delivery after actuation during a slow, deep inhalation. However, this is impossible to control in animals. The addition of spacers enables MDIs to be used in animals. Spacers decrease the amount of drug deposited in the oropharynx (up to 80% of the actuated dose with the MDI alone), thereby reducing systemic drug absorption. Drugs available

in MDI formulations include β_2 -agonists, glucocorticoids, ipratropium bromide, cromolyn sodium, and nedocromil. Each product delivers a set amount of drug per actuation (puff). In the USA, MDIs are labeled according to the amount of drug delivered at the mouthpiece, whereas in Canada and the EU they are labeled according to the amount of drug delivered from the valve. MDIs are color-coded to aid identification. Even in human medicine, the relative potencies, risks of adverse effects, and optimal dose of the different inhaled asthma medications remain unclear. Unfortunately, some drugs that would be useful in veterinary patients are not available in MDIs; dry powder inhalers are not suitable for use in animals. Clinical use of MDI medications in asthmatic cats, dogs with chronic bronchitis, and horses with recurrent airway obstruction is promising but mostly anecdotal, and clinical trials are needed to determine the most efficacious therapies.

Spacers: MDIs (eg, OptiChamberTM, AeroChamber[®]) used in human patients may be modified for use in dogs and cats, and small animal-specific spacers are available (eg, AeroKatTM, AeroDawgTM, Feline Breathe EasyTM, NebulairTM). The OptiChamberTM must be modified with a suitable face mask, such as the type used to "mask" cats for anesthesia. The AeroChamber is available with a variety of face masks intended for infants, children, and adults that will conform to a variety of veterinary patients. The Nebulair and Feline Breathe Easy spacers are valveless, so the actuation must occur with the mask applied to the face of the animal. The AeroKat and AeroDawg are equipped with "flapper" valves so the dog or cat can be visualized breathing in the medication. MDIs were originally used in horses via the Aero-maskTM, but the mask is bulky and rather expensive. The AerohippusTM is similar to the AeroKat and AeroDawg, with a large, bell-shaped cone that fits over a horse's nostril. It also has a valve indicator.

β_2 -Agonists: Short-acting β_2 -agonists such as **albuterol (salbutamol)** in MDIs are the medications of choice to treat acute exacerbations of bronchoconstriction, because they relax smooth muscle and promptly increase airflow. Although effective for symptomatic relief, β_2 -agonists do not control inflammation. Airway obstruction may persist despite appropriate use of inhalant bronchodilators because of bronchial wall edema and airway mucus

plugging. In general, β_2 -agonists are extremely safe for use in animals when used as needed for bronchoconstriction. Toxicity typically requires a large overdose, such as when dogs chew on and puncture the inhaler, receiving a very large dose at one time (there are 200 doses in an albuterol/salbutamol inhaler). Massive overdose may induce severe tachycardia and hypokalemia, which, in turn, lead to extreme weakness, incoordination, and potentially cardiac standstill. Other less serious signs include dilated pupils, severe agitation and hyperactivity, hypertension, and vomiting.

Albuterol (salbutamol) is the medication of choice in all species for inhalation therapy of acute airway obstruction. It relaxes smooth muscle and increases airflow within minutes of administration; effects last 3–6 hr. Although effective for symptomatic relief, the β_2 -agonists do not control inflammation, and monotherapy may exacerbate asthma and increase morbidity and mortality. Racemic albuterol (R, S albuterol) is the most commonly prescribed short-acting β_2 -agonist and is composed of a 1:1 mixture of (R)-albuterol (the R enantiomer) and (S)-albuterol (the S enantiomer). The R-enantiomer has bronchodilatory and anti-inflammatory effects, and the S-enantiomer paradoxically is associated with increased airway hyperreactivity and pro-inflammatory effects. The paradoxical exacerbation of asthma with regular use of inhaled racemic albuterol in people is thought to be linked to preferential accumulation of S-albuterol in the lung, which has a much slower metabolism than R-albuterol. Neutrophilic airway inflammation in healthy cats was induced when receiving treatment with albuterol containing the S-enantiomer. These data suggest that the form of albuterol commonly prescribed to asthmatic cats can actually cause inflammation in "healthy" cats without preexisting airway disease. The S-enantiomer also exacerbates eosinophilic airway inflammation in experimentally asthmatic cats. This increase in airway inflammation associated with use of albuterol can be attenuated by concurrent use of glucocorticoids. Proper control of the underlying inflammation should reduce albuterol use to an as-needed only basis. One actuation (100 mcg Canada; 90 mcg USA) of albuterol can be administered for relief of bronchoconstriction as needed until clinical signs resolve.

Salmeterol is a long-acting β_2 -agonist; its onset of action is slow (15–30 min), but its duration of action is >12 hr. The long

duration of action is due to diffusion into the plasma membrane of the pulmonary cells followed by slow release from the cells to interact with β_2 receptors. It is not recommended for use in acute bronchoconstriction, but daily use with glucocorticoids provides better control of symptoms than simply increasing the glucocorticoid dose. It is not available in an MDI in all countries, and the dry powder inhaler is not suitable for animal use.

Other β_2 -agonists that may be available in MDIs include isoproterenol, fenoterol, formoterol, and terbutaline. Isoproterenol was commonly used to treat asthma before the more widespread use of albuterol, which has more selective effects on the airways. In Europe, an epidemic of deaths due to cardiotoxicity from overuse of isoproterenol inhalers led to withdrawal of the products. North American products have clear warning labels regarding the potential toxicity.

Glucocorticoids: Inhaled glucocorticoids are the most potent inhaled anti-inflammatory drugs available. In people, early intervention with inhaled glucocorticoids improves asthma control, normalizes lung function, and may prevent irreversible airway damage. The potential risk of adverse effects is well balanced by their efficacy in management of chronic inflammation. Oral candidiasis (thrush), dysphonia, and reflex cough and bronchospasm are the most common adverse effects in people; all of these effects are reduced by use of a spacer. The risk of systemic adverse effects, such as suppression of the hypothalamic-pituitary axis, is less than with oral prednisone therapy. Inhaled glucocorticoid formulations include fluticasone, beclomethasone, flunisolide, and triamcinolone. Currently, fluticasone is considered the most potent formulation with the longest duration of action and is the most commonly used inhaled glucocorticoid in veterinary patients.

Ipratropium Bromide: Ipratropium bromide is a quaternary derivative of atropine that lacks its adverse effects and is available in an MDI (500 mcg/actuation), alone or in combination with albuterol. In people with asthma, ipratropium bromide is used as an additional reliever medication to reverse bronchoconstriction when inhaled short-acting β_2 -agonists do not provide enough relief. Its anticholinergic action also decreases mucous secretions. In an experimental model of feline asthma, long-term antigen sensitization caused an

augmented muscarinic receptor response to acetylcholine. Modulation of muscarinic receptors with anticholinergic drugs may be useful to treat asthmatic cats. Ipratropium has shown efficacy for recurrent airway obstruction in horses. It is not well absorbed after inhalation, so it does not cause systemic anticholinergic effects.

Cromolyn Sodium and Nedocromil:

Cromolyn sodium and nedocromil sodium are chloride-channel blockers that modulate mast cell–mediator release and eosinophil recruitment. They are both available in MDIs. Cromolyn sodium and nedocromil sodium have strong human safety profiles, but nedocromil sodium has been reported to have a broader spectrum of efficacy. In people, the clinical response to these drugs is less predictable than the response to glucocorticoids. There are no published reports of the use of cromolyn or nedocromil in asthmatic cats or dogs with bronchitis; however, pretreatment with nedocromil sodium aerosols attenuated viral-induced airway inflammation in Beagle puppies. Further investigation of these drugs in asthmatic cats seems warranted given the sensitivity of this species to serotonin released from degranulating mast cells.

Lidocaine: Lidocaine, commonly used as a local anesthetic and antiarrhythmic agent, is used as a steroid-sparing treatment in human asthma. Initially used topically to prevent cough during bronchoscopic procedures, lidocaine, administered via nebulization, is effective for intractable cough and asthma by inhibition of eosinophil-active cytokines. Nebulization provides direct drug delivery to the lung, with minimal systemic drug absorption and few adverse effects. Nebulized lidocaine reduced airway hyperresponsiveness in experimentally asthmatic cats but did not affect airway eosinophilia, so it probably should be combined with glucocorticoids in management of feline asthma.

Suggested Treatment Regimens: For emergency management of dyspnea in cats and dogs, 2–4 puffs of albuterol should be given every 5 min until clinical signs resolve. Additional therapy may include oxygen and an IV dose of a rapid-acting glucocorticoid.

Current recommendations for therapy of feline asthma and canine bronchitis are to use albuterol only as needed for bronchodilation and fluticasone bid. For initial therapy of moderately affected animals, a 5-day course of oral prednisone (or prednisolone)

at 1 mg/kg may be helpful. Severely affected animals may require 1 mg/kg of prednisone (or prednisolone) every other day. Adjunctive therapy with other inhaled or orally administered anti-inflammatories and bronchodilators may be useful in some animals. Therapy must be individualized for each animal.

For horses with recurrent airway obstruction, environmental management and a combination of bronchodilator and anti-inflammatory therapy is recommended. Current recommendations are to use 500 mcg of albuterol every 2 hr as needed and fluticasone at 2–4 mcg/kg bid. Beclomethasone has also been used at 1–3 mcg/kg, bid, but it causes more adrenal suppression in horses than fluticasone at these doses.

EXPECTORANTS AND MUCOLYTIC DRUGS

Expectorants and mucolytic drugs are used to increase the output of bronchial secretions, enhance the clearance of bronchial exudate, and promote a productive cough. Saline expectorants are promoted to stimulate bronchial mucous secretions via a vagally mediated reflex action on the gastric mucosa. However, there are no well-designed studies that support these claims. Examples of these drugs include ammonium chloride, ammonium carbonate, potassium iodide, calcium iodide, and ethylenediamine dihydroiodide. Iodine-containing products should not be administered to pregnant, hyperthyroid, or milk-producing animals.

Direct stimulants of respiratory secretions include the volatile oils, such as eucalyptus oil and oil of lemon. They are believed to directly increase respiratory tract secretions. Their efficacy in animals is unknown.

Guaifenesin (glyceryl guaiacolate) is a centrally acting muscle relaxant that may also have an expectorant effect. It may stimulate bronchial secretions via vagal pathways. The volume and viscosity of bronchial secretions does not change, but particle clearance from the airways may accelerate. It is a common component of human cold remedies in combination with dextromethorphan.

N-acetylcysteine is available as a 10% solution that can be nebulized. Its mucolytic effect is the result of the exposed sulfhydryl groups on the compound, which interact with disulfide bonds on mucoprotein. Acetylcysteine helps to break down respiratory mucus and enhance clearance. It may also increase the levels of gluta-

thione, which is a scavenger of oxygen-free radicals. Aerosolization of acetylcysteine can cause reflex bronchoconstriction due to irritant receptor stimulation, so its use should be preceded by bronchodilator therapy.

Dembrexine is a phenolic benzylamine available in some countries for respiratory disease in horses. The proposed effect is through an alteration of the constituents and viscosity of abnormal respiratory mucus and an improved efficiency of respiratory clearance mechanisms. It also has an antitussive action and enhances concentrations of antibiotics in lung secretions. It is supplied as a powder that is sprinkled on the feed at a dosage of 0.33 mg/kg, bid.

DECONGESTANTS

Decongestants are commonly used in people to treat allergic rhinitis, but they are rarely used for this purpose in animals. The α -adrenergic agonist drugs cause local vasoconstriction in mucous membranes, which reduces swelling and edema. They are used topically as nasal decongestants in allergic and viral rhinitis, or systemically in combination with antihistamines as respiratory tract decongestants. Antihistamines are effective for treatment of allergic rhinitis in people when combined with the α -adrenergic agonist drugs, but their effectiveness in animals has not been demonstrated. The topical α -adrenergic agonist drugs act within minutes with few adverse effects, but extended use may cause rebound hyperemia and mucosal damage. Systemic administration can result in hypertension, cardiac stimulation, urinary retention, CNS stimulation, and mydriasis. Systemic administration of antihistamines often causes sedation.

RESPIRATORY STIMULANTS

Doxapram stimulates the medullary respiratory center and the chemoreceptors of the carotid artery and aorta to increase tidal volume. Other portions of the CNS are stimulated only when high doses are administered. Doxapram is used primarily in emergency situations during anesthesia or to decrease the respiratory depressant effects of opiates and barbiturates. Recommended dosages are 1–5 mg/kg, IV, in dogs and cats, or 1–2 drops under the tongue of apneic neonates. In adult horses, the dosage is 0.5–1 mg/kg, IV, while foals are dosed carefully at 0.02–0.05 mg/kg/min, IV.

SYSTEMIC PHARMACOTHERAPEUTICS OF THE URINARY SYSTEM

See also PRINCIPLES OF THERAPY OF URINARY DISEASE, p 1496.

BACTERIAL URINARY TRACT INFECTIONS

Bacterial urinary tract infections (UTIs) typically result from normal skin and GI tract flora ascending the urinary tract and overcoming the normal urinary tract defenses that prevent colonization. Bacterial UTI is the most common infectious disease of dogs, affecting 14% of all dogs during their lifetime. Although UTIs are uncommon in young cats, the incidence of UTI is much higher in older cats, which may be more susceptible to infection because of diminished host defenses secondary to aging or concomitant disease (such as diabetes mellitus, renal failure, or hyperthyroidism). Approximately two-thirds of those cats also have some degree of renal failure. Bacterial UTIs in ruminants are associated with catheterization or parturition in females and as both a cause and consequence of urolithiasis in males. In horses, UTIs are uncommon and typically associated with bladder paralysis, urolithiasis, or urethral damage.

Unlike human patients, veterinary patients are often asymptomatic, and the UTI may be an incidental finding. The consequences of untreated UTI include lower urinary tract dysfunction, urolithiasis, prostatitis, infertility, septicemia, and pyelonephritis with scarring and eventual kidney failure. Coagulase-positive staphylococci are involved in the formation of struvite (MgNH_4PO_4) calculi in dogs. In intact male dogs, UTI frequently extends to the prostate gland. Because of the blood-prostate barrier, it is difficult to eradicate bacteria from the prostate, and the urinary tract may be reinfected after appropriate treatment, causing a systemic bacteremia, infecting the rest of the reproductive tract, or causing an abscess within the prostate.

Large, retrospective studies have documented the most common species of uropathogens in dogs and cats, with *Escherichia coli* being the single most common pathogen in both acute and recurrent UTIs. The other common pathogens include *Staphylococcus*, *Proteus*, *Streptococcus*, *Klebsiella*, and

Pseudomonas spp. In UTIs in horses, *E. coli*, *Streptococcus*, and *Enterococcus* spp predominate, whereas *Corynebacterium renale* and *E. coli* are the most common pathogens in ruminants. In immunocompromised animals, funguria from *Candida* spp may occur.

Antimicrobials are the cornerstone of UTI therapy, and many animals with recurring UTIs are managed empirically with repeated courses (see TABLE 24). This approach fails if the underlying pathophysiology predisposing the animal to the UTI is not addressed; as well, it encourages emergence of resistant bacteria. With chronic UTI from highly resistant bacteria, therapeutic options are extremely limited.

Antimicrobial Therapy: Urine culture is the "gold standard" for diagnosis of UTI. Indications to perform urine culture include visualization of bacteria during urine sediment examination, evidence of pyuria, dilute urine (<1.013 SG), immunosuppression, and diabetes mellitus or hyperadrenocorticism. Antimicrobial susceptibility testing should be done with complicated or recurrent cases of UTIs, immunosuppressed animals, animals recently catheterized, or animals treated with antimicrobials within the preceding 3 wk (because of selection for antimicrobial resistance). In addition, culture and susceptibility testing should be performed in cases that do not respond within 7 days of therapy for UTI or in cases associated with multiple pathogens.

High urine concentrations of antimicrobials are correlated with efficacy in treatment of uncomplicated cystitis. But in complicated cases and in pyelonephritis, tissue concentrations may be equally important. Most antimicrobials undergo renal elimination to a great extent, so urine concentrations may be up to 100 times peak plasma concentrations. Drug excretion through the kidney involves various processes such as secretion and/or reabsorption in different parts of the nephron, depending on the molecular structure of the drug, its pK_a , the pH in the tubular fluid, and degree of protein binding. The flow of urine through the urinary tract is part of the defense against invading pathogens, because the flow of fluid rinses the

TABLE 24

DRUGS COMMONLY USED TO TREAT URINARY TRACT INFECTIONS IN SMALL ANIMALS

Drug	Suggested Dosage	Typical Antimicrobial Activity
Amoxicillin	11 mg/kg, PO, bid-tid	Staphylococci, streptococci, enterococci, <i>Proteus</i> , some <i>E coli</i>
Ampicillin	25 mg/kg, PO, tid	Staphylococci, streptococci, enterococci, <i>Proteus</i> , some <i>E coli</i>
Amoxicillin-clavulanic acid	25 mg/kg, PO, tid	Staphylococci, streptococci, enterococci, <i>Proteus</i> , some <i>E coli</i>
Cephalexin/cefadroxil	20–30 mg/kg, PO, bid-tid	Staphylococci, streptococci, <i>Proteus</i> , <i>E coli</i> , <i>Klebsiella</i>
Cefovecin	8 mg/kg, SC, every 14 days	<i>Proteus</i> , <i>E coli</i>
Cefpodoxime	5–10 mg/kg/day, PO	<i>Proteus</i> , <i>E coli</i>
Ceftiofur	2 mg/kg/day, SC	<i>Proteus</i> , <i>E coli</i>
Chloramphenicol	Dogs: 25–50 mg/kg, PO, bid-tid Cats: 50 mg/kg, PO, bid	Staphylococci, streptococci, enterococci, <i>E coli</i>
Doxycycline	5 mg/kg, PO, bid	Streptococci, some activity against <i>E coli</i> , staphylococci, and enterococci at high urine concentrations
Enrofloxacin, orbifloxacin, marbofloxacin, pradofloxacin (cats only)	2.5–10 mg/kg/day, PO	Staphylococci, <i>E coli</i> , <i>Proteus</i> , <i>Klebsiella</i> , <i>Pseudomonas</i> , <i>Enterobacter</i>
Gentamicin	4–6 mg/kg/day, SC	Staphylococci, some streptococci, some enterococci, <i>E coli</i> , <i>Proteus</i> , <i>Klebsiella</i> , <i>Pseudomonas</i> , <i>Enterobacter</i>
Nitrofurantoin	5 mg/kg, PO, tid	Staphylococci, some streptococci, enterococci, <i>E coli</i> , <i>Klebsiella</i> , <i>Enterobacter</i>
Tetracycline	18 mg/kg, PO, tid	Streptococci, some activity against <i>E coli</i> , staphylococci, and enterococci at high urine concentrations
Trimethoprim-sulfa	15 mg/kg, PO, bid	Streptococci, staphylococci, <i>E coli</i> , <i>Proteus</i> , some activity against <i>Klebsiella</i>

epithelial linings. High urine antimicrobial concentrations are important for eradication of bacteria in the urine, but for infection of the bladder wall or renal tissue it is necessary to use antimicrobials that have active concentrations in the tissues. Serum or plasma concentrations are useful surrogate markers for antimicrobial concentrations in the renal or bladder tissues.

In addition to having the appropriate antimicrobial activity and achieving effective concentrations in urine, the

selected antimicrobial should be easy for owners to administer, have few adverse effects, and be relatively inexpensive. Once urine culture and sensitivity results are known, the bacterial minimum inhibitory concentration (MIC) can be compared with the mean urinary concentration of the drug and an appropriate antimicrobial chosen.

Amoxicillin and **ampicillin** are bactericidal and relatively nontoxic, with a spectrum of antibacterial activity greater than that of penicillin G. They have

excellent activity against staphylococci, streptococci, enterococci, and *Proteus*, and may achieve urinary concentrations high enough to be effective against *E coli* and *Klebsiella*. *Pseudomonas* and *Enterobacter* are resistant. Amoxicillin is more bioavailable in dogs and cats (better absorbed from the GI tract) than ampicillin, hence the lower dosage. Absorption of ampicillin is also affected by feeding, so therapeutic success may be easier to achieve with amoxicillin. As penicillins, they are weak acids with a low volume of distribution, so they do not achieve therapeutic concentrations in prostatic fluid.

Amoxicillin-clavulanic acid has an increased spectrum of activity against gram-negative bacteria because of the presence of clavulanic acid. Clavulanic acid irreversibly binds to β -lactamases, allowing the amoxicillin fraction to interact with the bacterial pathogen. This combination usually has excellent bactericidal activity against β -lactamase-producing staphylococci, *E coli*, and *Klebsiella*. *Pseudomonas* and *Enterobacter* remain resistant. However, clavulanic acid undergoes some hepatic metabolism and excretion, so much of the antimicrobial activity in the bladder may be due to the high concentrations of amoxicillin achieved in urine. Thus, despite an unfavorable susceptibility report for amoxicillin, clinically amoxicillin alone may be as effective as amoxicillin-clavulanic acid to treat UTIs.

Cefadroxil and cephalixin are first-generation cephalosporins. Cefadroxil is a veterinary-labeled suspension product, whereas cephalixin is available in both human and veterinary formulations as tablets, paste, or suspension products. Like the penicillins, they are bactericidal, acidic drugs with a low volume of distribution and are relatively nontoxic. Vomiting and other GI signs may occur in dogs and cats treated with cephalosporins. Cephalosporins have greater stability to β -lactamases than penicillins, so they have greater activity against staphylococci and gram-negative bacteria. They have excellent activity against *Staphylococcus* spp, *Streptococcus* spp, *E coli*, *Proteus*, and *Klebsiella*. *Pseudomonas*, enterococci, and *Enterobacter* are resistant.

Cefovecin is an injectable, third-generation cephalosporin approved for treatment of dogs with a UTI due to *E coli* or *Proteus*. In cats, it is only approved for skin infections but may be used in an extra-label manner for UTIs. With SC dosing, therapeutic concentrations are achieved for 14 days, making this an attractive treatment choice for fractious animals.

Cefpodoxime is an oral, third-generation cephalosporin approved for use in dogs for skin infections (wounds and abscesses), but it is used extra-label for treatment of canine UTI. Cefpodoxime has a relatively long half-life in dogs, so it is dosed once daily.

Ceftiofur is an injectable cephalosporin approved for respiratory disease in horses, swine, and cattle and for treatment of canine UTI caused by *E coli* and *Proteus*. Ceftiofur has pharmacokinetic properties very different from those of other cephalosporins. After injection, ceftiofur is immediately metabolized to desfuroylceftiofur, which has different antimicrobial activity than the parent compound. Desfuroylceftiofur has equivalent activity to ceftiofur against *E coli* (MIC 4 mcg/mL) but is much less active against *Staphylococcus* spp and has variable activity against *Proteus* (MIC 0.5–16 mcg/mL). Because of the instability of desfuroylceftiofur, microbiology services use a ceftiofur disk when performing susceptibility testing, so a false expectation of therapeutic efficacy may result for some pathogens. *Pseudomonas*, enterococci, and *Enterobacter* spp are resistant to ceftiofur and desfuroylceftiofur. Ceftiofur is associated with a duration- and dose-related thrombocytopenia and anemia in dogs, which would not be expected with the recommended dosage regimen.

Chloramphenicol has a high volume of distribution, and high tissue concentrations can be achieved, including in the prostate of male dogs and cats. It is active against a wide range of gram-positive and many gram-negative bacteria, against which it is usually bacteriostatic. Chloramphenicol is typically active against enterococci, staphylococci, streptococci, *E coli*, *Klebsiella*, and *Proteus*. *Pseudomonas* are resistant. North American isolates of methicillin-resistant *Staphylococcus aureus* and *Staphylococcus pseudintermedius* are typically susceptible. Well known for causing idiosyncratic (non-dose-dependent) anemia in people and dose-dependent bone marrow suppression in animals, its use in both human and veterinary medicine is increasing because of resistance to other antimicrobial drugs.

Enrofloxacin, orbifloxacin, and marbofloxacin are all fluoroquinolones approved to treat UTIs in dogs; although all are used in cats, only some are approved for this use. **Pradofloxacin** is only approved for skin infections in cats in North America, but it is approved for treatment of UTI in dogs in Europe and is used to treat feline UTI. The fluoroquinolones are bactericidal,

amphoteric drugs. They possess acidic and basic properties but are very lipid soluble at physiologic pH (pH 6–8) and thus have a high volume of distribution. All fluoroquinolones usually have excellent activity against staphylococci and gram-negative bacteria, but they may have variable activity against streptococci and enterococci. The therapeutic advantages of these drugs are their gram-negative antimicrobial activity and high degree of lipid solubility. They are the only orally administered antimicrobials effective against *Pseudomonas*. Therefore, fluoroquinolones should be reserved for UTIs that involve gram-negative bacteria, especially *Pseudomonas*, and for UTIs in intact male dogs and cats because of their excellent penetration into the prostate gland and activity in abscesses. They are concentration-dependent killers with a long postadministration effect, so once daily, high-dose therapy for a relatively short duration of treatment is effective.

Fluoroquinolones should be avoided for chronic, low-dose therapy, because this encourages emergence of resistant bacteria that are cross-resistant to other antimicrobial drugs as well. Cases that involve *Pseudomonas* should be carefully investigated for underlying pathology, which must be corrected if at all possible. Once *Pseudomonas* spp become resistant to the fluoroquinolones, there are no other convenient therapeutic options.

Gentamicin and the other aminoglycosides are very large, polar (water-soluble) molecules, so they have a low volume of distribution and do not penetrate the blood-prostate barrier. They are not absorbed orally and must be given by SC, IM, or IV injection. The aminoglycosides have a similar spectrum of activity to that of the fluoroquinolones, but their use for UTI is limited because of the necessity of parenteral injections and the risk of toxicity with anything but short-term use. Like the fluoroquinolones, the aminoglycosides are concentration dependent, bactericidal killers with a long postadministration effect, so once-daily therapy of short duration is effective and minimizes the risk of nephrotoxicity. They can be considered for in-hospital or outpatient treatment of UTI due to fluoroquinolone-resistant pathogens; however, the importance of identifying and correcting underlying pathology must be emphasized.

Nitrofurantoin is a human product available as tablets, capsules, and a pediatric suspension. It is not commonly used in veterinary medicine. It is typically used only for treatment of UTI in people,

because it has a very low volume of distribution, and therapeutic concentrations are attained only in urine. It is considered a carcinogen, so it is banned for use in food-producing animals, but its use in small animals is increasing with the rising rates of antimicrobial resistance to veterinary antimicrobials. Nitrofurantoin is used for infections caused by *E. coli*, enterococci, staphylococci, *Klebsiella* spp, and *Enterobacter* spp. It is increasingly indicated for treatment of UTIs caused by multidrug-resistant bacteria, which are otherwise difficult to treat using conventional veterinary antimicrobial agents. The pharmacokinetics and adverse effect profile of nitrofurantoin have not been investigated in dogs, cats, or horses, and the need for multiple daily dosing makes it inconvenient for owners.

Tetracyclines are bacteriostatic, amphoteric drugs with a high volume of distribution. Tetracyclines are broad-spectrum antimicrobials, but because of plasmid-mediated resistance, susceptibility is variable in staphylococci, enterococci, *Enterobacter*, *E. coli*, *Klebsiella*, and *Proteus*. In most tissues, *Pseudomonas* spp are resistant. However, the tetracyclines are excreted unchanged in urine, so high urinary concentrations may result in therapeutic efficacy. **Doxycycline** is a very lipid-soluble tetracycline better tolerated in cats and reaches therapeutic concentrations in the prostate, so it may be useful for some UTIs. Doxycycline may also be effective to treat methicillin-resistant staphylococcal UTIs. If capsules are administered, it is critical to have the animal drink afterward to ensure passage into the stomach. If capsules remain in the esophagus, severe local necrosis with subsequent esophageal stricture can occur.

Trimethoprim-sulfonamides (TMP-sulfas) are combinations of two very different drugs that act synergistically on different steps in the bacterial folic acid pathway. Trimethoprim is a bacteriostatic, basic drug with a high volume of distribution and a short elimination half-life, whereas the sulfonamides are bacteriostatic, acidic drugs with a medium volume of distribution and long half-lives (ranging from 6 to >24 hr). These drugs are formulated in a 1:5 ratio of TMP to sulfa, although the optimal bactericidal concentration is a ratio of 1:20 TMP:sulfa. Microbiology services use the 1:20 ratio in susceptibility testing; however, the widely varying pharmacokinetic properties of this drug combination make it difficult to determine a therapeutic regimen that achieves the 1:20

ratio at the infection site. Although the combination does penetrate the blood-prostate barrier, sulfa drugs are ineffective in purulent material because of freely available para-aminobenzoic acid from dead neutrophils. The combination of TMP-sulfa is synergistic and bactericidal against staphylococci, streptococci, *E. coli*, and *Proteus*. Activity against enterococci and *Klebsiella* is variable, and *Pseudomonas* is resistant. TMP-sulfas are associated with a number of adverse effects, and chronic low-dose therapy may result in bone marrow suppression and keratoconjunctivitis sicca in dogs.

Dosage Regimens for UTI: Currently, the duration of therapy for UTI is controversial. Although animals are routinely treated with antimicrobial drugs for 10–14 days, shorter duration antimicrobial regimens are routinely prescribed in human patients, including single-dose fluoroquinolone therapy. A clinical comparison of 3 days of therapy with a once-daily high dose of enrofloxacin with 2 wk of twice daily amoxicillin-clavulanic acid showed equivalence in the treatment of simple UTI in dogs. However, further studies are needed to determine the optimal dosage regimens for different classes of antimicrobials, and it is inappropriate to use fluoroquinolones as first-line therapy for simple UTIs. Animals with complicated UTI may require longer courses of therapy, and underlying pathology must be addressed. Chronic complicated cases of UTI, pyelonephritis, and prostatitis may require antimicrobial treatment for 4–6 wk, with the risk of selecting for antimicrobial resistance. A follow-up urine culture should be performed after 4–7 days of therapy to determine efficacy. If the same or a different pathogen is seen, then an alternative therapy should be chosen and the culture repeated again after 4–7 days. Urine should also be cultured 7–10 days after completing antimicrobial therapy to determine whether the UTI has resolved or recurred.

Managing Multiple Episodes of UTI:

In dogs and cats, if UTI occurs only once or twice yearly, each episode may be treated as an acute, uncomplicated UTI. If episodes occur more often, and predisposing causes of UTI cannot be identified or corrected, chronic low-dose therapy may be necessary. Low antimicrobial concentrations in the urine may interfere with fimbriae production by some pathogens and prevent their adhesion to the uroepithelium. In dogs, recurrent UTIs are due to a different strain

or species of bacteria ~80% of the time; therefore, antimicrobial culture and susceptibility is still indicated. Antimicrobial therapy should be started as previously described and when urine culture is negative, continued daily at ½ the total daily dose. The antimicrobial should be administered last thing at night to ensure that the bladder contains urine with a high antimicrobial concentration for as long as possible.

Appropriate antimicrobials for chronic, low-dose therapy include amoxicillin, ampicillin, amoxicillin-clavulanic acid, doxycycline, cephalexin, cefadroxil, and nitrofurantoin. A trimethoprim-sulfonamide can be used, but folate supplementation should be provided (15 mg/kg, bid) to prevent bone marrow suppression; there is also the risk of keratoconjunctivitis sicca developing with longterm use. Although attractive for owner convenience, third-generation cephalosporins such as cefpodoxime and cefovecin and fluoroquinolones should not be used for longterm therapy. During longterm therapy, urine culture should be repeated every 4–6 wk. As long as the culture is negative, therapy is continued for 6 mo. If bacteriuria occurs, the infection is treated as an acute episode with an appropriate antimicrobial. After 6 mo of bacteria-free urine, the longterm, low-dose antimicrobial therapy may be discontinued, and many animals will not have additional recurrences. In some cases, longterm therapy may be continued for years in animals that continue to have recurrent UTIs.

Therapeutic Failures: Treatment failures may be due to poor owner compliance, inappropriate choice of antimicrobials, inappropriate dose or duration of treatment, antimicrobial resistance, superinfection, or an underlying predisposing cause (eg, urolithiasis, neoplasia, urachal diverticula). If treatment for a simple or complicated UTI fails, a thorough evaluation should be performed to determine and, when possible, address the cause of failure. When faced with a therapeutic failure, the practitioner must consider whether the UTI is due to a relapse or a reinfection. Relapses due to infection by uropathogens with enhanced intrinsic virulence occur with what should be effective antimicrobial therapy. Strains of uropathogenic *E. coli* have a number of virulence mechanisms that enable them to invade, survive, and multiply within the uroepithelium. The sequestration of uropathogenic *E. coli* within the bladder uroepithelium presents a great therapeutic challenge in both human and veterinary patients. There is no clear consensus in the human medical

literature about how to approach these recurrent and persistent UTIs.

Antimicrobial Resistance in Uropathogens: Acquired resistance to antimicrobials by uropathogens is of great concern in both human and veterinary medicine. The prevalence of multidrug resistance in uropathogens is increasing, particularly in infections in dogs and cats. Extended-spectrum β -lactamase genes are increasingly identified in *E coli* isolates from companion animals. Increases in the occurrence of fluoroquinolone-resistant *E coli* in dogs have been widely reported. Because the mechanism of resistance to fluoroquinolones frequently involves efflux pumps, it also conveys multidrug resistance. Fluoroquinolone resistance is also increasing in other uropathogens, including enterococci, *Proteus mirabilis*, and *Staphylococcus pseudintermedius* isolates. Methicillin-resistant staphylococci have been identified in cases of canine UTI. There is increasing evidence that animals are an important reservoir of antimicrobial-resistant bacteria causing infections in people. Enterococci isolated from canine UTIs have been associated with several different resistant phenotypes, with most exhibiting resistance to three or more antimicrobials. One *Enterococcus faecium* isolate displayed high-level resistance to vancomycin and gentamicin. Sequence analysis suggested that resistance was due to gene exchange between human and canine enterococci. The use of "last resort" human antimicrobials in veterinary patients with resistant infections is controversial. Vancomycin, imipenem-cilastatin, meropenem, fosfomycin, quinupristin-dalfopristin, and tigecycline should not be used routinely in treatment of UTI in animals. Nonantimicrobial control of infection should be considered whenever feasible. Custom-made vaccines, cranberry juice/extract, probiotics and adherence/colonization inhibitors, and establishment of asymptomatic bacteriuria may help preserve the efficacy of antimicrobials.

FUNGAL URINARY TRACT INFECTIONS

Although uncommon, most fungal UTIs in dogs and cats are caused by *Candida* spp. Finding *Candida* organisms in the urine may indicate sample contamination; however, finding *Candida* organisms in two serial urine samples collected by cystocentesis is consistent with infection and warrants culture and definitive

identification. Treatment includes eliminating potential predisposing factors (eg, excessive endogenous or exogenous corticosteroids, urinary catheters) and administering antifungal drugs with or without urinary alkalization. Fluconazole is the antifungal drug of choice for treatment of candidal cystitis. The dosage in cats is 50 mg/cat, PO, once to twice daily, and in dogs is 2.5–5 mg/kg/day, PO, divided bid. The duration of treatment needed to eliminate infection is unknown but may be as short as 7 days.

BACTERIAL PROSTATITIS

Bacterial prostatitis is a common prostate disease in sexually intact male dogs and may be seen in intact male cats. It can develop as an acutely fulminating systemic disorder or, most commonly, as a chronic problem associated with recurrent UTIs. Care should be taken when rectally palpating an acutely infected prostate, because septicemia/endotoxemia can occur. Most, if not all, sexually intact male dogs with UTI also have infectious prostatitis. The prostate gland is uniquely different from the rest of the urinary tract because of the acidity of the prostate glands, leading to a decreasing pH gradient from the blood through the tissue to the acinar glands. The distribution of antimicrobials in the prostatic tissue as well as in the prostatic secretions depends completely on the local pH (6.4) and the pK_a of the drugs. For alkaline drugs, a high degree of ionic trapping leads to high antimicrobial concentrations in the tissue and secretions, whereas the acidic drugs such as the β -lactam antimicrobials do not reach concentrations equivalent to plasma concentrations. The choice of antimicrobial for treatment should be based on culture and susceptibility results, and on the ability of the drug to penetrate the blood-prostate barrier. Ideal antimicrobials should be very lipid-soluble, basic, and not highly protein-bound. Fluoroquinolones are the best empirical choice for *E coli* infections, whereas chloramphenicol, doxycycline, or trimethoprim-sulfas can otherwise be considered with favorable culture and susceptibility results. Antimicrobial therapy may need to be continued for up to 2 mo, which may promote emergence of antimicrobial resistance. Chronic bacterial prostatitis may be difficult to cure. Neutering the dog may increase the likelihood of successful therapy and prevent recurrence.

DIURETICS

Diuretics are used to remove inappropriate water volume in animals with edema or volume overload, correct specific ion imbalances, and reduce blood pressure and pulmonary capillary wedge pressure (see TABLE 25). They are classified by their mechanism of action as loop diuretics, carbonic anhydrase inhibitors, thiazides, osmotic diuretics, and potassium-sparing diuretics. The efficacy and use of each class of diuretic depends on the mechanism and site of action. Patterns of electrolyte excretion vary between classes, whereas maximal response is the same within a class. Therefore, if one drug within a class is ineffective, a different drug from the same class will likely be ineffective as well. Combining diuretics from different classes can lead to additive and potentially synergistic effects. *See also* p 2525.

Furosemide: Furosemide is a sulfonamide derivative and the most commonly administered diuretic in veterinary medicine. Furosemide is a loop diuretic; it inhibits the reabsorption of sodium and chloride in the thick, ascending loop of Henle, resulting in loss of sodium, chloride, and water into the urine. Furosemide induces beneficial hemodynamic effects before the onset of diuresis. Vasodilation increases renal blood flow, thereby increasing renal perfusion and lessening fluid retention. It appears that renal vasodilation depends on the local synthesis of prostaglandins.

The elimination half-life of furosemide is short in most animals (~15 min). The effect peaks 30 min after IV administration and 1–2 hr after PO administration. The duration

of diuretic action is 2 and 6 hr after IV and PO administration, respectively. Furosemide is highly protein bound (91%–97%), almost totally to albumin. It is cleared through the kidneys by renal tubular secretion. Bioavailability of oral furosemide is low (only 50% is absorbed).

Furosemide is usually dosed to effect. For acute, short-term therapy, single IV, IM, or SC doses of 4–6 mg/kg are given. The major adverse effect from acute administration of large doses is acute intravascular volume reduction, which worsens cardiac output and hypotension and may precipitate acute renal failure. Chronic therapy in cats and some dogs can be accomplished by therapy every second or third day. Higher than normal doses of furosemide may be required in animals with renal disease due to functional abnormalities of the renal tubule and binding of furosemide to protein in the urine. If escalating doses of furosemide are required to control fluid retention, adding other types of volume-modifying medications, such as a potassium-sparing diuretic or an angiotensin-converting enzyme (ACE) inhibitor, may help avoid adverse effects.

Furosemide therapy is associated with a number of adverse effects. By nature of its mechanism of action, it causes dehydration, volume depletion, hypokalemia, and hyponatremia, which may be excessive and detrimental. Furosemide's most important drug interaction is with the digitalis glycosides digoxin and digitoxin. The hypokalemia induced by furosemide-diuresis potentiates digitalis toxicity. As long as animals continue to eat, hypokalemia does not usually develop. Hypokalemia also predisposes animals to

TABLE 25 DOSAGES OF DIURETICS

Drug	Dosage
Furosemide	4–6 mg/kg IV, IM, or SC, as needed for acute therapy Dogs: 2–4 mg/kg, PO, once to three times daily Cats: 1–2 mg/kg, PO, once or twice daily Large animals: 0.5–1 mg/kg/day, IV or IM
Hydrochlorothiazide	Dogs and cats: 2–4 mg/kg, PO, once or twice daily
Chlorothiazide	Dogs and cats: 20–40 mg/kg, PO, once or twice daily
Spironolactone	Dogs: 2–4 mg/kg, PO, bid
Mannitol	0.25–0.5 g/kg, IV
Dimethyl sulfoxide	Large animals: 1 g/kg, IV or via nasogastric tube

hyponatremia by enhancing antidiuretic hormone secretion and the exchange of sodium ions for lost intracellular potassium ions. Concurrent administration of NSAIDs may interfere with furosemide's prostaglandin-controlled renal vasodilation and reduce the diuretic effect. Furosemide-induced dehydration of airway secretions may exacerbate respiratory disease.

Thiazide Diuretics: The thiazide diuretics, **hydrochlorothiazide** and **chlorothiazide**, are not as potent as furosemide and thus are infrequently used in veterinary medicine. The thiazides act on the proximal portion of the distal convoluted tubule to inhibit sodium resorption and promote potassium excretion. They may be administered to animals that cannot tolerate a potent loop diuretic such as furosemide. They should not be administered to azotemic animals, because they decrease renal blood flow. Because the thiazides act on a different site of the renal tubule than other diuretics, they may be combined with a loop diuretic or potassium-sparing diuretic for treatment of refractory fluid retention. Adverse effects are electrolyte and fluid balance disturbances, similar to furosemide. Thiazides decrease renal excretion of calcium, so they should not be used in hypercalcemic animals.

Potassium-sparing Diuretics: Potassium-sparing diuretics include **spironolactone**, **amiloride**, and **triamterene**. Spironolactone is the one most frequently used in veterinary medicine and is a competitive antagonist of aldosterone. Aldosterone is increased in animals with congestive heart failure when the renin-angiotensin system is activated in response to hyponatremia, hyperkalemia, and reductions in blood pressure or cardiac output. Aldosterone is responsible for increasing sodium and chloride reabsorption and potassium and calcium excretion from renal tubules. Spironolactone competes with aldosterone at its receptor site, causing a mild diuresis and potassium retention. Spironolactone is well absorbed after administration PO, especially if given with food. It is highly protein bound (>90%) and extensively metabolized by the liver to the active metabolite, canrenone. It is primarily eliminated by the kidneys. The onset of action for spironolactone is slow, and effects do not peak for 2–3 days. Spironolactone is not recommended as monotherapy but can be added to furosemide or thiazide therapy to treat cases of

refractory heart failure. Because of the potential for hyperkalemia, spironolactone should not be administered concurrently with potassium supplements. It has been shown to be safe when used at low doses with concurrent ACE inhibitor therapy.

Carbonic Anhydrase Inhibitors:

Carbonic anhydrase inhibitors act in the proximal tubule to noncompetitively and reversibly inhibit carbonic anhydrase, which decreases the formation of carbonic acid from carbon dioxide and water. Reduced formation of carbonic acid results in fewer hydrogen ions within proximal tubule cells. Because hydrogen ions are normally exchanged with sodium ions from the tubule lumen, more sodium is available to combine with urinary bicarbonate. Diuresis occurs when water is excreted with sodium bicarbonate. As bicarbonate is eliminated, systemic acidosis results. Because intracellular potassium can substitute for hydrogen ions in the sodium resorption step, carbonic anhydrase inhibitors also enhance potassium excretion.

Osmotic Diuretics: Osmotic diuretics include **mannitol**, **dimethyl sulfoxide (DMSO)**, **urea**, **glycerol**, and **isosorbide**. Mannitol is commonly used in small animals but is expensive for use in adult large animals, so DMSO is often used in its place. Mannitol acts as a protectant against further renal tubular damage and initiates an osmotic diuresis. The initial dosage is 0.25–0.5 g/kg, given IV over 3–5 min. A response should be noted within 20–30 min. If a response is seen, the dose can be repeated every 6–8 hr, or a constant-rate infusion of 2–5 mL/min of a 5%–10% solution can be given. The total daily dosage should not exceed 2 g/kg. If diuresis is not seen, the initial dose can be repeated up to a total dosage of 1.5–2 g/kg. However, repeated doses usually are not more effective and increase the likelihood of complications (eg, edema).

DMSO is an oxygen-derived free radical scavenger and an osmotic diuretic. It is used in large animals to treat inflammatory and edematous conditions. It is a very potent solvent that can penetrate intact skin and carry other chemicals along with it. It penetrates all body tissues and produces an odor that many people cannot tolerate. The dosage is 1 g/kg, IV or via nasogastric tube, as a 10% solution diluted in 5% dextrose or lactated Ringer's solution (higher concentrations can cause intravascular hemolysis).

DOPAMINE

Dopamine, an adrenergic neurotransmitter with specific receptors in the renal vasculature, is frequently used to combat reductions in renal blood flow that may contribute to acute renal failure. It also increases glomerular filtration and sodium excretion. Dopamine has a very short half-life and is administered as a constant-rate infusion of 2–5 mcg/kg/min. Higher dosages cause tachycardia, cardiac arrhythmias, and peripheral vasoconstriction. Animals that do not produce urine with dopamine alone may respond to a combination of dopamine and furosemide. Dopamine is given as above, and furosemide is given at 1 mg/kg/hr, by IV bolus. If no improvement occurs within 6 hr, conversion is unlikely, and infusion should be discontinued. Dialysis (hemodialysis or peritoneal dialysis) may be required to maintain these animals.

GLOMERULAR DISEASE

Angiotensin-converting enzyme (ACE) inhibitors may be beneficial in management of dogs and cats with chronic renal failure (CRF). Renal disease progresses to CRF as a consequence of functional adaptations of the remaining nephrons, including glomerular hyperperfusion and hypertension controlled by angiotensin II. These responses initially enhance nephron filtration capacity and compensate for the decrease of glomerular filtration rate but are detrimental in the long term and cause further nephron loss. Administration of ACE inhibitors lowers glomerular pressure by decreasing systemic blood pressure and locally inhibiting angiotensin II. In animals with CRF, ACE inhibitors may decrease proteinuria caused by changes in glomerular membrane permeability and selectivity from mechanical injury induced by glomerular hypertension, potentially slowing disease progression. ACE inhibitors also tend to increase appetite and body weight in animals with renal failure.

Enalapril is used in dogs at a dosage of 0.5 mg/kg, PO, once or twice daily; **benazepril** is used in cats at a dosage of 0.5–1 mg/kg/day, PO.

Dimethyl sulfoxide (DMSO) has been used in dogs with anlyoidosis with variable results. It is given at a dosage of 80 mg/kg/day, divided tid, and given as a 10% solution either PO or SC. Thromboembolism and systemic hypertension are frequent complications of glomerular diseases in dogs, and to a lesser extent in cats, and

should be managed as the need arises. Thromboembolism may be prevented by giving aspirin at 0.5–5 mg/kg bid, to high-risk animals such as those with serum albumin <2 g/dL, plasma fibrinogen >400 mg/dL, or plasma antithrombin III activity <70%.

DIABETES INSIPIDUS

Nephrogenic diabetes insipidus is a physiologic condition in which the kidneys fail to concentrate urine despite adequate amounts of antidiuretic hormone (ADH). Central, or pituitary-dependent, diabetes insipidus develops when there is a lack of ADH production. Animals with central diabetes insipidus can be given **desmopressin acetate**. The nasal spray formulation can be used, with 1–4 drops administered into the conjunctival sac once or twice daily. Alternatively, the parenteral form can be given at 0.5–2 mcg, SC, once or twice daily. **Thiazide diuretics** may reduce polyuria by 30%–50% in animals with nephrogenic or central diabetes insipidus. Inhibition of sodium resorption in the ascending loop of Henle leads to decreased total body sodium and contraction of the extracellular fluid volume. The net effect is to increase sodium and water resorption in the proximal renal tubule. Chlorothiazide is given at 20–40 mg/kg, PO, bid.

CONTROLLING URINE pH

The ideal urine pH should be 7.0–7.5 in dogs and 6.3–6.6 in cats. If the urine pH remains below these values after diet modification, **potassium citrate** at 80–150 mg/kg/day, PO, divided bid-tid, can be given to increase the pH. **Ammonium chloride** (200 mg/kg/day, PO, divided tid) and **DL-methionine** (1,000–1,500 mg/cat/day, PO) are the urinary acidifiers of choice. Chronic urine acidification, and ensuing acidosis, can be harmful and should not be instituted without complete evaluation of the animal.

CYSTINE-BINDING AGENTS

Cystinuria, with subsequent cystine urolith formation, results from an inherited disorder of renal tubular transport. Cystine stones are dissolved by dietary modification, urinary alkalization or neutralization, and the use of cystine-binding agents. Urinary alkalization or neutralization is accomplished as described above. **Tiopronin** at 15 mg/kg, PO, bid, or **D-penicillamine** at 15 mg/kg, PO, bid, given with food, are both cystine-binding agents. Tiopronin has fewer adverse effects and is

the recommended choice. Both agents can cause Coombs'-positive anemia, thrombocytopenia, increased liver enzyme activity, glomerulonephritis, lymphadenopathy, cutaneous hypersensitivity, and delayed wound healing. Penicillamine also causes vomiting. Once stones are dissolved, a prevention protocol can be instituted. Dietary modification with or without urinary alkalization may be all that is needed to prevent stone formation; however, tiopronin may also be needed if uroliths recur.

URINARY INCONTINENCE

Urinary incontinence is most commonly caused by urethral sphincter incompetence. It is most common in large breed, spayed female dogs (11%–20% incidence) but may be seen in intact females, male dogs, and cats. Estradiol-17 β concentrations decrease after ovariectomy in bitches, resulting in deterioration of urethral closure within 3–6 mo. Currently, there are no approved drugs to treat incontinence in animals, and most of the human products traditionally used have been removed from the market because of toxicity concerns. Some estrogen compounds and α -adrenergic drugs may still be available to veterinarians through compounding pharmacies (see TABLE 26).

Diethylstilbestrol (DES) is a nonsteroidal estrogen derivative that closely resembles the natural estrogen, estradiol. Because it is inexpensive and infrequently administered, it is the first choice to treat urinary incontinence in female dogs. It is orally bioavailable and reaches peak plasma concentrations in 1 hr in dogs; it has an elimination half-life of 24 hr because of

enterohepatic recirculation. Estrogens sensitize the urethral sphincter to α -adrenergic stimulation; therefore, DES therapy is synergistic with α -adrenergic drugs. DES is given as a daily loading dose for 7–10 days and then reduced to once weekly dosing, if possible, to avoid toxicity. Treated dogs are susceptible to bone marrow suppression from estrogen, typified by early thrombocytopenia and potentially fatal aplastic anemia. Hematopoietic toxicity is rarely seen in cats. Other adverse effects seen in dogs include alopecia, cystic ovaries, cystic endometrial hyperplasia, pyometra, prolonged estrus, and infertility. When used once weekly in spayed female dogs, adverse effects from DES are rare.

α -Adrenergic agonists such as phenylpropanolamine (PPA), ephedrine, pseudoephedrine, and phenylephrine act directly on smooth muscle receptors to increase urethral tone and maximal urethral closure pressure. Although often more clinically effective than DES, their action is short lived, usually requiring dosing bid-tid. Of this class of drugs, PPA is the most effective and results in fewer cardiovascular adverse effects. Previously available in over-the-counter cold medications and appetite suppressants, it was withdrawn from the human market because of toxicity associated with overuse as a diet aid. Ephedrine, pseudoephedrine, or phenylephrine may be tried but are less efficacious than PPA. Adverse effects of α -adrenergic drugs include excitability, restlessness, hypertension, and anorexia.

In male dogs, testosterone injections are used to treat urinary incontinence but are generally less effective than estrogen therapy in female dogs.

TABLE 26 DRUGS USED TO TREAT URINARY INCONTINENCE

Drug	Dosage
Diethylstilbestrol	Dogs: 0.1–0.3 mg/kg/day, PO, for 7–10 days, followed by 1 mg/dog/wk
Phenylpropanolamine	Dogs: 1.5–2 mg/kg, PO, once to three times daily
Ephedrine	Dogs: 1.2 mg/kg, PO, bid-tid Cats: 2–4 mg/kg, PO, bid-tid
Pseudoephedrine	Dogs >25 kg: 30 mg/dog, PO, tid Dogs <25 kg: 15 mg/dog, PO, tid
Testosterone propionate	Dogs: 2.2 mg/kg, IM, every 2–3 days
Testosterone cypionate	Dogs: 2.2 mg/kg, IM, every 30–60 days

URINE RETENTION

Disorders of micturition characterized by urine retention and a distended bladder are usually caused by hypocontractility of the bladder or by urethral obstruction. Prolonged bladder distention leads to breakdown of the tight junctions between detrusor muscle cells of the bladder, which prevents normal depolarization and contraction of the detrusor muscles.

An adrenergic antagonist may be indicated when manual expression or voluntary voiding is nonproductive because urethral sphincter tone is excessive, as is often the case in cats after relief of obstruction. **Phenoxybenzamine**, an

irreversible antagonist, has been used with some success. The dosage for dogs or cats is 0.25 mg/kg, PO, bid.

Diazepam is a benzodiazepine anxiolytic that is also a central muscle relaxant. Dosages sufficient to allow for urethral relaxation may also cause sedation. The dosage in dogs is 0.2 mg/kg, PO, tid, and in cats is 0.5 mg/kg, IV. Diazepam given PO may cause idiosyncratic acute hepatic necrosis in cats.

In animals with detrusor hyporeflexia or bladder atony, **bethanechol chloride** may be of some benefit. This cholinergic agonist stimulates the initiation of detrusor muscle contraction. The dosage for dogs is 5–25 mg/dog, PO, tid, and for cats is 2.5–7.5 mg/cat, PO, tid.

CHEMOTHERAPEUTICS INTRODUCTION

Treatment with any chemotherapeutic agent involves an understanding of the complex interrelationships among the host animal, the infecting pathogen, and the drug, the interactions of which comprise the chemotherapeutic triangle. The advent of resistance places further emphasis on consideration of these factors when selecting a dosing regimen. That the FDA struggles to identify the most reasonable way to approve antimicrobials while

maintaining high standards of proof of efficacy and safety as well as clinician flexibility in the design of dosing regimens is a testament to the complex host, drug, and microbial interactions associated with infections.

Chemotherapy is the use of chemical agents in treatment or control of disease. However, the term is most often used in the context of controlling harmful pathogens through their chemical destruction. As such,

Chemotherapeutic triangle

the chemotherapeutic armamentarium includes antibacterial, antiviral, antifungal, antiparasitic, and antineoplastic compounds.

Chemotherapeutic agents may be selectively toxic to invade micro- or macroorganisms, but in many cases, they can also result in adverse effects in the host. This is particularly true when the infecting pathogen is eukaryotic (eg, fungal organisms, cancer cells) versus prokaryotic (eg, bacterial). To avoid toxic manifestations, particularly for drugs targeting eukaryotes, the dose rate often becomes critical; additionally, the clinical condition of the animal and concurrently administered drugs can be responsible for adverse events.

This discussion of chemotherapeutic agents focuses on infecting bacterial pathogens; fungal and viral pathogens are discussed in their respective chapters. Any time a drug is used with the intent to kill the target, multiple factors impact therapeutic success. The most obvious is that the target organism will implement mechanisms whereby it can avoid harm, the most notable being resistance mechanisms. However, microbes in particular are associated with numerous virulence factors and other mechanisms for self-protection, often also making the host sick at the same time. Likewise, host factors, which seemingly should help the host fend off infection, can become detrimental to therapeutic success. For most infections, a functional immune system is paramount to therapeutic success. Drug factors also influence therapeutic success, most notably because drugs must be able to penetrate any body tissue to successfully kill the microbe. These include the interactions between the three points of the chemotherapeutic triangle: host, microbe, and drug. If the goal of antimicrobial therapy is to simply resolve clinical signs of infection, then attention may not be given to the critically important aspects of therapy. In general, the use of an antimicrobial to which an isolate is susceptible will reduce the size of the infecting inoculum but is likely to leave behind a residual, yet resistant, inoculum. Immunocompetent animals are more likely to eradicate this residual population, but at-risk animals may not. As such, the population may regrow to a size capable of once again causing clinical signs (eg, 10^3 – 10^5 CFU in the urinary tract). Much of the following discussion is intended to support the design of dosing regimens (appropriate choice of drug, dose, and interval) that maximize antimicrobial efficacy while minimizing the risk of emergent antimicrobial resistance.

ANTIMICROBIAL DRUG FACTORS

Mechanism of Action

Understanding the mechanism of action (MOA) of antibacterial agents is important for several reasons. The MOA determines whether the antibacterial action is likely to be bactericidal or bacteriostatic, and whether the relationship between plasma drug concentration (PDC) and organism minimum inhibitory concentration (MIC) is concentration dependent or time dependent. Further, MOA often is related to the mechanism(s) by which resistance emerges. For some antimicrobials, the MOA also relates to the mechanism(s) of toxicity. Finally, if combination therapy is to be considered, drugs with MOAs that complement one another should be chosen.

The major MOA of antimicrobial agents, with examples of each type, are as follows (see also ANTIBACTERIAL AGENTS, p 2652): 1) inhibition of cell wall synthesis: β -lactams (penicillins, cephalosporins, and cephamycins), glycopeptides (vancomycin), bacitracin, fosfomycin; 2) impairment of cell membrane function: polymyxin B, colistin; 3) inhibition of protein synthesis through binding either to a single (tetracyclines, chloramphenicol, macrolides, lincosamides) or both (aminoglycosides) ribosomal subunits; 4) inhibition of DNA synthesis and replication: novobiocin, quinolones, metronidazole; 5) inhibition of DNA-dependent RNA polymerase: rifamycins; and 6) inhibition of folic acid and consequently DNA synthesis: sulfonamides, trimethoprim.

Most mechanisms will result in killing (rather than static) efficacy, with notable exceptions being drugs that inhibit a single ribosomal unit, or the use of a sulfonamide without a diaminopyridine potentiator such as trimethoprim or ormetoprim. Knowing whether a drug is concentration or time dependent is important for design of a dosing regimen. Concentration-dependent drugs include the fluoroquinolones and aminoglycosides. They are more effective when peak drug concentrations at the site of infection exceed the MIC of the infecting microbe by 10 or more. Such drugs also exhibit a long **postantibiotic effect**, particularly toward gram-negative organisms. This effect results in continued inhibition of microbial growth after brief exposure to the drug. Thus, for such drugs, the dose rather than the interval, is important. For time-dependent drugs, dosing regimens should be designed such that drug concentrations remain above the MIC for most of the dosing interval. For

such drugs, the dose may need to be increased to surpass the MIC of the organisms, but the interval should be designed to maintain the concentrations. Examples of time-dependent drugs include the β -lactams, "bacteriostatic" drugs, and the sulfonamides. Designing a convenient dose for time-dependent drugs with very short-half lives is difficult. For example, most penicillins have an elimination half-life of ~1–2 hr, and as such, the majority (~90%) will be eliminated in 3–6 hr (for amoxicillin, ~4 hr). As such, dosing regimens should be at least every 8, if not every 6, hr. Choosing a drug with a longer half-life, if the isolate is sufficiently susceptible, is more prudent. Some drugs are both concentration and time dependent; eg, efficacy of the fluoroquinolones can be enhanced by adding a second dose in the face of treatment of an organism with a high, yet susceptible, MIC.

Drug Disposition

Drug disposition (absorption, distribution, metabolism, and excretion) of antimicrobials can impact therapeutic efficacy and should influence the design of the dosing regimen. Most antimicrobials are administered orally. Exceptions include those destroyed by GI acidity (eg, some β -lactams, and particularly penicillins) or microbes (ie, ruminants) and those insufficiently unstable for oral preparation. Food can impact absorption of some drugs, most notably tetracyclines (except doxycycline) and the fluoroquinolones (rate but not extent impacted). A drug that has a very high oral bioavailability in one species cannot be assumed to have a similarly high oral bioavailability in another. For example, the oral bioavailability of ciprofloxacin is good in people but fair or negligible in dogs and horses. Most antimicrobials must potentially reach any body tissues. Antimicrobials that have a distribution limited to extracellular fluid, ie, "water-soluble" drugs, include the β -lactams, fosfomycin, aminoglycosides, and some members of the sulfonamides and tetracyclines. Lipid-soluble drugs distribute to total body water and include the fluoroquinolones, macrolides, clindamycin, many sulfonamides, and doxycycline or minocycline. In general, drugs that are water soluble distribute well to extracellular fluid of most organs, but there are exceptions. For example, only ~30% of amoxicillin reaches tracheobronchial secretions, and distribution into sanctuaries is limited. Doses of such drugs should be increased, particularly for

susceptible isolates with MICs approaching the breakpoint. Lipid-soluble drugs, in contrast, distribute to total body water and, therefore, are better able to reach intracellular organisms or infections in sanctuaries. Some drugs are characterized by volumes of distribution that exceed 1 L/kg, indicating the drug accumulates or becomes trapped at some sites. Few antimicrobials appear to be tightly bound to plasma proteins. Exceptions include doxycycline, minocycline, and cefovecin. For cefovecin, its tight binding to circulating albumin accounts for its very long half life. Several antimicrobials undergo hepatic metabolism, with some drugs (eg, ceftiofur, enrofloxacin) metabolized to an active metabolite that can contribute substantively to antimicrobial activity. Some drugs undergo substantive to exclusive excretion in the bile, including the macrolides, minocycline (and some of doxycycline), and clindamycin. For such drugs, care must be taken in those species that have a GI microflora subject to antimicrobial disruption; use for urinary tract infections should be avoided. Many drugs are excreted renally and subsequently concentrated in the urine, including β -lactams, aminoglycosides, most fluoroquinolones, and several tetracyclines.

Adverse Effects and Toxicity

Toxicity is associated with harm in the animal and thus is discriminated from adverse effects, although such effects are rarely life threatening. Because bacteria are prokaryotic, most antimicrobials do not interact with eukaryotic host targets. As such, mechanisms of antimicrobial toxicity are generally not related to mechanisms of antibacterial action. An exception is drugs that target microbial cell membranes (polymyxins), the use of which is generally limited to topical administration. Additionally, mammalian mitochondrial topoisomerases are subject to damage by fluorinated quinolones, resulting in a diversity of adverse effects. Drugs that disrupt microbial flora may be lethal to some species, particularly hindgut fermenters (horses, rabbits). The release of endotoxin when treating a large, gram-negative inoculum may be problematic for some drugs (especially penicillins), particularly in horses. Several classes of antimicrobials exhibit toxicity unrelated to their (known) mechanism of action. For example, the aminoglycosides are nephrotoxic because they are actively accumulated in and eventually disrupt renal tubular cells, and selected fluoroquinolones cause retinal

degeneration in cats due to phototoxicity in the retina. Chloramphenicol is associated with irreversible bone marrow suppression in people, because it is converted to a toxic metabolite. Drug interactions might contribute to some adverse effects as well. For example, chloramphenicol is a marked inhibitor of drug-metabolizing enzymes, and its use with potentially toxic drugs metabolized by the liver should be avoided. Selected fluoroquinolones inhibit selected drug-metabolizing enzymes. Macrolides as a class may compete for both P-glycoprotein and thus impact all aspects of drug movement, as well as inhibit some drug-metabolizing enzymes.

Virulence and Resistance

Antimicrobial resistance is a common reason for therapeutic failure. Resistance is a natural response to exposure to toxins, including antimicrobials. However, although resistance is not desirable in an infecting pathogen, resistance by itself, including multidrug resistance (MDR), is not the problem. Rather, it is the virulent organism that causes harm to the animal. Acquisition of virulence factors or genes necessary for survival in a hostile environment is responsible for illness. A virulent, MDR organism is particularly problematic.

Bacterial resistance to drugs can be either inherent or acquired. Genes coding inherent resistance are present in all strains of an organism, with expression independent of antimicrobial exposure. The "spectrum" of antimicrobial drugs reflects inherent resistance. For example, bacterial wall-defective variants (such as L-forms, spheroblasts, and protoplasts) are resistant to cell-wall inhibitors. Conversely, cell-wall access to some drugs is prevented because of impermeability reflecting very small porins in selected gram-negative bacteria (eg, *Pseudomonas aeruginosa*).

In contrast to inherent resistance, acquired resistance occurs only in selected strains of an organism, usually emerging in response to exposure to an antimicrobial. Genes for resistance can be acquired either spontaneously due to mutations or through sharing of genetic material via plasmids or transposons. Mutations most commonly occur by chance, with the likelihood that at least one CFU in any given population being resistant to any chosen drug increasing as the population reaches 10^7 CFU. Because the mutation is transmitted to daughter cells, it will remain in the population genome ("vertical" resistance). Selection pressure causes less susceptible isolates to

succumb to the drug, resulting in a residual population that expresses resistance to the drug even though exposure has been discontinued. However, with time, mutated bacteria, which are often physiologically impaired, also will disappear. Generally, mutations confer resistance only to the drug or drug class, and mutated cells may be less virulent. There are exceptions, with fluorinated quinolones being an example of a mutation that emerges in the presence of the drug and targets multiple drugs. This reflects their MOA, which results in damaged DNA. Subsequent mutations include those that alter regulators of efflux pumps. A marked increase in efflux activity results in MDR.

Acquired resistance also can be shared horizontally by transfer from one organism to another. Such resistance emerges in response to the presence of the drug. Shared resistance occurs rapidly, often during the course of therapy and often resulting in the transmission of multiple genes targeting multiple drugs. Transfer via plasmids is the most recognized mechanism of shared resistance. Plasmids are composed of extrachromosomal DNA, ie, DNA not vital to cell function. Plasmids are replicons, meaning they are capable of replicating autonomously in the host. Multiple mechanisms exist whereby plasmids can enter a bacterial cell.

Transformation, which occurs in only a limited number of bacteria, is accomplished by passage of naked DNA from donor to recipient. Transduction involves transfer via a bacteriophage that inserts itself into recipient bacteria. Phage-mediated transduction occurs in some gram-positive (especially *Staphylococcus aureus*) as well as gram-negative species. The most common method is conjugation in which DNA passes from the donor cell to the recipient via a bridge formed during direct cell-to-cell contact. This is the most sophisticated form of transmission, because the donor must have the necessary surface appendage (sex pilus) to form the bridge that is coded for by a resistance transfer factor on the plasmid. A single CFU may contain multiple plasmids, each of which in turn may carry multiple genes conferring resistance to multiple drugs. Among the disadvantages of plasmid-mediated resistance is the ease of sharing between gram-negative organisms and less commonly between gram-positive organisms; transfer can also occur between gram-positive and gram-negative organisms. Although plasmid-mediated resistance can occur rapidly, plasmids are

generally shed by the bacterium once the drug is no longer present.

Among the mechanisms whereby genetic sequences can be transferred between extrachromosomal (plasmid) and chromosomal DNA is the transposon, which is a DNA sequence that can change position in a genome. Transposons can carry chromosomal DNA from one bacterial cell to a plasmid and back. These transpositional sequences may be carried on gene cassettes. Integrons are gene-capturing systems found in plasmids, chromosomes, and transposons. Integrons can carry genes imparting antimicrobial resistance; generally, such resistance impacts multiple drugs. Once incorporated into chromosomal or plasmid DNA, the genes are subsequently expressed or disseminated even further. Problematically, in addition to resistance genes, these cassettes may also include virulence factors. This is exemplified in certain strains of methicillin-resistant *Staphylococcus aureus* (MRSA), which reflects acquisition of the *mec* gene, encoding for a mutated penicillin-binding protein-2, which prevents binding by any β -lactam drug.

Infection by MRSA has transitioned from hospital acquired, occurring only in the immunocompromised, to community acquired because of acquisition of a virulence gene that facilitates infectivity. Acquired resistance primarily reflects three major cellular mechanisms: 1) Intracellular drug concentrations can be reduced. Multiple mechanisms can accomplish this. Drug movement into the microbial cell can be prevented by decreasing porin number or size or, more commonly, by transporting the drug out of the cell through efflux transport pumps located in the cell membrane. These mechanisms result in resistance to multiple drug classes. 2) Microbes can produce enzymes that destroy certain drugs or drug classes. This mechanism generally targets only a single drug class. Examples include β -lactamases and enzymes that target fosfomycin, aminoglycosides, or phenicols. These enzymes can be expressed constitutively, or on exposure to the drug, induced such that expression is increased. In general, the addition of larger R groups on the drug molecule sterically hinders the ability of destructive enzymes from reaching the vulnerable site of the drug molecule. 3) Microbes can acquire mutations that change the target such that it no longer binds to the drug. Examples include mutated penicillin-binding proteins that confer methicillin resistance to staphylococci, mutations in DNA gyrases that confer

resistance to fluoroquinolones, or mutations in ribosomal subunits that confer resistance to various ribosomal inhibitors. Mutations also generally cause single-drug resistance.

Other less common methods include the presence of alternative metabolic pathways that circumvent the effect of the drug (eg, sulfonamides) or increased synthesis of a key metabolic intermediate that would thus require higher concentrations of the drug (eg, para-aminobenzoic acid in sulfonamide resistance).

Acquired resistance will be clinically manifested as an increase in the MIC of the isolate to the drug in question. Notably, resistance can emerge in an isolate that yet remains susceptible if the increase in MIC has not exceeded the MIC breakpoints determined for that drug. For recurrent infections, identifying the underlying cause is likely to be paramount to avoiding antimicrobial resistance, including MDR. Among the clinically relevant gram-negative isolates developing MDR are *E coli* and *Klebsiella*. Gram-positive organisms developing MDR include MRSA and its canine and feline counterpart, methicillin-resistant *S pseudintermedius* (MRSI). Enterococcus is another gram-positive isolate for which MDR is both natural and emerging. *Clostridium difficile* is an example of an obligate anaerobic organism for which MDR is clinically important.

Antimicrobial Resistance and the Veterinarian:

Two major aspects of antimicrobial use are of particular concern to veterinarians: the likelihood of causing a pathogenic organism to become resistant to current antimicrobial therapy and the likelihood of commensal organisms, regardless of location in the body, becoming resistant to future antimicrobial therapy. Although designing the dosing regimen such that all infecting organisms are killed will minimize the risk of acquired resistance in the patient, any and all antimicrobial use contributes to global concerns regarding antimicrobial resistance. Historically, veterinary use of antimicrobials has focused on agricultural (eg, food-animal) applications. Yet, the concern is shifting to also include use in companion animals, particularly with greater awareness of the risk of transfer of resistant commensal organisms between pets and people.

The role of antimicrobial therapy in the advent of antimicrobial resistance is well recognized. Minimizing the risk of emerging resistance might be approached based on following the "3 Ds": decontamination,

de-escalation, and designing a dosing regimen.

Decontamination decreases the spread of potentially resistant microbes and includes attentiveness to hygiene not only in the hospital but also in the home environment.

De-escalation includes avoiding inappropriate or unnecessary systemic antimicrobial use. For example, the use of low levels of antibiotics (as in animal feeds) or improper dosing regimens may lead to a high incidence of acquired resistance in a given population; as such, this practice increasingly is coming under critical scrutiny. Identifying the need to treat with systemic antimicrobials is among the most important questions to be addressed. Clinical signs consistent with infection (fever, inflammation, pain, neutrophilia) are not diagnostic of infection. The presence of bacteria does not necessarily indicate that systemic antimicrobial therapy is indicated. Bacteria may reflect normal flora, which must be distinguished from pathogenic microbes. If in a culture, this may reflect a poorly collected sample. Single rather than multiple (three or more) organisms is more indicative of a pathogen. The extent of growth may be used to support infection; for example, the presence of bacteria in urine collected by cystocentesis is not considered an infection unless $>1,000$ – $100,000$ CFUs are present. Presence of infection alone does not justify systemic treatment with antimicrobials. For example, despite approval of antimicrobials to treat feline abscesses, most might be better managed by local treatment. Asymptomatic bacteriuria might be more wisely not treated with systemic antimicrobials until clinical signs become evident; nonvirulent organisms may be acting as commensals, preventing infection with more virulent pathogens. The use of topical therapy should be considered when possible; not only can much higher concentrations be achieved at the site of infection, the systemic impact of antimicrobials on microbiota can be minimized.

De-escalation might also reflect shorter duration of therapy. Identifying the most appropriate duration can be problematic. Short-term therapy at high doses and short intervals should be sufficient to kill the infecting microbe, negating the need for longer duration therapy at lower concentrations or shorter intervals that might facilitate resistance. However, for slower growing organisms or nonhealing tissues, longer durations might be prudent. The longterm use of antimicrobials for

infections associated with an underlying cause is particularly problematic. Resistance is more likely in these animals, particularly if dosing regimens are (inadvertently) designed for promotion rather than for avoidance of resistance. Data are just beginning to emerge in veterinary medicine indicating that shorter duration of appropriately designed dosing regimens can be just as effective as longer-term therapy.

De-escalation also might be accomplished by initiating therapy with a higher-tier drug and switching to a lower-tier drug as soon as possible. Reasons that an antimicrobial might be considered a higher-tier drug, with use supported by culture and susceptibility data, versus a lower-tier drug, which might be used empirically, include the following: spectrum, with more narrow-spectrum drugs being reserved for problematic infection (eg, aminoglycosides and gram-negative infections, vancomycin and MRSA), safety, mechanisms of resistance that will emerge should therapy fail (eg, drugs causing emergence of extended-spectrum β -lactamases or MDR), and importance to human health (eg, vancomycin, linezolid, fosfomycin, etc).

Designing the dosing regimen should be approached such that the entire infecting inoculum is killed by the chosen antimicrobial. It may be among the most difficult “D” to implement, because it requires not only understanding the relationship between plasma or tissue drug concentrations and the MIC of the infecting microbe but also being willing to modify routine recommended dosing regimens as needed for individual patients. This requires delineation of host, microbial, and drug factors that might impact antimicrobial therapy, either negatively or positively. Even if a microbe is historically considered “susceptible,” the amount of drug required to effectively inhibit its growth is likely to be greater now than it was when the drug was originally approved. Successful treatment of infection (ie, resolution of clinical signs) does not avoid the advent of resistance. In healthy, immunocompetent animals, adequate reduction of pathogen inoculum might be sufficient for the host to overcome residual microbial growth, whereas in an animal at risk, this residual growth may emerge as a resistant population after an initial response. The more “at risk” the animal is in being unable to overcome a residual resistant inoculum, the more important that dosing regimens be designed to kill the microbes. “Dead bugs don’t mutate” should

be the guiding impetus for antimicrobial use.

Designing appropriate dosing regimens requires the following: 1) The pathogen(s) should be identified and characterized, including antimicrobial susceptibility, so that the drug matches the organism as closely as possible, narrowing the spectrum of drug used. The role of culture and susceptibility testing in selecting the drug and designing the dosing regimen is becoming increasingly important. With notable exceptions, the ability to predict infecting pathogens is limited. Exceptions include respiratory tract infections in food animals, pyoderma in dogs and, with limitations, urinary tract infections in dogs and cats. However, for urinary tract infections, *E. coli* is a cause in only 50% of cases. The more complicated the infection, the less likely it is that the infecting pathogen can be predicted. Likewise, even if the correct pathogen is identified, predicting susceptibility in all but the most uncomplicated infections is likely to be limited. This is true both historically and in the individual patient. Even historically "susceptible" organisms are characterized by higher MIC. For example, only 50% of clinical *E. coli* collected from dogs or cats are susceptible to amoxicillin. If the animal has previously received antimicrobials, patterns of assumed susceptibility may no longer be relevant for that animal. 2) Once drugs to which the isolates are susceptible are identified, one that is more likely to penetrate the infected tissue should be chosen. This includes taking into consideration host and microbial responses to infection. Often, this requires that the drug be lipid soluble. A variety of host and microbial factors contribute to antimicrobial failure by presenting barriers to drug penetration. Debris (eg, inflammatory materials, necrotic tissue, foreign bodies) and biofilm or reduced blood flow and hypoxia contribute to failure. The organism is intracellular in location and able to avoid detrimental effects by phagocytic cells. Even urinary tract infections may present several barriers. Simply choosing a drug that is renally excreted may not be adequate. Renal function may not be normal, such that urine (and drug) is not concentrated. Bacteria are in the urine and also inside uroepithelial cells. Particularly with chronic infections, the microbes may be protected by biofilm and in a state of quiescence such that they are less susceptible to many antimicrobial drugs.

Other factors must be considered when designing the dosing regimen. Immunocom-

promise as a result of disease, malnutrition, or concurrent drug therapy, or local immunocompromise caused by invasive procedures may contribute to failure. The more "at risk" the animal is in being unable to overcome a residual resistant inoculum, the more important that dosing regimens be designed to kill the microbes (ie, "dead bugs don't mutate"). Because dosing regimens should be designed to kill, bactericidal drugs should be chosen whenever possible. Bactericidal drugs include β -lactams (penicillins and cephalosporins), fluoroquinolones, aminoglycosides, and potentiated (not single) sulfonamides. Tetracyclines, chloramphenicol, macrolides (eg, azithromycin), and lincosamides (eg, clindamycin) are bacteriostatic. However, the distinction between "cidal" and "static" is based on in vitro conditions and may not reflect what occurs in the animal. In general, however, it is easier to achieve killing concentrations of a bactericidal than of a bacteriostatic drug.

Special Considerations for Food Animal Veterinarians:

The use of antibiotics in food animals, including use as growth promotants, contributes to the transfer of resistance genes among bacteria and ultimately from food animals to people. Additionally, contamination of food with resistant pathogenic bacteria during the processing of food is a concern. Carcasses may be contaminated at slaughter and processing, and subsequent improper handling or cooking of the product may lead to infection in people. The development of resistant pathogenic bacteria in poultry treated with fluoroquinolones has been documented. Infection of the human population is of particular concern, because the bacterial resistance created in the animal after veterinary use of a drug or drug class may result in resistance to human drugs of the same class. Whereas the organism developing resistance might be nonpathogenic, transfer of the resistance gene to other bacteria in the human GI tract may result in a pathogenic organism becoming resistant and ultimately in therapeutic failure in people. When selecting drug therapies for food animals, veterinarians must be aware of the potential for resistance. Use of antibacterial drugs should be in the context of a valid veterinarian-client-patient relationship. Selection should be based on all information available (clinical findings, experience, laboratory data, physical examination findings, culture and sensitivity data). Pathogens should be identified, and drugs with the narrowest

spectrum of activity with known effectiveness against the pathogen should be used. Client education is important to prevent unnecessary use of antibacterial agents (such as using “leftover” antibacterial drugs to treat a new occurrence of disease), to advise on proper withdrawal guidelines of any prescribed drugs, and to ensure that drugs of the proper classes are administered at proper doses and through appropriate routes.

The Veterinary Feed Directive (VFD):

In June 2015, the FDA released the final version of the VFD rule. The VFD amends the Animal Drug Availability Act of 1996 (21 CFR Part 558), and it delineates the FDA's strategy to promote the judicious use of antimicrobials in food animals. A VFD drug (which includes prescription drugs and over-the-counter drugs as a third potential category) is defined as “a drug intended for use in or on animal feed.” The drug may be an approved new animal drug. A veterinary feed directive, or order, is the written statement issued by a licensed veterinarian, in the course of practice, that orders the use of the VFD drug, or combination VFD drug, in or on animal feed. A VFD order can only be issued under the supervision of a licensed veterinarian, and issuing veterinarians can only do so within the framework of a valid veterinary-client-patient relationship as defined by the state in which the issuing veterinarian is licensed and practicing (or federal definition in the absence of a state definition of a veterinary-client-patient relationship). The rule describes the federal process to authorize VFD drugs, which must be subject to a new animal drug approval, and to establish an antimicrobial considered medically necessary as a VFD drug. The rule further defines two categories of VFD drugs: category I, which is not associated with a withdrawal time, and category II, which requires some withdrawal time in at least one species in which the product is approved. Mixing of category II medicated feeds requires a medicated feed mill license. Guidelines by the FDA delineate the specific information that should be included on the VFD. These guidelines indicate that extra-label use of a medicated feed is not permitted.

DOSING REGIMENS

The design of a dosing regimen begins with an assessment of the minimal inhibitory concentration (MIC) of the antibacterial agent for a particular pathogen. Depending on the antimicrobial, plasma or tissue drug concentrations should either markedly

exceed the MIC by 10- to 12-fold (for concentration [sometimes referred to as dose-dependent antimicrobials], such as the aminoglycosides and the fluorinated quinolones) or be above the MIC ($T > MIC$) for most (50%–75%) of the dosing interval (time-dependent antibiotics, such as cell-wall inhibitors [β -lactams, fosfomycin, vancomycin], sulfonamides, and most “bacteriostatic” drugs). To compensate for drug disposition to tissue sites and the effect of host factors on antibiotics, dosages for most drugs should result in plasma drug concentrations several times higher than the calculated concentration-dependent or time-dependent MIC in the infected tissues or fluids. For dose-dependent drugs, efficacy is enhanced by increasing the dose; for time-dependent drugs, therapeutic efficacy is enhanced by increasing the dose and shortening the dosing interval or by choosing a drug with a long half-life.

In today's infectious disease environment, appropriate design of a dosing regimen should depend not on labeled doses, but rather on access to information regarding the current pharmacodynamics of the infecting microbe (ie, MIC from the pathogen cultured from the patient, or the MIC_{90} of a sample population of the pathogen collected from the target animal) and the pharmacokinetics of that drug in the target species. Appropriate pharmacokinetic parameters on which the dosing regimen should be designed include maximum plasma concentration, or C_{max} , for concentration-dependent drugs, and C_{max} and drug elimination half-life for time-dependent drugs. Supportive information for design of dosing regimens often can be found in the literature. For example, if the MIC of a *Pseudomonas aeruginosa* isolate for amikacin (a concentration-dependent drug) is 4 mcg/mL, the dose should be selected so that peak plasma drug concentrations achieve 40–48 mcg/mL. Ideally, tissue concentrations should be that high as well. As such, the dose should be adjusted further if the drug does not penetrate the tissue well in the presence of marked inflammatory debris. Cephalexin is a time-dependent drug. If *Staphylococcus pseudintermedius* cultured from a skin biopsy in a dog has an MIC of 2 mcg/mL, then the dosing regimen should be selected to assure that drug concentrations are >2 mcg/mL for at least 50%–75% (and ideally 100%) of the dosing interval. The half-life of cephalexin is ~ 3 hr in dogs. Using data reported in the literature for dogs, an oral dosage of cephalexin at 22 mg/kg will achieve a C_{max} of 25 mcg/mL.

In one half-life, concentrations (mcg/mL) will decline to 12.5; in the second, to 6.25, in the third to 3.125, with concentrations below target by the fourth half-life, or 6 hr. Thus, three elimination half-lives, or 9 hr, can elapse before the target MIC is reached, and the next dose should occur by 9 hr. Shortening the interval is generally more cost-effective than increasing the dose of time-dependent drugs, particularly for drugs with a short half-life—for each half-life to be added to the $T > \text{MIC}$, the dose must be doubled. Amoxicillin (with or without clavulanic acid) has been an extremely popular lower-tier drug used for urinary tract and soft-tissue infections. For the latter, at 10 mg/kg, the drug achieves a concentration of ~5 mcg/mL in plasma. At an MIC of 2 mcg/mL, only one half-life can lapse. The half-life of amoxicillin is only 1–1.5 hr, indicating that dosing should occur every 3 hr. As such, amoxicillin may not be an appropriate choice for soft-tissue infections, and if used, it should be dosed at least every 8 hr, if not more often. However, because it is excreted in the urine, it is a good first choice to treat uncomplicated urinary tract infections, as long as urine is retained in the bladder.

The integration of pharmacokinetics and pharmacodynamics can also be accomplished based on package insert information of more recently approved drugs. For example, for concentration-dependent drugs, the C_{max} should be at least $10 \times$ the MIC_{50} of the target microorganism for that drug. For time-dependent drugs, plasma drug concentrations should be above the MIC_{50} of the infecting microbe for $\geq 50\%$ of the dosing interval.

REQUIREMENTS FOR SUCCESSFUL ANTIMICROBIAL THERAPY

Clinical Diagnosis: Successful chemotherapy usually requires a specific diagnosis, even though a reasonable preliminary diagnosis is often all that is possible, at least initially. The presence of bacteria requiring systemic therapy should be confirmed as much as possible; fever, inflammation, and leukocytosis are supportive of but not diagnostic for bacterial infection.

Microbiologic Diagnosis: Treatment should be aimed at a specific pathogen whenever feasible. Care must be taken when predicting the infecting pathogen based on historic data, because often such

data did not discriminate between commensal and pathogen. The use of cytology should not be overlooked. Examination of a direct smear stained with Wright's or Gram's stain may help to establish the types of pathogens involved (gram-positive or gram-negative rods or cocci) and direct initial antibacterial therapy. However, even if the pathogen is correctly identified, the ability to predict the susceptibility pattern of the infecting pathogen has markedly decreased in recent years. If the animal has not been previously exposed to antimicrobials, it is safer to assume that standard expected susceptibility patterns for first-tier drugs (eg, amoxicillin with or without clavulanic acid for *E. coli* or cephalixin for *Staphylococcus pseudintermedius*) may be relevant. However, if exposure to antimicrobials has previously occurred, eg, because of recurrence of the current infection, treatment of a different infection, or even exposure to antimicrobials through another household member, culture and susceptibility testing might be prudent. Under field conditions, culture and susceptibility testing may be difficult to accomplish. Use of an antibiogram, either generated locally for the practice or based on national data, might help identify current susceptibility patterns. Antibiograms reflect current population susceptibility patterns. Package insert data or recent literature may also help select a drug based on population MIC statistics; such data can also be useful for design of dosing regimens. Even in the event of culture submission, empirical antimicrobial therapy may need to be initiated before susceptibility data are received. If susceptibility data indicate the isolate is resistant, therapy should not change if the animal has responded to the chosen drug. Reculture might be important after therapy has been completed. If the animal has not responded, the data collected before treatment may no longer accurately predict the infecting population because the drug may have changed susceptibility patterns.

Culture and Susceptibility Testing:

Isolation and characterization of the causative pathogen, susceptibility testing, and determination of the MIC provide a sound foundation from which to select the antimicrobial drug and the dosage regimen. However, culture and susceptibility data are only as good as how the sample was collected, handled, and tested. Samples must be collected without contamination. Free catch urines, swabs from endotracheal tubes, culture of drain tubes, and swabs

from the surface of a contaminated wound are all examples of unacceptable culture samples. Swabs are less than ideal; not only is the temptation to collect a contaminated sample greater, but the swab itself can be inhibitory to growth. Whenever possible, a tissue or fluid sample is preferred, with handling of the sample left to the laboratory. Equally important is proper refrigeration. For example, with a reproduction rate as short as 20 min, *E. coli* in an unrefrigerated urine sample can rapidly grow from 10^1 to $>10^5$ CFUs, thus transitioning from no infection to infection while overgrowing the true pathogens. The laboratory must also be selected carefully; it should follow guidelines promulgated by the Clinical Laboratory Standards Institute (CLSI), use veterinary rather than human materials, and be directed by a veterinary clinical microbiologist.

● If the culture and susceptibility procedures routinely used by laboratories, tube (or micro) dilution procedures are preferred to agar gel procedures, because they can provide a minimum inhibitory concentration (MIC) of the drug toward an isolate of the infecting organism that has been cultured from the animal. The MIC can be used to not only select the drug but also to design the dosing regimen. Some key points regarding susceptibility testing may facilitate interpretation. The S (susceptible), I (intermediate), or R (resistant) indicator accompanying each MIC is determined by comparing the MIC of the isolate to MIC "breakpoints" determined by CLSI. An isolate with an MIC below the breakpoint established for each drug is considered "S," versus an isolate with an MIC at or above the breakpoint, which is considered "R." Although the actual concentrations tested for all drugs are generally the same, the range tested varies for each drug, as do the breakpoints. For example, for enrofloxacin, tested concentrations generally range from 0.5 to 2 mcg/mL; for amikacin, from 4 to 32 mcg/mL; and for ticarcillin, from 16 to 128 mcg/mL. The current susceptible and resistant CLSI breakpoints (mcg/mL), respectively, established for each drug are <0.5 and >4 for enrofloxacin, and <4 and >64 for amikacin. These breakpoints are followed by any laboratory in the USA that follows CLSI protocols or guidelines. That the concentrations differ for each drug, reflects, in part, the different drug concentrations achieved in plasma (and thus tissues) for each drug when administered at recommended dosing regimens. Because the concentrations tested and achieved in the animal vary for each drug, an MIC of

0.25 mcg/mL for enrofloxacin should not be interpreted as being better than an MIC of 2 mcg/mL for amikacin. The drug to which the isolate is most susceptible to, based on susceptibility data, is the drug with the MIC most below the C_{max} achieved in the animal at the recommended dose. However, this may not necessarily be the best drug to treat the infection, based on other host, microbial, and drug factors. Finally, just because an isolate has been indicated as "S" on a culture report does not mean the isolate has not developed some level of resistance. Rather, particularly for commonly used drugs, MIC for a specific isolate may be approaching the CLSI breakpoint. Therefore, it is still considered "S," despite it having developed some level of resistance. Therefore, doses for antimicrobials ideally should err on the side of higher doses (concentration- or time-dependent drugs) or shorter intervals (time-dependent drugs); the more at risk the animal is for therapy to fail, with development of a recurrent, resistant infection, the more important the design of the dosing regimen.

In addition, data from even appropriately collected samples tested under ideal conditions remain subject to limitations. Testing cannot take into account the impact of distribution to the site of infection, host factors such as inflammation, or microbial factors, including the size of the inoculum. These and other factors may indicate a need to modify the dosing regimen to assure adequate concentrations at the site of infection. Lipid-soluble drugs may become increasingly important as infection becomes more complex. Most antimicrobials are lipid soluble, with the β -lactams (penicillins, cephalosporins) being common exceptions.

COMBINATION THERAPY

Treatment with antimicrobial combinations may be necessary in certain cases. The administration of two or more agents may be beneficial in the following situations: 1) to treat mixed bacterial infections in which the organisms are not susceptible to a common agent, 2) to achieve synergistic antimicrobial activity against particularly resistant strains (eg, *Pseudomonas aeruginosa*), or 3) to reduce the risk of or overcome bacterial resistance. In general, combination therapy is most appropriate with a mixed infection or when an empirical selection must be made in a life-threatening situation.

Additive or synergistic effects are seen when antibacterial agents are used in combination. Prime examples are the

combination of clavulanic acid with amoxicillin or ticarcillin (or sulbactam with ampicillin), in which the first agent prevents β -lactamase destruction of the second agent, or the combination of a diaminopyrimidine such as trimethoprim or ormetoprim with a sulfonamide. Antibacterial antagonism may also emerge, sometimes with serious consequences. Generally, bacteriostatic agents act in an additive fashion with one another, whereas bactericidal agents are often synergistic when combined. However, the effects of several bactericidal antibiotics are substantially impaired by simultaneous use of drugs that impair microbial growth or "bacteriostatic" drugs (eg, most ribosomal inhibitors). This is a general guideline only; many exceptions are known, and confounding factors also play a role. Classification of antimicrobials as bactericidal or bacteriostatic can also be misleading, because "bactericidal" drugs can be rendered bacteriostatic if sufficient drug concentrations are not achieved at the site of infection. However, in general, the following common antimicrobials at MIC concentrations are likely to be bactericidal: penicil-

lins, cephalosporins, aminoglycosides, trimethoprim/sulfonamides ("potentiated"), metronidazole, quinolones, rifampin, and glycopeptides. The following antimicrobials at usual concentrations are generally bacteriostatic: tetracyclines, the phenolics (eg, chloramphenicol, florfenicol), macrolides, lincosamides, spectinomycin, and the sulfonamides (nonpotentiated).

Ideally, antimicrobial selection should be based on different mechanisms of action and on complementary spectra of activity. β -Lactams are often selected, because their action may facilitate movement of other drugs through the damaged cell wall into the microbe. Examples of combination therapy for mixed infections include the use of clindamycin, metronidazole, or the semisynthetic penicillins for their anaerobic coverage in combination with aminoglycosides for their gram-negative efficacy. Synergism against certain bacterial pathogens frequently can be achieved with combinations of penicillins or cephalosporins and aminoglycosides. The combined use of trimethoprim with selected sulfonamides or clavulanic acid with other β -lactams are other examples of synergistic effects.

ANTHELMINTICS

Many highly effective and selective anthelmintics are available, but such compounds must be used correctly, judiciously, and with consideration of the parasite/host interaction to obtain a favorable clinical response, accomplish good control, and minimize selection for anthelmintic resistance. Any decrease or increase of the recommended dose rate must always be discouraged. Underdosing is likely to result in lowered efficacy and possibly increased pressure for development of resistance. Overdosing may result in toxicity without necessarily increasing product efficacy.

Most anthelmintics generally have a wide margin of safety, considerable activity against immature (larval) and mature stages of helminths, and a broad spectrum of activity. Nonetheless, the usefulness of any anthelmintic is limited by the intrinsic efficacy of the drug itself, its mechanism of action, its pharmacokinetic properties, characteristics of the host animal (eg,

operation of the esophageal groove reflex), and characteristics of the parasite (eg, its location in the body, its degree of hypobiosis, susceptibility of the life stage, or susceptibility to the anthelmintic).

There are several classes of anthelmintics: benzimidazoles and probenzimidazoles, salicylanilides and substituted phenols, imidazothiazoles, tetrahydropyrimidines, organophosphates, macrocyclic lactones and, more recently introduced, the amino-acetonitrile derivatives, the cyclic octadepsipeptides, and the spiroindoles. Although it may be thought that chemotherapeutic control of helminth infections is currently satisfactory, selection for parasite resistance is an increasing concern.

MECHANISMS OF ACTION

Anthelmintics must be selectively toxic to the parasite. This is usually achieved either by inhibiting metabolic processes that are vital to the parasite but not vital to or absent

in the host, or by inherent pharmacokinetic properties of the compound that cause the parasite to be exposed to higher concentrations of the anthelmintic than are the host cells. While the precise mode of action of many anthelmintics is not fully understood, the sites of action and biochemical mechanisms of many of them are generally known. Parasitic helminths must maintain an appropriate feeding site, and nematodes and trematodes must actively ingest and move food through their digestive tracts to maintain an appropriate energy state; this and reproductive processes require proper neuromuscular coordination. Parasites must also maintain homeostasis despite host immune reactions. The pharmacologic basis of the treatment for helminths generally involves interference with the integrity of parasite cells, neuromuscular coordination, or protective mechanisms against host immunity, which lead to starvation, paralysis, and expulsion or digestion of the parasite.

Cellular Integrity: Several classes of anthelmintics impair cell structure, integrity, or metabolism: 1) inhibitors of tubulin polymerization—benzimidazoles and probenzimidazoles (which are metabolized in vivo to active benzimidazoles and thus act in the same manner); 2) uncouplers of oxidative phosphorylation—salicylanilides and substituted phenols; and 3) inhibitors of enzymes in the glycolytic pathway—clorsulon.

The benzimidazoles inhibit tubulin polymerization; it is believed that the other observed effects, including inhibition of cellular transport and energy metabolism, are consequences of the depolymerization of microtubules. Inhibition of these secondary events appears to play an essential role in the lethal effect on worms. Benzimidazoles progressively deplete energy reserves and inhibit excretion of waste products and protective factors from parasite cells; therefore, an important factor in their efficacy is prolongation of contact time between drug and parasite. Cross-resistance can exist among all members of this group, because they act on the same receptor protein, β -tubulin, which is altered in resistant organisms such that none of the benzimidazoles can bind to the receptor with high affinity.

Uncoupling of oxidative phosphorylation processes has been demonstrated for the salicylanilides and substituted phenols, which are mainly fasciolicides. These compounds act as protonophores, allowing hydrogen ions to leak through the inner

mitochondrial membrane. Although isolated nematode mitochondria are susceptible, many fasciolicides are ineffective against nematodes in vivo, apparently due to a lack of drug uptake. Exceptions are the hematophagous nematodes, eg, *Haemonchus* and *Bunostomum*.

Clorsulon is rapidly absorbed into the bloodstream. When *Fasciola hepatica* ingest it (in plasma and bound to RBCs), they are killed because glycolysis is inhibited and cellular energy production is disrupted.

Neuromuscular Coordination:

Interference with this process may occur by inhibiting the breakdown or by mimicking or enhancing the action of neurotransmitters. The result is paralysis of the parasite. Either spastic or flaccid paralysis of an intestinal helminth allows it to be expelled by the normal peristaltic action of the host. Specific categories include drugs that act via a presynaptic latrophilin receptor (emodipside), various nicotinic acetylcholine receptors (agonists: imidazothiazoles, tetrahydropyrimidines; allosteric modulator: nonepantel; antagonist: spiroindoles), glutamate-gated chloride channels (avermectins, milbemycins), GABA-gated chloride channels (piperazine), or via inhibition of acetylcholinesterases (coumaphos, naphthalophos).

Organophosphates inhibit many enzymes, especially acetylcholinesterase, by phosphorylating esterification sites. This phosphorylation blocks cholinergic nerve transmission in the parasite, resulting in spastic paralysis. The susceptibility of cholinesterases by host and parasite varies, as does the susceptibility of these different species to organophosphates.

The imidazothiazoles are nicotinic anthelmintics that act as agonists at nicotinic acetylcholine receptors of nematodes. Their anthelmintic activity is mainly attributed to their ganglion-stimulant (cholinomimetic) activity, whereby they stimulate ganglion-like structures in somatic muscle cells of nematodes. This stimulation first results in sustained muscle contractions, followed by a neuromuscular depolarizing blockade resulting in paralysis. Hexamethonium, a ganglionic blocker, inhibits the action of levamisole.

Nonepantel, the only commercially available amino-acetonitrile derivative, is a direct agonist of the mptl-1 channel, which is a homomeric channel belonging to the DEG-3 family of nicotinic acetylcholine receptors. Binding of nonepantel to the

receptor results in a constant, uncontrolled flux of ions and finally in a depolarization of muscle cells, leading to irreversible paralysis of the nematodes. These receptors are unique in that they are found only in nematodes.

Derquantel, a semisynthetic member of the spiroindole class of anthelmintics, is an antagonist of B-subtype nicotinic acetylcholine receptors located at the nematode neuromuscular junction; it inhibits 45-pS channels, leading to a flaccid paralysis of nematodes.

Piperazine acts to block neuromuscular transmission in the parasite by hyperpolarizing the nerve membrane, which leads to flaccid paralysis. It also blocks succinate production by the worm. The parasites, paralyzed and depleted of energy, are expelled by peristalsis.

The macrocyclic lactones act by binding to glutamate-gated chloride channel receptors in nematode and arthropod nerve cells. This causes the channel to open, allowing an influx of chloride ions. Different chloride channel subunits may show variable sensitivity to macrocyclic lactones and different sites of expression, which could account for the paralytic effects of macrocyclic lactones on different neuromuscular systems at different concentrations. The macrocyclic lactones paralyze the pharynx, the body wall, and the uterine muscles of nematodes. Paralysis (flaccid) of body wall muscle may be critical for rapid expulsion, even though paralysis of pharyngeal muscle is more sensitive. As the macrocyclic lactone concentration decreases, motility may be regained, but paralysis of the pharynx and resultant inhibition of feeding may last longer than body muscle paralysis and contribute to worm deaths. None of the macrocyclic lactones are active against cestodes or trematodes, presumably because these parasites do not have a receptor at a glutamate-gated chloride channel. Emodepside acts presynaptically at the neuromuscular junction, where it attaches to a latrophilin-like receptor. This receptor belongs to the group of so-called G-protein coupled receptors. Stimulation of the latrophilin-like receptor by emodepside activates a signal transduction cascade via G α -protein and phospholipase C, causing an increase in intracellular calcium and diacylglycerol levels. At the end of the signal transduction cascade, vesicles containing inhibitory neuropeptide fuse with presynaptic membranes. After fusion of these membranes, inhibitory neuropeptides may be released into the synaptic cleft to then

stimulate a postsynaptic receptor. Recent findings indicate that a second emodepside target is the calcium-activated potassium channel slo-1. Binding to the latrophilin receptor and the slo-1 ion channel leads to inhibition of pharyngeal pumping, paralysis, and death.

The mode of action of praziquantel is not certain, but it rapidly causes tegumental damage and paralytic muscular contraction of cestodes, followed by their death and expulsion.

PHARMACOKINETICS

After administration, anthelmintics are usually absorbed into the bloodstream and transported to different parts of the body, including the liver, where they may be metabolized and eventually excreted in the feces and urine. The disposition of anthelmintics throughout the body is considerably more complex than can be described by a set of pharmacokinetic parameters in the peripheral circulation. Improved drug performance requires knowledge of drug behavior in the multicompartmental system, including the complex interaction between formulation and route of administration, physicochemical properties of the compound, and physiology of the compartment into which the drug is distributed.

Although many helminth parasites reside in the lumen or close to the mucosa, others live at sites such as the liver and lungs; for action against these, absorption of drug from the GI tract, injection site, or skin is essential. Intestinal parasites come in contact not only with the unabsorbed drug passing through the GI tract but also with the absorbed fraction in the blood as they feed on the intestinal mucosa, and with any that is recycled into the gut. This is an important aspect of efficacy of many of the benzimidazoles.

The pharmacokinetics of an anthelmintic, its rate of metabolism and excretion, and its safety profile determine the length of the withdrawal time; this period can vary among species and can also be affected by route of administration and dose. The usual site of metabolism of anthelmintics is the liver, where oxidation and cleavage reactions commonly occur.

Benzimidazoles and Probenzimidazoles: With a few exceptions, eg, albendazole, oxfendazole, and triclabendazole, only limited amounts of any of the benzimidazoles are absorbed from the GI tract of the host. The limited absorption is

probably related to the poor water solubility of these drugs. The little absorption that occurs is generally rapid, 2–7 hr after dosing with flubendazole and 6–30 hr after dosing with albendazole, fenbendazole, and oxfendazole, depending on the species. Many of the benzimidazoles and their metabolites re-enter the GI tract by passive diffusion, but the biliary route is the most important pathway for secretion and recycling of benzimidazoles in the GI tract.

A number of benzimidazoles (eg, febantel, thiophanate, netobimin) exist in the form of prodrugs that must be metabolized in the body to the biologically active benzimidazole carbamate nucleus. Febantel is hydrolyzed to the active metabolite fenbendazole, and netobimin undergoes processes of reduction, cyclization, and oxidation to yield albendazole sulfoxide. Benzimidazole sulfoxides such as oxfendazole and albendazole sulfoxide bind poorly to parasite β -tubulin and probably act as prodrugs for fenbendazole and albendazole, respectively. The thiometabolites have high affinity for helminth tubulin.

Metabolism of the benzimidazoles is variable and may alter their activity; eg, albendazole is rapidly and reversibly oxidized to its sulfoxide form. The sulfoxide may be irreversibly oxidized to its sulfone, which is significantly less active than the sulfoxide. Similarly, fenbendazole and oxfendazole (fenbendazole sulfoxide) are interchangeable, but the oxidation product fenbendazole sulfone is less active and is not reduced back to the sulfoxide or thio metabolites.

In ruminants, the benzimidazoles are most effective if deposited into the rumen. Administration directly into the abomasum, via the esophageal groove, may shorten the duration for drug absorption and increase the rate of excretion in the feces, which may reduce efficacy. For example, immediate arrival of oxfendazole in the abomasum after dosing reduces its efficacy from 91% to 45% against thiabendazole-resistant strains of *Haemonchus contortus*. The rumen acts as a drug reservoir from which plasma concentrations can be sustained, slowing the passage of unabsorbed drug through the GI tract.

Imidazothiazoles: The absorption and excretion of levamisole is rapid and not affected by the route of administration or ruminal bypass, because it is highly soluble. In cattle, blood concentrations of levamisole peak <1 hr after SC administration. These concentrations decline rapidly; 90% of the total dose is excreted in 24 hr, largely in the urine.

Tetrahydropyrimidines: Pyrantel tartrate (or citrate) is well absorbed by pigs and dogs, less well by ruminants. The pamoate salt (synonym embonate) of pyrantel is poorly soluble in water; this offers the advantage of reduced absorption from the gut and allows the drug to reach and be effective against parasites in the large intestine, which makes it useful in horses and dogs. Metabolism of pyrantel is rapid, and the metabolites are excreted rapidly in the urine (40% of the dose in dogs); some unchanged drug is excreted in the feces (principally in ruminants). Blood concentrations usually peak 4–6 hr after PO administration.

Morantel is the methyl ester analogue of pyrantel and, in ruminants, it tends to be safer and more effective than pyrantel. It is absorbed rapidly from the upper small intestine of sheep and metabolized rapidly in the liver; ~17% of the initial dose is excreted in the urine as metabolites within 96 hr after dosing.

Macrocyclic Lactones: Macrocyclic lactones are hydrophobic, an important characteristic of this class of anthelmintics. Regardless of their route of administration, macrocyclic lactones are distributed throughout the body and some concentrate in adipose tissue. Liver tissue contains the highest residue for the longest, reflecting the route of elimination. Although the magnitude of lipophilicity differs among chemical types, the limited vascularization and slow turnover rate of body fat and the slow rate of release or exchange of drug from these lipid reserves can prolong the residence of drug in the peripheral plasma. Ivermectin is arguably the least lipophilic macrocyclic lactone, with the possible exception of eprinomectin. Moxidectin is ~100 times more lipophilic than ivermectin. Doramectin is less lipophilic than moxidectin but more than ivermectin or eprinomectin.

Ivermectin was the first commercially available macrocyclic lactone and has been the most extensively studied. When given IV, ivermectin has an elimination half-life of 32–178 hr, depending on species. Despite the higher dose rate of the injectable formulation in pigs (300 mcg/kg) compared with that of cattle (200 mcg/kg), the maximum concentration (C_{max}) and area under the curve (AUC) in peripheral plasma in pigs are about one-third those in cattle. Although the elimination half-life after SC and IV administration of ivermectin is of similar duration, slow absorption from the injection site may broaden the concentration-time profile, with C_{max} in peripheral

plasma of cattle occurring as late as 96 hr. The C_{max} and AUC in pigs and goats are considerably lower than those in cattle, horses, and sheep. Pigs, and possibly goats, may metabolize ivermectin faster than other species.

In ruminants, the macrocyclic lactones are, like benzimidazoles, most effective if deposited directly into the rumen. A 3- to 4-fold decrease in C_{max} and AUC of ivermectin after intra-abomasal compared with intraruminal administration has been reported. Significantly, time to maximal concentration of ivermectin was reduced from 23 hr to 4 hr with the former route of delivery.

Concentrations of ivermectin are high in digesta sampled from the distal intestine, indicating that biliary secretion is an important pathway for clearance of macrocyclic lactones. This pathway also has been conclusively demonstrated for clearance of benzimidazole compounds. The extended high concentration in bile is influenced by prolonged exchange of drug from lipid reserves and the enterohepatic recycling of biliary compounds through the portal and biliary pools. The macrocyclic lactones are primarily excreted in the feces, the remainder (<10%) in the urine. The more lipophilic macrocyclic lactones are also excreted in milk.

Salicylanilides and Substituted Phenols:

Secretion via the liver and bile is especially important for drugs active against adult *Fasciola* spp. The fasciolicidal effects of salicylanilides (such as rafoxanide) in sheep depend on persistence of the drug in plasma, which influences their transport throughout the body and rate of elimination. Closantel, rafoxanide, and oxclozanide have long terminal half-lives in sheep (14.5, 16.6, and 6.4 days, respectively), which are related to the high plasma-protein binding (>99%) of these three drugs. Residues in liver are detectable for weeks after administration. Associated with persistence, however, is the need for longer withholding periods. Oxclozanide also is bound to plasma protein and then metabolized in the liver to the anthelmintically active glucuronide and excreted in high concentration in the bile duct, where it encounters the mature flukes.

Immature flukes in the liver parenchyma ingest mainly liver cells, which contain little anthelmintic; plasma-protein binding limits entry of the drug into the tissue cells. As the flukes grow and migrate through the liver, they cause extensive hemorrhaging and come into contact with anthelmintic bound

to plasma protein. When they reach the bile ducts, they are in the main excretory channels for the active metabolites of the fasciolicides and are exposed to toxic concentrations. This may explain why mature flukes are more vulnerable to most fasciolicides than immature ones. The higher concentrations of fasciolicides and their metabolites in feces than in urine suggest that the bile ducts are their main excretory pathways.

It is important to understand the pharmacokinetics of prescribed anthelmintics. For example, nitroxylin has good efficacy against *F. hepatica* in cattle and sheep and against *H. contortus*, but because rumen bacteria metabolize and destroy the activity of nitroxylin, it must be injected.

Amino-acetonitrile Derivatives: After PO administration, monepantel is quickly absorbed into the bloodstream and metabolized to a major extent within 4 hr into monepantel sulfone. The sulfone expresses in vitro anthelmintic activity similar to that of the parent molecule and is responsible for the anthelmintic effect in animals, because 95% of the administered dose is metabolized into the sulfone. The C_{max} of monepantel sulfone was 4 fold-higher compared with that measured for the parent compound. After PO administration in sheep of the recommended dosage of 2.5 mg/kg, the elimination half-life of the sulfone metabolite in plasma was 48.7 hr, with a mean residence time of 79.3 hr. Approximately 27% of the administered dose is excreted through the feces in the form of the sulfone derivative. The remaining amount is further metabolized and partly excreted through urine (up to 30% of the administered dose). In addition to the sulfone, the parent monepantel contributes to the anthelmintic activity against abomasal nematodes, because the concentration of the parent monepantel is considerably higher in the abomasum than in plasma.

Cyclic Octadepsipeptides: Studies in rats have been done to assess the general distribution, metabolism, and excretion patterns of emodepside after PO and IV administration. Bioavailability after PO administration is ~50%. Emodepside is distributed throughout the whole organism, but highest concentrations are found in fat tissues, where it forms a deposit that is slowly released. Emodepside is excreted predominantly via the bile and then eliminated in the feces. Approximately half of the administered dose is excreted within

the first 24 hr. The elimination half-life after both PO and IV administration is 39–51 hr. Approximately 45%–56% of the administered dose is excreted unchanged, the rest in the form of inactive metabolites. After topical administration in cats, emodepside is absorbed slowly into the bloodstream. Maximum plasma levels are reached 2–3 days after treatment. Absorption after PO administration in dogs is higher if administered to fed animals.

Spiroindoles: Pharmacokinetics demonstrate that after a single oral administration, maximum concentrations of derquantel were reached at 4.2 hr. The terminal half-life of derquantel was 9.3 hr, and the absolute bioavailability was 56.3%. Metabolism of derquantel is extensive and complex. Derquantel undergoes biotransformation to a large number of metabolites over a short time and, as a result, extensive variation in metabolites has been found in tissues and overtime periods.

Praziquantel: Praziquantel is rapidly and almost completely absorbed from the GI tract. After absorption, praziquantel is distributed to all organs; it is believed to re-enter the intestinal lumen via the mucosa and bile in dogs. Praziquantel is rapidly hydroxylated into inactive forms in the liver and secreted in bile. It has a wide safety margin.

WITHHOLDING PERIODS

Most anthelmintics have withholding periods if milk or meat from treated animals is intended for human consumption; the specific requirements for each must be observed. Of the benzimidazoles, thiabendazole is absorbed and excreted most quickly; fenbendazole, oxfendazole, and albendazole are absorbed and excreted over a longer period, which necessitates withholding periods of 8–14 days before slaughtering for meat and 3–5 days before milking for human consumption. Other members of the group have withholding periods between these extremes, but withholding periods are longer for bolus formulations.

A similar relationship between the rate of metabolism and activity against immature parasites also exists with certain fasciolicides. Closantel, rafoxanide, and nitroxylin bind more strongly to blood proteins than does oxyclozanide, and therefore remain in the blood for longer periods. While this greater persistence is associated with greater activity against immature liver flukes, the withholding period for slaughter

is also longer: 21–77 days for closantel, rafoxanide, and nitroxylin, compared with 3–14 days for oxyclozanide. The low plasma-protein binding of dianfenetide, coupled with the rapid excretion of its active metabolite, necessitates only a short withdrawal time. Similarly, withholding periods for milk vary widely. Closantel and nitroxylin cannot be used in lactating animals when milk is intended for human consumption, whereas oxyclozanide has a withdrawal time of only 60 hr.

Levamisole and morantel are rapidly excreted; thus, withholding periods for meat are short, and frequently there is no, or only a short, withholding period for milk. However, in some countries, levamisole cannot be used in lactating animals when milk is intended for human consumption.

Ivermectin and doramectin are excreted in milk and are not recommended when milk is intended for human consumption. Commensurate with the long period of activity of macrocyclic lactones, ivermectin, abamectin, doramectin, and moxidectin have significant withholding periods before slaughter (eg, 35 days), which vary with the formulations and local regulations. Residual concentrations of moxidectin in milk after topical administration are below threshold limits, resulting in no milk withholding period in many countries. The chemical structure of the macrocyclic lactone molecule has been manipulated to change the milk partitioning coefficients in lactating dairy animals. For example, only 0.1% of the total dose of eprinomectin is eliminated in the milk, resulting in no withholding period for milk worldwide.

Monepantel has a withdrawal period of 7–14 days for meat and is not approved for use in lactating animals producing milk for human consumption.

In combination with abamectin, derquantel has a withholding period of 14 days for meat and is not approved for use in lactating animals producing milk for human consumption.

SAFETY

Most anthelmintics have wide safety margins, ie, the dosage that can be given to an animal before adverse effects are induced is much higher than the dosage recommended for use. The wide safety margin of benzimidazoles is because of their greater selective affinity for parasitic β -tubulin than for mammalian tissues. Nonetheless, this selective toxicity is not absolute; some toxic effects based on

antimitotic activity (teratogenicity or embryotoxicity) can occur in some target species, and some benzimidazoles, depending on the dose rate, are contraindicated in early pregnancy.

The safety index (SI) is not as wide for levamisole (SI = 4–6), nor for most of the chemicals active against liver flukes (SI = 3–6). Mammalian toxicity with levamisole is seen more often than with benzimidazoles, although toxic signs are unusual unless the normal therapeutic dosage is exceeded. Levamisole toxicity in the host animal is largely an extension of its antiparasitic effect, ie, cholinergic-type signs of salivation, muscle tremors, ataxia, urination, defecation, and collapse. In fatal levamisole poisoning, the immediate cause of death is asphyxia due to respiratory failure. Atropine sulfate can alleviate such signs. Levamisole may cause some inflammation at the site of SC injection, but usually this is transient. Toxicity increases if other anticholinergic drugs (eg, organophosphates) are given at the same time.

Because of their low absorption from the gut, tetrahydropyrimidines have a high safety margin. Adverse effects (vomiting in dogs and cats) are rare. Toxicity increases when other cholinergic drugs (eg, levamisole, organophosphates) are used simultaneously.

The margin of safety for organophosphates is generally less than that of the benzimidazoles, and strict attention to dosage is necessary. Generally, their toxicity is additive; thus, concurrent use of other cholinesterase-inhibiting drugs should be avoided. Atropine and 2-PAM are used as antidotes to organophosphate toxicity (*see also* p 3064). Organophosphates also can be hazardous to people. Being lipid soluble, they are readily absorbed through unbroken skin. Sprays, collars, and washes of organophosphates used for small animals can present significant hazards to young infants after ingestion, inhalation, or transcutaneous absorption.

Mammals are generally not adversely affected by macrocyclic lactones. The SI for the macrocyclic lactones is typically wide, but both abamectin and moxidectin are contraindicated in calves and foals <4 mo old, respectively, because of narrow safety margins in these classes of stock. Otherwise, single administration at ~10 times and multiple administration at 3 times the recommended therapeutic dose levels do not have any secondary effects on healthy host animals.

Manmalian safety appears to depend on P-glycoprotein activity in the blood-brain

barrier. A P-glycoprotein deficiency in certain animals decreases the ability to pump avermectins, milbemycins, and other drugs across cell membranes. The net effect is an increase in systemic bioavailability, because animals deficient in P-glycoprotein are not able to actively pump the macrocyclic lactones out of the CNS or efficiently process these drugs. This decreases the ability to redistribute, metabolize, and excrete macrocyclic lactones, as well as antineoplastic drugs, opioids, acepromazine, digoxin, and ondansetron, resulting in toxicity with what would be considered normal doses in most animals. There have been cases of CNS depression in cattle breeds (Murray Grey) and in individual dogs of multiple breeds, but these were first recognized in purebred and crossbred Collies. Nervous signs (idiosyncratic reactions), including depression, muscle weakness, blindness, coma, and death, were seen when high doses were administered.

Because salicylanilides, substituted phenols, and aromatic amides are general uncouplers of oxidative phosphorylation, their SIs are lower than those of many other anthelmintics. Nonetheless, they are safe if used as directed. Adverse effects are most commonly seen in animals that are severely stressed, in poor condition nutritionally or metabolically, or have severe parasitic infections. Mild anorexia and unformed feces may be seen after treatment at recommended dosages. High dosages may cause blindness, hyperthermia, convulsions, and death—classic signs of uncoupled phosphorylation.

The amino-acetonitrile derivatives target a nematode-specific receptor that is absent in mammals and other organisms. Because of this specific mode of action, monepantel has a very favorable safety profile. Monepantel has been administered to lambs in doses up to 30 times higher than the recommended dose without any adverse effects. In addition, repeated oral administration of monepantel at three times the recommended dose every 5 days over an entire reproductive cycle was not associated with any treatment-related adverse effects on the reproductive performance of rams or ewes or on the viability of their offspring, and it was systemically very well tolerated.

Emodepside appears to be of low acute toxicity in a variety of laboratory animal species and by a variety of routes. Although overt signs of toxicity include depressed neurologic and respiratory function, they occur only at dose rates far in excess of the recommended therapeutic dose in cats.

Repeated treatment at three times the therapeutic dose was tolerated in pregnant and lactating dams/queens, so adverse effects on reproductive function of the dams and/or kitten health are not anticipated when the product is administered at the recommended treatment dose. Safety in dogs was established only for puppies ≥ 12 wk old.

The combination of derquantel and abamectin did not result in any adverse clinical effects in ewes and lambs under field conditions, other than a commonly reported, mild, transient coughing.

RESISTANCE

The development of nematode and trematode resistance to various groups of anthelmintics is a major problem. Compared with development of antibiotic resistance in bacteria, resistance to anthelmintics in nematodes has been slower to develop under field conditions. However, resistance is becoming widespread, because relatively few chemically dissimilar groups of anthelmintics have been introduced over the past several decades. Most of the commonly used anthelmintics belong to one of three chemical classes, benzimidazoles, imidazothiazoles, and macrocyclic lactones, within which all individual compounds act in a similar fashion. Thus, resistance to one particular compound may be accompanied by resistance to other members of the group (ie, side-resistance).

In nematodes of small ruminants, and especially in *Haemonchus contortus*, resistance to all classes of broad-spectrum anthelmintics has reached serious levels in many parts of the world. Resistance also has been found in *Trichostrongylus* spp, *Cooperia* spp, and *Teladorsagia* spp in sheep and goats. Reports of multiple resistance to most major classes of anthelmintics are increasing. Recently, resistance to monepantel has occurred in the field (New Zealand) in at least two nematode species (*Teladorsagia circumcincta* and *Trichostrongylus colubriformis*) after being administered on 17 separate occasions to different stock classes and in <2 yr of the product first being used on the farm.

Resistance to benzimidazoles is widespread in cyathostome nematodes of horses. *Parascaris equorum* resistance to macrocyclic lactones (ivermectin and moxidectin) has been reported in many countries. Macrocyclic lactone resistance in cyathostomes is only occasionally suspected, however, and the problem is still not considered to be serious.

There are limited reports of resistance against levamisole, pyrantel, and benzimidazoles in *Oesophogostomum dentatum* in pigs.

Multidrug (benzimidazoles and macrocyclic lactones) resistance in cattle nematodes has been documented on farms in New Zealand, the Americas, and Europe, and this will probably become more widespread. In most cases of resistance against macrocyclic lactones, *Cooperia* spp were identified as the resistant worm species, but macrocyclic lactone resistance is also emerging in *Ostertagia ostertagi*. The full extent of anthelmintic resistance in cattle nematodes is unknown.

The development of significant levels of resistance seems to require successive generations of helminths exposed to the same class of anthelmintic. However, evidence suggests that genes for resistance are invariably present, at a low frequency, for any given anthelmintic. Selection for resistance simply requires the preferential killing of the susceptible parasites and survival of the parasites with the resistance genes. Side-resistance is frequently seen between members of the benzimidazole group because of their similar mechanisms of action; control of benzimidazole-resistant parasites by levamisole can be expected because of its different mode of action. Although there is no evidence for cross-resistance between levamisole and benzimidazoles, this does not mean that worms resistant to both kinds of drugs will not evolve if both types of anthelmintics are used frequently. Nematodes resistant to levamisole are cross-resistant to morantel because of the similarities of their mechanisms of action. When resistance to the recommended dose rate of an avermectin appears in some species of nematodes, a milbemycin, at its recommended dose rate, may still be effective. However, there is side-resistance among the avermectins and the milbemycins, which are within the same class of anthelmintics, and continued use of either subgroup will select for macrocyclic lactone resistance.

Recently, it was demonstrated in *Haemonchus contortus* and *Onchocerca volvulus* that macrocyclic lactone anthelmintics can affect β -tubulin, although no mechanistic explanation for this has been published. However, it suggests that macrocyclic lactone use may select for benzimidazole resistance, because benzimidazole resistance appears to be largely due to a single polymorphism being selected. However, benzimidazole resistance was widely reported before the

commercial use of macrocyclic lactones. Ivermectin resistance has usually been reported in areas of the world where benzimidazole resistance is already widespread. In using anthelmintic combinations or rotations, consideration should be given to the genetic interactions in the parasite between benzimidazole and macrocyclic lactone anthelmintics in terms of selection for the alleles that confer benzimidazole resistance.

Every exposure of a target parasite to an anthelmintic exerts some selection pressure for development of resistance. Therefore, management practices designed to reduce exposure to parasites and to minimize the frequency of anthelmintic use should be recommended. The development of an anthelmintic resistance problem may theoretically be delayed by rotating chemicals with different modes of action annually between dosing seasons. Drug combinations may be another appropriate choice, provided the anthelmintics used in the combination are both effective and select for different resistance mechanisms.

In parasite control, economic benefit is best obtained by careful management practices. Planned (or targeted) treatment of a whole flock or herd should be based on the biology, ecology, and epidemiology of the parasite(s), with particular reference to climatic conditions. There is a trend among parasitologists to recommend replacing current practice for worm control involving repeated dosing of whole groups of animals with "targeted selective treatments" in which only individual animals showing clinical signs or reduced productivity are given drugs.

BENZIMIDAZOLES

The benzimidazoles are a large chemical family used to treat nematode and trematode infections in domestic animals. They also have limited activity against cestodes. However, with the widespread development of resistance and the availability of more efficient and easier to administer compounds, their use has decreased in ruminants. They are characterized by a broad spectrum of activity against roundworms (nematodes), an ovicidal effect, and a wide safety margin. Those of interest are mebendazole, flubendazole, fenbendazole, oxfendazole, oxi-bendazole, albendazole, albendazole sulfoxide, thiabendazole, thiophanate, febantel, netobimin, and triclabendazole. Netobimin, albendazole, and triclabendazole are also active against liver flukes; however, unlike

all the other benzimidazoles, triclabendazole has no activity against roundworms. Because most benzimidazoles are sparingly soluble in water, they are generally given PO as a suspension, paste, or bolus, although topical formulations have also been developed. Differences in the rate and extent of absorption from the GI tract depend on such factors as species, dosage, formulation, solubility, and operation of the esophageal groove reflex. Flubendazole and fenbendazole are also available as an oral suspension or emulsion for application through drinking water, for administration to pigs and chickens.

The most effective of the group are those with the longest half-life, such as oxfendazole, fenbendazole, albendazole, and their prodrugs, because they are not rapidly metabolized to inactive products. Effective concentrations are maintained for an extended period in the plasma and gut, which increases efficacy against immature and arrested larvae and adult nematodes, including lungworms.

They are more effective in ruminants and horses, in which their rate of passage is slowed by the rumen or cecum. Because the nature of their antiparasitic action depends on prolongation of contact time, repeated (2–3 times) PO administration of a full dose at 12-hr intervals increases their efficacy, even against benzimidazole-resistant worms. In addition, a reduced feed intake, which reduces the flow rate of digesta, increases the availability of benzimidazoles.

In the case of oxfendazole, and probably other benzimidazoles, the major route of exposure is biliary metabolites, followed by enterohepatic recycling of the drug after absorption from the small and large intestine. Worms in the mucosa of the small intestine may be exposed to more recycled anthelmintic than to drug contained in the passing ingesta in the GI tract.

Ruminants: In ruminants, PO treatment with the benzimidazoles removes most of the major adult GI parasites and many of the larval stages. The relative rates of oxidation in the liver and reduction in the GI tract vary between cattle and sheep, with the metabolism and excretion of benzimidazole compounds being more extensive in cattle than in sheep. Consequently, the systemic anthelmintic activity of most benzimidazoles is greater in sheep than in cattle, and dose rates in cattle are often higher than those in sheep. Albendazole, fenbendazole, oxfendazole, and febantel are active against inhibited fourth-stage larvae of *Ostertagia* spp; however, inconsistent

efficacy has been reported. Efficacy against *Dictyocaulus viviparus* has also been noted for these insoluble benzimidazoles. Oxfendazole, albendazole, and febantel are minimally teratogenic in sheep, whereas fenbendazole, mebendazole, and oxfendazole are not. An oxfendazole pulse-release bolus for intraruminal use has been developed for cattle in Europe; five or six therapeutic doses of oxfendazole (750 or 1,250 mg/tablet) are released approximately every 3 wk in the rumen. A sustained-release fenbendazole bolus is also available for cattle in some European countries; it contains 12 g fenbendazole and has a continual release profile of >140 days. An albendazole slow-release capsule has been marketed in Europe and Australasia for small ruminants. This device contains 3.85 g of albendazole and delivers a daily dose of 36.7 mg for 105 days. It is an efficient device to control benzimidazole-susceptible nematodes. It may also prevent infection with benzimidazole-resistant larvae but does not reduce existing infections.

In cattle and sheep, triclabendazole at 10 mg/kg, PO, is highly effective against immature *Fasciola hepatica* in the liver parenchyma and against the mature stage in the bile ducts. Albendazole and netobimin at 20 mg/kg are active against mature *F. hepatica*; the other benzimidazoles and probenzimidazoles used for nematode control have only a marginal efficacy against liver flukes. Because of the lack of efficacy against the immature stages, only triclabendazole is indicated for treatment of acute fascioliosis. However, triclabendazole resistance has been reported in several countries. Triclabendazole is not approved for use in ruminants in the USA.

Benzimidazoles also have some anthelmintic activity against *Moniezia* spp in sheep and cattle.

Horses: In horses, the benzimidazoles are characterized by effective removal (90%–100%) of almost all mature strongyles, but third- and fourth-stage larvae are more difficult to eliminate. High levels and repeated administration may be necessary for extra-intestinal migrating stages of large strongyles and for small-strongyle larvae embedded or encysted in the wall of the intestine. However, widespread resistance to benzimidazoles in cyathostome nematodes of horses limits their usage. Repeated doses are thought to be advantageous, because the lethal effect of benzimidazoles is a slow process—hence, their recent incorporation into feed supplements. Ascarid removal in horses varies with

various members of the benzimidazole group. Activity against *Strongyloides westeri* varies also, but *Oxyuris equi* is usually removed by any of the benzimidazoles at the recommended dose.

Swine: Benzimidazoles (eg, fenbendazole, flubendazole) show high efficacy against both adult and immature stages of *Ascaris suum*. Benzimidazoles are also highly effective against most other swine nematodes.

Dogs and Cats: In dogs and cats, mebendazole, fenbendazole, febantel, oxfendazole, oxfendazole, and flubendazole are used for treatment of roundworms, hookworms, and tapeworms. However, treatment must be given for 3 days.

Birds: Mebendazole, flubendazole, and fenbendazole can be used effectively against nematodes of the GI and respiratory tracts of birds.

IMIDAZOTHIAZOLES

The anthelmintic activity of tetranisole, a racemic mixture, resides in the *l*-isomer, levamisole. It is commonly used in cattle, sheep, pigs, goats, and poultry to treat nematode infections; it has no activity against flukes and tapeworms. It is normally administered PO or SC, and efficacy is generally considered equivalent with either route. Topical preparations for cattle have been developed.

Levamisole acts on the roundworm nervous system and is not ovicidal. Its broad spectrum of activity, ease of use (being water soluble), reasonable safety margin, and lack of teratogenic effects have allowed it to be used successfully. Because of its mechanism of action, the peak blood concentration is more relevant to its antiparasitic activity than the duration of concentration. Levamisole resistance appears to be associated with a loss of cholinergic receptors. Levamisole has immunostimulant effects at dosage rates higher than those used for anthelmintic activity, and it has been used in people and to a limited extent in other animals in several diseases.

Ruminants: In ruminants, levamisole (pour-on, injectable, and oral formulations) is highly effective against the common adult GI nematodes and lungworms and many larval stages. It lacks efficacy against arrested larvae, such as those of *Ostertagia ostertagi*. Levamisole slow-release boluses

are available in some countries and contain 22.05 mg levamisole. They release 2.5 mg during the first 24 hr and the remainder over a 60-day period.

Swine: Levamisole (injectable and oral formulations) is highly effective against both adult and immature stages of *Ascaris suum*. Levamisole is also highly effective against other adult swine nematodes, except for *Trichuris suis*.

Dogs: In some countries, levamisole is available as an oral formulation for treatment of *Toxocara canis* infections.

Birds: In poultry, levamisole is mainly used to remove ascarid infections. Because it is water soluble, it is available as an oral formulation for administration through drinking water.

TETRAHYDROPYRIMIDINES

Pyrantel was first introduced as a broad-spectrum anthelmintic against GI nematodes of sheep and has also been used in cattle, horses, dogs, cats, and pigs. It is available as a citrate, tartrate, embonate, or pamoate salt.

Aqueous solutions are subject to isomerization on exposure to light, with a resultant loss in potency; therefore, suspensions should be kept out of direct sunlight. It is not recommended for use in severely debilitated animals because of its levamisole-type pharmacologic action.

Pyrantel is used PO as a suspension, paste, drench, or tablets. Both pyrantel and morantel are effective against adult gut worms and larval stages that dwell in the lumen or on the mucosal surface.

Ruminants: Pyrantel tartrate is effective as a broad-spectrum anthelmintic in ruminants; however, its activity is mainly limited to the adult GI nematodes.

Horses: Pyrantel is effective against adult ascarids, large and small strongyles, and pinworms. At double the recommended dose, it has limited activity against the ileocecal tapeworm *Anoplocephala perfoliata*.

Swine: Pyrantel tartrate is used in swine to treat *Ascaris* and *Oesophagostomum*.

Dogs and Cats: Pyrantel pamoate or embonate is effective against the common GI nematodes, except for whipworms. Oxantel, a phenol analogue of pyrantel, is

combined with pyrantel in some anthelmintic preparations for dogs (and people) to increase activity against whipworms.

MACROCYCLIC LACTONES

The macrocyclic lactones (avermectins and milbemycins) are products or chemical derivatives of soil microorganisms belonging to the genus *Streptomyces*. The avermectins in commercial use are ivermectin, abamectin, doramectin, eprinomectin, and selamectin. Commercially available milbemycins are milbemycin oxime and moxidectin. The macrocyclic lactones have a potent, broad antiparasitic spectrum at low dose levels. They are active against many immature nematodes (including hypobiotic larvae) and arthropods. The published literature contains reports of use to treat infections of >300 species of endo- and ectoparasites in a wide range of hosts. Moreover, a single therapeutic dose can persist in concentrations sufficient to be effective against new nematode infections for prolonged periods after treatment.

The macrocyclic lactones are well absorbed when administered PO or parenterally; the pour-on formulations exhibit greater variability. Regardless of the route of administration, macrocyclic lactones are extensively distributed throughout the body and concentrate particularly in adipose tissue. However, the route of administration and formulation may affect the drug pharmacokinetics. The residence time of macrocyclic lactones administered SC may also be influenced by the body condition of the animal.

Effective levels are reached in the GI system, lungs, and skin regardless of the route of administration. There is, however, a very complex interaction between pharmacokinetic compartments and the quantitative and qualitative availability of drug/metabolite in one compartment. For example, the association of macrocyclic lactones with digesta affects absorption; systemic availability and elimination of ivermectin given PO may differ significantly with feed quantity or composition in sheep. Also, the practice of feed withdrawal before PO treatment broadens the pharmacokinetic profile, significantly increasing anthelmintic efficacy.

Environmental Effects

Although there has long been concern over the use of chemical additives in livestock

feed (eg, potential consequences of insect-free manure), the effects on nontarget dung insects and dung dispersal primarily became a concern with the macrocyclic lactones. The commercially available macrocyclic lactones are primarily excreted in the feces, and a broad range of insecticidal activities has been observed against dung-inhabiting insect species.

Extensive fate and effects studies have been conducted with the macrocyclic lactones, with most data reported for ivermectin. Ivermectin in feces or soil degrades at a slow but significant rate. In a northern hemisphere winter environment, decomposition is slow (half-life of 91–217 days); when exposed to an outdoor summer environment, ivermectin in soil has a half-life of 7–14 days.

Although macrocyclic lactones are highly toxic to some species of aquatic organisms, their tight soil-binding mitigates against aquatic exposure via run-off or leaching. Macrocyclic lactones have little adverse effect on freshwater algae and virtually none on germination or growth of plants; however, residues in animal feces have the potential to affect arthropod development in a variety of ways. The larvae of cyclorhaphous Diptera are generally more sensitive to ivermectin and other macrocyclic lactones than are Coleopteran larvae. Mature adult Coleoptera are usually unaffected by macrocyclic lactone residues found in dung, probably because they are exposed to less macrocyclic lactone residue than their bulk-feeding larvae. Overall, the commercially available milbemycins appear to be less harmful to fly and beetle larvae tested than the avermectins. There is no evidence that ivermectin residues exert any direct effect on the development or survival of earthworms; however, effects on other dung-feeding organisms, in particular fly and beetle larvae, may disturb the processes of succession.

Although macrocyclic lactones have the potential to disrupt the ecology of dung fauna if given in persistent formulations or sustained-release devices, there is no evidence for long-term adverse effects of macrocyclic lactone residues on the degradation of dung pats or on the accumulation of dung on pasture. In most husbandry systems, a large proportion of the feces will not contain residues of macrocyclic lactones, thus providing a large reservoir of safe habitat for dung insects. Therefore, it is unlikely that use of macrocyclic lactones will have a significant ecotoxicologic impact on a global or regional scale.

Persistent Efficacy

A single therapeutic dose of an avermectin can persist in concentrations sufficient to be effective against susceptible nematode infections for prolonged periods. The clinical significance of prolonged efficacy is important. Sustained availability protects animals from reinfection by some nematode (and arthropod) species for several weeks, which helps control pests that intermittently or constantly challenge livestock. Large variations in the persistent efficacy of a particular macrocyclic lactone against a particular worm species have been reported. Potential reasons for these variable results include study design and host- and parasite-related factors. Persistent efficacy has been investigated mainly against the three major cattle nematodes *Ostertagia ostertagi*, *Cooperia oncophora*, and *Dictyocaulus viviparus*, and the sheep nematodes *Haemonchus contortus* and *Teladorsagia circumcincta*. The duration of persistent efficacy varies according to the macrocyclic lactone and formulation used and may be (excluding specific long-acting formulations) 14–45 days for *Ostertagia*, 0–35 days for *Cooperia*, and 21–42 days for *Dictyocaulus*. The persistent efficacy of oral moxidectin (2–5 wk) gives it a special role in control of haemonchosis and *T. circumcincta* in sheep and in resistance development.

Cattle: Ivermectin, eprinomectin, abamectin, doramectin, and moxidectin are variously available as PO, SC, and pour-on formulations for use in cattle. The SC and PO formulations are given at 0.2 mg/kg, whereas the pour-on formulation is used at 0.5 mg/kg. Topical administration (ie, pour-on formulations) is more convenient but results are more variable between animals than when administration is SC or PO. Grooming behavior of cattle has a major influence on the plasma disposition of topical macrocyclic lactones. Undesirable subtherapeutic concentrations in both treated and untreated cattle may contribute to development of drug resistance.

An oil-based, long-acting formulation of ivermectin (3.15% w/v ivermectin) is available in Brazil and most Latin American and African countries. One low-volume SC dose (1 mL/50 kg, equivalent to ivermectin at 630 mcg/kg) effectively treats and prophylactically controls many internal and external parasites of cattle for up to 77 days. A long-acting parenteral formulation for moxidectin has also been developed. The injectable solution (1 mg/kg, SC,

behind the ear) is an oil-based formulation containing 10% moxidectin; it is registered in Latin America, Australasia, and some European countries. In controlled studies, the periods of protection against some nematode infections using this long-acting moxidectin formulation were 90–150 days according to the species. Recently, a long-acting injectable formulation of eprinomectin (1 mg/kg, SC, in front of the shoulder) was registered for use in cattle. Treatment provides persistent parasite control for 100–150 days, depending on parasite species.

The macrocyclic lactones have a very high (>98%) efficacy against all stages (including inhibited forms) of the common cattle nematodes. The least susceptible nematodes are *Cooperia* and *Nematodirus* spp. Because of their high potency and elimination through milk, the macrocyclic lactones are not recommended for use in animals that produce milk for human consumption. Eprinomectin and moxidectin pour-ons are exceptions and have no milk withdrawal time in many countries.

A wide range of effective chemoprophylactic systems has been developed to prevent outbreaks of parasitic gastroenteritis and control infections in first-season grazing calves. Strategic anthelmintic medication during the first half of the grazing season, using carefully timed administration of macrocyclic lactones, has proved to be highly effective in western Europe for the control of GI nematodes of grazing calves during their first year. Because of differences in management, pasture infectivity, and climate, it is difficult to identify which program is most effective. Any chemoprophylactic program should be beneficial, as long as it is adapted to the epidemiologic situation and farm management.

Small Ruminants: Ivermectin, doramectin, and moxidectin are variously available as PO, SC, and IM formulations for use in small ruminants. As for cattle, the macrocyclic lactones have a very high (>98%) efficacy against all stages, including inactive forms, of the common sheep and goat nematodes. However, because of management practices leading to selection for resistance to macrocyclic lactones among nematodes of small ruminants, mainly in the southern hemisphere, their use is more problematic (see p 2644). Although moxidectin, at its recommended dose rate, can initially be effective against some parasite strains resistant to ivermectin, there is side-resistance between the

ivermectins and the milbemycins, so this efficacy is temporary. Oral moxidectin has a persistent efficacy of up to 5 wk for *Haemonchus contortus* and *Teladorsagia circumcincta*. Ivermectin controlled-release capsules have been used by sheep producers. The delivery rate, maintained for 100 days, is 0.8 mg ivermectin/day for sheep 20–40 kg in weight and 1.6 mg/day for sheep weighing 41–80 kg.

Swine: In pigs, ivermectin and doramectin are given at 0.3 mg/kg body wt, SC, or ivermectin is given in feed for 7 days at 0.1 mg/kg body wt/day for the treatment of all adult and larval stages of the common swine parasites, including the kidney worm *Stephanurus*. The exception is *Trichuris suis*, in which efficacy is ~80%.

Horses: Ivermectin and moxidectin are the two most common macrocyclic lactones available for use in horses. In certain regions, abamectin is also available. Ivermectin and abamectin are used in horses at a dosage of 200 mcg/kg, whereas moxidectin is used at 400 mcg/kg. Ivermectin, abamectin, and moxidectin are effective against a broad range of adult and migrating larval stages of nematode (including large and small strongyles) and arthropod (*Gasterophilus* spp) parasites. The only reported difference in efficacy of the two products is that at therapeutic dosages, ivermectin has not shown significant efficacy against the arrested stages and intramucosal developing stages of the cyathostomes, and moxidectin appears less potent against stomach bots (*Gasterophilus* spp). The persistence of moxidectin in circulation can provide horses with 2–3 wk of protection from infective cyathostome larvae. Moxidectin and ivermectin may not be the drugs of choice to treat infections with *Parascaris equorum* because of emerging resistance.

Dogs and Cats: Ivermectin, selamectin, moxidectin, and milbemycin oxime may be used in dogs for the prevention of heartworm disease and control of GI roundworms. Many canine parasites are susceptible to ivermectin at the dosages used in other animals; however, because some dogs are adversely affected at these levels, ivermectin is used in dogs at 6 mcg/kg body wt, PO, given at 1-mo intervals, to prevent development of *Dirofilaria immitis*, the cause of heartworm disease. At higher dosages (>100 mcg/kg), some Collies and individual dogs of other breeds

are adversely affected by ivermectin. At a dosage of 0.5 mg/kg, PO, milbemycin oxime is used for prevention of heartworm infection and for treatment of hookworms, ascarids, and whipworms in dogs. Moxidectin is also effective for prevention of heartworm infection at a dose rate of 3 mcg/kg, PO. The safety of milbemycin and moxidectin in dogs, including those sensitive to macrocyclic lactones, appears to be similar to that of ivermectin.

Selamectin, an avermectin monosaccharide, and moxidectin are available in topical formulations. Selamectin and moxidectin are also true endectocides at their recommended dosages, because their activity encompasses common intestinal nematodes (eg, *Toxocara*), heartworms, and external parasites (fleas, biting lice, and mites).

Other Species: Ivermectin and other avermectin/milbemycin compounds have been used extensively as antiparasitic agents in a wide variety of exotic pets, including ferrets, rabbits, rodents, birds, and reptiles. Although the activity of these compounds was first established in laboratory animal parasite systems, their use in rodents and other exotic pets is extra-label, and treatment protocols are often established through empirical clinical experience rather than controlled studies.

SALICYLANILIDES, SUBSTITUTED PHENOLS, AND AROMATIC AMIDE

The members of this chemical grouping include salicylanilides (brotianide, clioxanide, closantel, niclosamide, oxyclozanide, rafoxanide), substituted phenols (bithionol, disophenol, hexachlorophene, niclofolan, menichlopholan, nitroxylin), and the aromatic amide diamfenetide (diamphenethide). All members of these groups are active mainly against adult stages of liver flukes. They are used extensively against fasciolosis and haemonchosis in sheep and cattle. Diamfenetide is unique in that it has exceptionally high activity against the youngest immature stages of the liver fluke in sheep, with a diminution of activity as the flukes mature. The lowered efficacy of a number of the salicylanilides and substituted phenols against immature flukes may be due to the high protein binding of these drugs in the blood. A number of these compounds, however, appear to have activity against 6-wk-old flukes in cattle and sheep, by affecting them either at the

time of administration or, more likely, by persisting in blood until the flukes start to ingest blood and become exposed to higher drug concentrations. They are all given PO, except nitroxylin, which is typically given SC.

Niclosanide is used PO to treat cestode infections (*Dipylidium caninum* and *Taenia* spp) in dogs.

PRAZIQUANTEL AND EPSIPRANTEL

Praziquantel and epsiprantel are closely related analogues that have high efficacy against cestode parasites at relatively low dose rates but no effect on nematodes.

Praziquantel PO is highly effective against cestodes of ruminants (eg, *Moniezia* spp, *Stilesia*), horses (*Anoplocephala perfoliata*), dogs, cats, and poultry. The PO (5 mg/kg), SC (5.8 mg/kg), or spot-on (cats, 12 mg/kg) administration of praziquantel in dogs and cats is 100% effective against *Dipylidium caninum*, *Taenia* spp, and *Echinococcus* spp (both adult and immature forms). Praziquantel at a dosage of 40 mg/kg is also effective against *Schistosoma* infections in cattle (and people).

Epsiprantel at 5 mg/kg is used specifically to treat the common tapeworms of dogs and cats, including adult *E. granulosus*.

AMINO-ACETONITRILE DERIVATIVES

Amino-acetonitrile derivatives are a class of synthetic compounds with high activity against GI nematodes, including isolates resistant to all other commercially available broad-spectrum anthelmintic classes, because of their novel mode of action. Efficacy studies have shown that monepantel (2.5 mg/kg, PO) effectively controls adult and L4 stages of ruminant nematodes, including strains that are resistant or multidrug resistant to the other currently available broad-spectrum anthelmintic classes.

CYCLIC OCTADESIPEPTIDES

Emodepside has demonstrated anthelmintic activity in studies conducted in sheep, cattle, horses, and dogs directed against trichostrongyles, roundworms, hookworms, whipworms, large and small strongyles, and lungworms. Emodepside has been shown to possess resistance-breaking properties against certain

ivermectin-, benzimidazole-, and levamisole-resistant nematode strains in sheep and an ivermectin-resistant nematode isolate in cattle. Emodepside is currently available in some countries in combination with praziquantel (for treatment of cestode infections) as a topical formulation (3 mg/kg) for the treatment of ascarids and hookworms in cats (including larval stages) and as an oral formulation (1 mg/kg) for the treatment of ascarids, hookworms, and *Trichuris* in dogs (including larval stages). For dogs, emodepside is also available in combination with toltrazuril as an oral suspension for coccidia and GI nematode control.

SPIROINDOLES

Derquantel has been approved as a combination anthelmintic product with abamectin. By adding abamectin to derquantel, the spectrum of parasite species against which this combination exhibits $\geq 95\%$ efficacy is significantly increased. At the dose rate selected for the combination product, derquantel has excellent anthelmintic activity against the adult and LA stages of *Trichostrongylus* spp and *Nematodirus* spp and the adult stage of *Haemonchus* spp, and has demonstrated variable efficacy against *Teladorsagia circumcincta* and the LA stages of *H. contortus*.

MISCELLANEOUS ANTHELMINTICS

Piperazine is rapidly absorbed from the GI tract, and piperazine base can be detected in the urine as early as 30 min after administration. The excretion rate is maximal at 1–8 hr, and excretion is practically complete within 24 hr. The spectrum of activity of piperazine is largely against ascarid parasites in all animal species (including people). The safety margin is wide.

Diethylcarbamazine (DEC), a derivative of piperazine, also acts to paralyze nematodes by interfering with nerve function. Historically, DEC was widely used for heartworm prevention in dogs. It was given daily PO throughout the mosquito season to prevent patent infections. Before DEC use, dogs must first be cleared of adult heartworms and microfilariae to avoid an often fatal reaction. DEC has also been used to treat prepatent *Dictyocaulus viviparus* infections (see LUNGWORM INFECTION, p 1421) in cattle, although it is relatively ineffective against the adult worms. It is routinely given IM at 22 mg/kg body wt for 3 consecutive

days, although it is reported that one injection at 44 mg/kg provides better relief of clinical signs.

Clorsulon is a sulfonamide given PO as a suspension for infections with (mainly) adult liver flukes in sheep and cattle and as a SC injection for cattle, in combination with ivermectin. In plasma, clorsulon is bound to protein and, when ingested by liver flukes, inhibits enzymes of the glycolytic pathway. Clorsulon has a wide safety margin and is licensed for use in some countries (eg, Australia, Europe) in lactating dairy cows producing milk for human consumption. It is not licensed in the USA.

Bunamidine is an anticestodal compound. It is used in small animals and is most effective if given after fasting. It is absorbed and metabolized in the liver and leads to digestion of tapeworms in the gut of the host. Vomiting and mild diarrhea may be seen, and exercise or excitement should be avoided in dogs soon after administration.

Nitroscanate, like the substituted phenols, probably acts by uncoupling oxidative phosphorylation. It is used in small animals against *Toxocara*, *Toxascaris*, *Taenia*, *Dipylidium*, *Ancylostoma*, *Uncinaria*, and *Echinococcus* spp. Vomiting occasionally occurs after treatment.

A number of organophosphates have been used as anthelmintics; however, because of their relative toxicity, limited efficacy against immature stages, narrow margin of safety, and contamination of the environment through fecal excretion, their use has declined. Dichlorvos is used as an anthelmintic in horses, pigs, dogs, and cats; trichlorfon in horses against bots, ascarids, and oxyurids; and coumaphos, crufomate, haloxon, and naphthalophos in ruminants. Because of its high volatility, dichlorvos is a particularly versatile organophosphate that can be incorporated as a plasticizer in vinyl resin pellets; it is released slowly from the inert pellets as they pass through the GI tract, providing a therapeutic concentration along the tract. Dichlorvos is particularly useful in pigs against all major adult nematodes and was one of the first broad-spectrum anthelmintics to be used in this species. There is little or no activity against larval migrating nematodes.

COMBINATION ANTHELMINTICS

The principle that combinations of chemotherapeutic agents benefit animals by maintaining drug efficacy in the presence of resistance has been repeatedly

demonstrated for diverse pathogens and builds on knowledge gained from insecticide, pesticide, and herbicide use. Also, combinations of anthelmintics are being used more and more. According to the recent guidelines of the World Association for the Advancement of Veterinary Parasitology, there are three main reasons to use fixed-dose combinations of anthelmintics:

1) To cover the desired breadth of spectrum. For example, derquantel (spiroindole class) has been approved for use in some countries as a combination anthelmintic product with abamectin (macrocyclic lactone class). The combination exhibits $\geq 95\%$ efficacy against a significantly increased spectrum of parasite species.

2) To minimize (delay) the development and spread of resistance to new and existing anthelmintic classes. Mathematical simulation studies have demonstrated that the full benefit of combination anthelmintic product therapy is realized when initial

resistance-allele frequencies are low, and that the likelihood of resistance occurring to a combination anthelmintic product will increase with increasing resistance-allele frequency to its individual constituent actives.

3) To overcome existing species-specific resistance profiles. The wide use of anthelmintic combinations, often necessitated by the very high frequency of resistance to one or more available constituent actives when used alone, has revealed no issues of special concern with the routine use of such products.

Three primary areas of concern are apparent with fixed-dose commercial anthelmintic combination products, viz, drug-drug interactions (safety and efficacy implications of pharmacokinetics and pharmacodynamics), common mechanisms of resistance, and best-practice management to ensure appropriate use for sustainability of parasite control with the products.

ANTIBACTERIAL AGENTS

β -LACTAM ANTIBIOTICS

β -Lactam antibiotics, named after the active chemical component of the drug (the 4-membered β -lactam ring), include the 6-membered ring-structured penicillins, monobactams, and carbapenems; and the 7-membered ring-structured cephalosporins and cephamycins. In addition to their chemical structure, the major difference between these two subclasses of β -lactams is their susceptibility to β -lactamase destruction, with the cephalosporins, in general, being more resistant.

Antimicrobial Activity

Mode of Action: β -Lactams impair the development of bacterial cell walls by interfering with transpeptidase enzymes responsible for the formation of the cross-links between peptidoglycan strands. These enzymes are associated with a group of proteins in both gram-positive and gram-negative bacteria called the penicillin-binding proteins (PBPs). At least nine different PBPs comprise the cell wall; different β -lactam antibiotics may target

different PBPs, accounting for differences in spectrum and resistance. During bacterial cell growth, while the peptidoglycan structure is being formed, autolysins continually cleave cell wall lattices, in anticipation of providing acceptor sites for new strands of bacterial cell synthesis. Normal bacterial growth depends on a balance between cell wall autolysis and synthesis. The β -lactam drug mimics the PBP substrate, thus inhibiting the PBP and thus cell wall synthesis. In the face of continued autolysin activity, the cell wall becomes deformed. The cell, which is generally hypertonic compared with its environment, is no longer impermeable to the flow of small molecules and is susceptible to osmotic lysis. The effect of the β -lactams when present in sufficient concentrations is generally bactericidal toward most bacteria (an exception is in listeriosis for which penicillins are bacteriostatic and cephalosporins are ineffective). However, at subinhibitory concentrations, β -lactam antibiotics do exert residual effects on bacterial structure and function that, in turn, promote host-mediated cell death.

Some bacterial isolates, when treated with inhibitors of cell-wall synthesis, undergo inhibition of growth but not lysis at usual concentrations. These "tolerant" organisms are defective in their production or use of autolytic enzymes and can survive exposure to β -lactam antibiotics. Clinically, relapses and failures in serious infections due to tolerant organisms may be prevented by the frequently synergistic effect of the aminoglycosides with β -lactam antibiotics. As with other bactericidal drugs, β -lactams are most effective during the log phase of growth. In any bacterial population, a few organisms will always be quiescent. Because the β -lactams are active against only growing bacteria, the static organisms are unaffected and may persist. These "persisters" may then develop normally after the antibiotic is removed.

β -Lactam antibiotics have little influence on formed bacterial cell walls, and even susceptible organisms must be actively multiplying or growing. β -Lactams are most active during the logarithmic phase of bacterial growth. They also tend to be somewhat more active in a slightly acidic environment (pH 5.5–6.5), perhaps because of enhanced membrane penetration. They also are likely to be less effective in the presence of hypertonic tissues.

Efficacy of the β -lactams is related to the time that plasma or tissue drug concentrations exceed the minimum inhibitory concentration (MIC) of the infecting organism ($T > \text{MIC}$). Generally, concentrations should remain above the MIC for approximately 25% (carbapenems) to 100% (amoxicillin) of the dosing interval.

Bacterial Resistance: Only microorganisms that have cell walls are susceptible to the action of β -lactam antibiotics. Within this range of bacteria, resistance to β -lactams is well recognized and takes a number of forms.

Permeability Barrier: In gram positive organisms, capsular materials may hinder access to the cytoplasmic membrane, but this rarely limits the diffusion of the cell-wall inhibitors. Gram-negative bacteria have a restricting sieving mechanism (porins) in their outer membranes (external cell wall), which reduces the penetration of several types of antibiotics. Different species of gram-negative bacteria exhibit varying permeability barriers to β -lactam antibiotics, and these impair access of the antibiotics to the membrane-associated binding proteins. For example, the permeability barrier of *Haemophilus*

influenzae is readily crossed by β -lactam antibiotics, *Escherichia coli* presents a greater obstacle to these agents, and the outer membranes of *Pseudomonas aeruginosa* are penetrated with great difficulty by most β -lactam compounds. Penicillins, aminopenicillins, first- and second-generation cephalosporins, and selected other β -lactams cannot penetrate the outer membrane of *P. aeruginosa*. In addition, porins are frequently associated with efflux proteins that effectively remove drug that has successfully penetrated the lipopolysaccharide covering of gram-negative organisms.

The chemical nature of β -lactams (penicillins, cephalosporins, and the β -lactamase inhibitors), as well as their concentration gradients, also greatly influence their penetration of bacteria to their targets at the surface of the cytoplasmic membrane, giving rise to the differences between antibacterial spectra of the various classes of penicillin. β -Lactams are often used in combination with other antibiotics that disrupt the integrity of the membranes and thereby facilitate access by β -lactams. The genetic loci controlling permeability generally have been considered to be chromosomally located, but they also may be plasmid-specified genes.

β -Lactamase Resistance: The most important mechanism of bacterial resistance to β -lactam antibiotics is enzymatic inactivation by β -lactamases by cleavage of the 4-member β -lactam ring. Cleavage results in the inability of the drugs to bind to the target PBPs. There currently are >800 different β -lactamases, representing six major classes, with the enzyme varying with the organism and drugs targeted varying with the enzyme. The increase in the number of enzymes reflects, in part, pressure brought with the increasingly widespread use of β -lactams and the continued manipulation of the drugs in an attempt to circumvent bacterial β -lactamase production. For example, the addition of larger R groups on the β -lactam structure rendered cephalosporins to be resistant to penicillinases. However, cephalosporinases emerged with continued use of first-generation cephalosporins. Second- and third-generation cephalosporins reflect modifications, including larger R groups that hindered β -lactamase access to the β -lactam ring. Inhibitors of β -lactamases (clavulanic acid, sulbactam) were added to minimize penicillin destruction. As a result, newer β -lactamases emerged. Approval and use of third-generation cephalosporins have been

associated with emergence of extended-spectrum β -lactamases (ESBLs), particularly by *E. coli*, *Klebsiella*, and *Proteus*, that target third-generation cephalosporins (but not cephamycins such as ceftiofur). In contrast, carbapenems (imipenem and meropenem) are not subject to ESBLs that target third-generation cephalosporins, but they are subjected to carbapenemases. β -Lactamases do not discriminate among the drugs within class, meaning both human and veterinary drugs will be targeted. Interestingly, clavulanic acid is not susceptible to ESBLs; susceptibility data indicating resistance to cephalosporins but susceptibility to amoxicillin-clavulanic acid indicates ESBL formation.

β -Lactamases are produced by both gram-positive (*Staphylococcus aureus*, *S. epidermidis*, *S. pseudointermedius* but generally not enterococci) and gram-negative organisms. Some of these enzymes are active exclusively against penicillins, others are principally active against cephalosporins, and several types hydrolyze both equally. The type and concentration of β -lactamases are also specific to bacterial species. Gram-positive β -lactamases generally are excreted into the external environment as exoenzymes, produced in large quantity, plasmid mediated (single determinant), usually inducible (rarely constitutive), unable to initiate self-transmission (rely principally on transduction), and are active primarily against penicillins. Staphylococcal strains are the main gram-positive bacteria in which β -lactamase resistance develops, often very quickly. Gram-negative β -lactamases generally are heterogeneous (wide range), retained within the periplasmic space, produced in small quantity, often constitutive (less often inducible), able to initiate self-transmission (conjugation mechanisms), and active against both penicillins and cephalosporins. The impact of β -lactamase protectors such as clavulanic acid may not be as positive for treatment of gram-negative versus gram-positive organisms. Gram-negative bacteria capable of resistance as a result of β -lactamase production include *Escherichia*, *Haemophilus*, *Klebsiella*, *Pasteurella*, *Proteus*, *Pseudomonas*, and *Salmonella* spp; resistance may take longer to develop in some of these strains.

Specific Bacterial-binding Proteins:

Resistance to β -lactam antimicrobial agents can be acquired by alterations in the PBP targets of these drugs. A loss or decrease in affinity of crucial PBP can lead to a significant increase in resistance to β -lactams. For example, resistance of enterococci to cephalosporins appears to

reflect the lack of affinity of a PBP to this subclass of drugs. Changes in PBP-2 of *Staphylococcus* spp render the organism resistant to all β -lactams. Methicillin resistance in *Staphylococcus* spp reflects acquisition of the *mec* gene, which results in a mutation in PBP-2. As such, no β -lactam can bind to this protein, resulting in resistance to all β -lactam drugs. Problematically, genes conferring methicillin resistance may be accompanied by genes conferring multidrug resistance.

Cell Wall-deficient Microbes:

Organisms that have no cell wall, such as *Mycoplasma*, are intrinsically resistant to β -lactams. A phenotypic form of resistance can occur when spheroplasts (incomplete cell wall) or protoplasts (absence of cell wall) are present. These so-called "L-forms" must be present in a hyperosmotic environment (eg, the renal medulla) to survive; otherwise, they will lyse. The clinical significance of this form of resistance is unclear.

PENICILLINS

The penicillins are among the earliest classes of antibacterial drugs. Penicillins are divided into subclasses based on chemical structure (eg, penicillins, monobactams, and carbapenems), spectrum (narrow, broad, or extended), source (natural, semisynthetic, or synthetic), and susceptibility to β -lactamase destruction. Manipulation of some drugs has improved the spectrum, resistance to β -lactamase destruction, or clinical pharmacologic characteristics that enhance efficacy.

Classes by Spectrum

All penicillins are ineffective toward cell wall-deficient microorganisms such as *Mycoplasma* or *Chlamydia* spp.

Narrow-spectrum β -Lactamase-sensitive Penicillins:

This group includes naturally occurring penicillin G (benzylpenicillin) in its various pharmaceutical forms and a few biosynthetic acid-stable penicillins intended for oral use (penicillin V [phenoxymethyl-penicillin] and phenethicillin). Penicillins in this class are active against many gram-positive but only a limited number of gram-negative bacteria. These drugs are also effective against anaerobic organisms. They are, however, susceptible to β -lactamase (penicillinase) hydrolysis.

Penicillin G and its oral congeners (eg, penicillin V) are active against both aerobic

and anaerobic gram-positive bacteria and, with a few exceptions (*Haemophilus* and *Neisseria* spp and strains of *Bacteroides* other than *B. fragilis*), are inactive against gram-negative organisms at usual concentrations. Organisms usually sensitive in vitro to penicillin G include streptococci, penicillin-sensitive staphylococci, *Trueperella* (*Arcanobacterium*) *pyogenes*, *Clostridium* spp, *Erysipelothrix rhusiopathiae*, *Actinomyces bovis*, *Leptospira* *Canicola*, *Bacillus anthracis*, *Fusiformis nodosus*, and *Nocardia* spp.

Broad-spectrum β -Lactamase-sensitive Penicillins: Penicillins in this class are derived semisynthetically and are active against many gram-positive and gram-negative bacteria. However, they are readily destroyed by the β -lactamases (produced by many bacteria). Many members of the group are acid stable and are administered either PO or parenterally. Of those used in veterinary medicine, aminopenicillins, eg, ampicillin and amoxicillin (which may also be produced naturally), are the best known. Several ampicillin precursors more completely absorbed from the GI tract also belong to this class (eg, hetacillin, pivampicillin, talampicillin).

A large number of gram-positive and gram-negative bacteria (but not β -lactamase-producing strains) are sensitive to the semisynthetic broad-spectrum penicillins (ampicillin and amoxicillin). Susceptible genera include *Staphylococcus*, *Streptococcus*, *Trueperella*, *Clostridium*, *Escherichia*, *Klebsiella*, *Shigella*, *Salmonella*, *Proteus*, and *Pasteurella*. Although bacterial resistance is widespread, the combination of β -lactamase inhibitors and broad-spectrum penicillins markedly enhances the spectrum and efficacy against both gram-positive and gram-negative pathogens. Clavulanate-potentiated amoxicillin is an excellent example of such a synergistic association.

Mecillinam is less active than ampicillin against gram-positive bacteria but is highly active against many intestinal organisms (except *Proteus* spp) that do not produce β -lactamases.

Broad-spectrum β -Lactamase-sensitive Penicillins with Extended Spectra: Several semisynthetic broad-spectrum penicillins are also active against *Pseudomonas aeruginosa*, certain *Proteus* spp, and even strains of *Klebsiella*, *Shigella*, and *Enterobacter* spp in certain cases.

Examples of this class include carboxypenicillins (carbenicillin, its acid-stable indanyl ester, and ticarcillin), ureido-penicillins (azlocillin and mezlocillin), and piperazine penicillins (piperacillin).

The anti-*Pseudomonas* and other extended-spectrum penicillins are active against most of the usual penicillin-sensitive bacteria. They often have a degree of β -lactamase resistance and are usually active against one or more characteristic penicillin-resistant organisms. Yet, as a class, they remain susceptible to destruction by β -lactamases. Examples include the use of carbenicillin, ticarcillin, and piperacillin against *P. aeruginosa* and several *Proteus* strains, and the use of piperacillin against *P. aeruginosa*, several *Shigella* and *Proteus* strains, and some *Citrobacter* and *Enterobacter* spp. *Streptococcus faecalis* is often resistant to these new extended-spectrum penicillins. Imipenem and meropenem are relatively resistant to β -lactamase destruction. Their spectrum includes a wide variety of aerobic and anaerobic microorganisms, including most strains of *Pseudomonas*, streptococci, enterococci, staphylococci, and *Listeria*. Anaerobes, including *Bacteroides fragilis*, are highly susceptible.

β -Lactamase-protected Penicillins:

Several naturally occurring and semisynthetic compounds can inhibit many of the β -lactamase enzymes produced by penicillin-resistant bacteria. When used in combination with broad- or extended-spectrum penicillins, there is a notable synergistic effect because the active penicillin is protected from enzymatic hydrolysis—and thus is fully active against a wide variety of previously resistant bacteria. Examples of this chemotherapeutic approach include clavulanate-potentiated amoxicillin and ticarcillin as well as sulbactam-potentiated ampicillin and tazobactam-potentiated piperacillin.

Narrow-spectrum β -Lactamase-resistant Penicillins:

This group, through substitution on the penicillin nucleus (6-aminopenicillanic acid), is refractory to a greater or lesser degree to the effects of various β -lactamase enzymes produced by resistant gram-positive organisms, particularly *Staphylococcus aureus*. However, penicillins in this class are not as active against many gram-positive bacteria as penicillin G and are inactive against almost all gram-negative bacteria. Acid-stable members of this group may be given orally and include

isoxazolyl penicillins, such as oxacillin, cloxacillin, dicloxacillin, and flucloxacillin. Methicillin and nafcillin are available as parenteral preparations. Temocillin is a semisynthetic penicillin that is β -lactamase stable but also active against nearly all isolates of gram-negative bacteria except *Pseudomonas* spp.

The semisynthetic β -lactamase-resistant penicillins, such as oxacillin, cloxacillin, floxacillin, and nafcillin, have spectra similar to those noted above (although often at higher MIC) but also include many of the β -lactamase-producing strains of staphylococci (especially *S aureus* and *S epidermidis*).

Carbapenems: Imipenem and meropenem are among the most active drugs against a wide variety of bacteria. Imipenem is derived from a compound produced by *Streptomyces cattleya*. Aztreonam is a related (monobactam) compound but differs from other β -lactams in that it has a second ring that is not fused to the β -lactam ring.

General Properties

Structure-activity Relationships:

The penicillins, particularly the β -lactam ring, are somewhat unstable, being sensitive to heat, light, extremes in pH, heavy metals, and oxidizing and reducing agents. Also, they often deteriorate in aqueous solution and require reconstitution with a diluent just before injection. Penicillins are poorly soluble, weak organic acids administered parenterally either as suspensions in water or oil or as water-soluble salts. For example, sodium or potassium salts of penicillin G are highly water soluble and are absorbed rapidly from injection sites, whereas organic esters in microcapsule suspension such as procaine penicillin G or benzathine penicillin G are gradually absorbed over 1–3 (or even more) days, respectively. The trihydrate forms of the semisynthetic penicillins have greater aqueous solubility than the parent compounds and are usually preferred for both parenteral and oral use.

The β -lactam nucleus that characterizes penicillins, when cleaved by a β -lactamase enzyme (penicillinase), produces penicilloic acid derivatives that are inactive but may act as the antigenic determinants for penicillin hypersensitivity. Modification of the 6-aminopenicillanic acid nucleus, either by biosynthetic or semisynthetic means, has produced the array of penicillins used clinically. These differ in their antibacterial spectra, pharmacokinetic characteristics,

and susceptibility to microbial enzymatic degradation.

Pharmacokinetic Features

The pharmacokinetics of the many penicillins differ substantially. The general guidelines below emphasize singularly significant aspects.

Absorption: Most penicillins in aqueous solution are rapidly absorbed from parenteral sites. Absorption is delayed when the inorganic penicillin salts are suspended in vegetable oil vehicles or when the sparingly soluble repository organic salts (eg, procaine penicillin G and benzathine penicillin G) are administered parenterally. Although prolonged absorption results in longer persistence of plasma and tissue drug concentrations, peak concentrations may not be sufficiently high to be effective against organisms unless MICs are low. The penicillin G repository salts should never be injected IV. Only selected penicillins are acid stable and can be administered PO at standard doses. Absorption from the upper GI tract differs markedly in amount and rate among the various penicillins. Penicillin V must be given at high oral doses. The aminopenicillins are orally bioavailable, although food impairs the absorption of ampicillin. Paracellular (as opposed to transcellular) transport may play a major role in oral absorption. The indanyl form of carbenicillin is orally bioavailable, but effective concentrations are likely to be achieved only in the urine. Serum concentrations of penicillins generally peak within 2 hr of PO administration. Penicillins may also be absorbed after intrauterine infusion. There is no information regarding bioavailability of human generic products when used off-label in veterinary patients.

Distribution: After absorption, penicillins are widely distributed in body fluids and tissues. The volume of distribution tends to reflect extracellular compartmentalization, although some penicillins (including carbapenems) penetrate tissues quite well. Potentially therapeutic concentrations of the various penicillins are generally found in the liver, bile, kidneys, intestines, muscle, and lungs, but only very low concentrations are found in poorly perfused areas such as the cornea, bronchial secretions, cartilage, and bone. The diethylamino salt of penicillin G produces particularly high concentrations in pulmonary tissue. The penicillins usually do not readily cross the

normal blood-brain, placental, mammary, or prostatic barriers unless massive doses are given or inflammation is present. Penicillins may be substrates for P-glycoprotein efflux from the CNS. Selected penicillins are able to penetrate nonchronic abscesses and pleural, peritoneal, or synovial fluids. Penicillins are reversibly and loosely bound to plasma proteins. The extent of this binding varies with particular penicillins and their concentration, eg, ampicillin is usually ~20% bound, and cloxacillin may be ~80% bound. Pregnancy increases the volume of distribution, which has the effect of lowering the concentration of drug produced by a given dose.

Biotransformation: Penicillins are generally excreted unchanged, but fractions of a given dose may undergo metabolic transformations by unknown mechanisms (usually <20% metabolized). Penicilloic acid derivatives that are formed tend to be allergenic.

Excretion: Most (60%–90%) of a parenterally administered penicillin is eliminated in the urine within a short time (eg, up to 90% of penicillin G within 6 hr), which results in high concentrations in urine. Approximately 20% of renal excretion occurs by glomerular filtration and ~80% by active tubular secretion—a process that may be deliberately inhibited (to prolong effective concentrations in the body) by probenecid and other weak organic acids. Anuria may increase the half-life of penicillin G (normally ~30 min) to 10 hr. The biliary route also may be a major excretory pathway for the broad-spectrum semisynthetic penicillins. Clearance is considerably lower in neonates than in adults. Penicillins are also eliminated in milk, although often only in trace amounts in the normal udder, and may persist for up

to 90 hr. Penicillin residues in milk also have been found after intrauterine infusion.

Pharmacokinetic Values: Selected pharmacokinetic values for some penicillins in a few species are listed in TABLE 27. Penicillins, in general, have very short elimination half-lives, which is problematic for time-dependent drugs. For example, ~90% of amoxicillin will be eliminated within 4 hr in dogs, suggesting that an 8-hr dosing interval is appropriate. Formulations that prolong absorption after IM administration are appropriate for time-dependent drugs, assuming peak concentrations surpass the MIC of the infecting microbes. Dosage modifications may be necessary because of age or disease. However, the general safety of β -lactams may negate the need for dose adjustment in all but profound renal disease.

Therapeutic Indications and Dose Rates

The penicillins are commonly used to treat or prevent local and systemic infections caused by susceptible bacteria. Several acute infectious disease syndromes are specifically responsive. Because of their synergistic interaction with other antimicrobials, they are often used as part of combination therapy. Penicillins also are used topically in the eye and ear as well as on the skin; intramammary administration is common for treatment or prevention of bovine mastitis. Amoxicillin with or without clavulanic acid is among the first-choice antimicrobials for treatment of canine or feline urinary tract infections.

A selection of general dosages for some penicillins is listed in TABLE 28. The dose rate and frequency should be adjusted as indicated by changes in MICs in target antimicrobial populations, and as necessary

TABLE 27 ELIMINATION, DISTRIBUTION, AND CLEARANCE OF PENICILLINS

Penicillin	Species	Elimination Half-life (min)	Volume of Distribution (mL/kg)	Clearance (mL/kg/min)
Penicillin G	Dogs	30	156	3.6
	Horses	38	301	5.5
Ampicillin	Dogs	48	270	3.9
Amoxicillin	Cattle	84	493	4.0
Ticarcillin	Dogs	48	347	4.9

TABLE 28 DOSAGES OF PENICILLINS

Penicillin	Dosage, Route, and Frequency
Sodium penicillin G	10,000–20,000 IU/kg, IV or IM, qid
Potassium penicillin G	25,000 IU/kg, PO, qid
Procaine penicillin G	10,000–30,000 IU/kg, IM or SC, once to twice daily
Benzathine penicillin G	10,000–40,000 IU/kg, IM (horses) or SC (cattle), every 48–72 hr
Penicillin V	15,000 IU/kg or 8–10 mg/kg, PO, tid-qid
Cloxacillin	10–25 mg/kg, IM or PO, qid
Ampicillin	5–10 mg/kg, IV, IM, or SC, bid-tid; 10–25 mg/kg, PO, bid-qid
Amoxicillin	4–10 mg/kg, IM, once to twice daily; 10–20 mg/kg, PO, bid-qid (dogs)
Sodium carbenicillin	10–20 mg/kg, IV or IM, bid-qid
Potassium clavulanate:amoxicillin (1:4)	10–20 mg/kg (amoxicillin) and 2.5–5 mg/kg (clavulanate), PO, bid-qid
Probenecid (prolongs blood concentrations of penicillins that have short plasma half-lives or that are costly)	1–2 mg/1,000 IU penicillin G (dogs), PO, qid
Amoxicillin-clavulanic acid	10–20 mg/kg, PO, bid-qid
Imepenem	1–7 mg/kg, IV or IM, bid-tid
Meropenem	12–24 mg/kg, IV or SC, bid-tid
Ticarcillin (with or without clavulanic acid)	40–110 mg/kg, IM or IV, tid-qid

to achieve and maintain an appropriate $T > MIC$ for circumstances presented in the individual animal.

Special Clinical Concerns

Adverse Effects and Toxicity: Organ toxicity is rare. Hypersensitivity reactions to penicillin as a hapten reflects, in part, formation of penicillinoic acid. Hypersensitivity (particularly in cattle) includes skin reactions, angioedema, drug fever, serum sickness, vasculitis, eosinophilia, and anaphylaxis. Cross-sensitivity among penicillins is well recognized. Intrathecal administration may result in convulsions. Guinea pigs, chinchillas, birds, snakes, and turtles are sensitive to procaine penicillin. The use of broad-spectrum penicillins may lead to superinfection, and GI disturbances may occur after PO administration of ampicillin. Potassium penicillin G should be administered IV with some caution, especially if hyperkalemia is present. The sodium salt of penicillin G may also

contribute to the sodium load in congestive heart failure.

Interactions: Active renal tubular secretion is delayed in the presence of selected organic ions, including salicylates, phenylbutazone, sulfonamides, and other weak acids. Gut-active penicillins potentiate the action of anticoagulants by depressing vitamin K production by gut flora. Absorption of ampicillin is impaired by the presence of food. β -lactams in general interact chemically with the aminoglycosides and should not be mixed in vitro. Ampicillin and penicillin G are incompatible with many other drugs and solutions and should not be mixed.

Effects on Laboratory Tests: Laboratory determinations may be altered, depending on the penicillin used. Alkaline phosphatase, AST, ALT, and eosinophil count may be increased. A false-positive Coombs' test may also result after penicillin

therapy. A positive test for urine glucose and protein is also possible. Procaine is detectable in the urine of horses for several days after administration of procaine penicillin; withdrawal time before competition may be up to 6 days.

Drug Withdrawal and Milk Discard

Times: Regulatory requirements for withdrawal times for food animals and milk discard times vary among countries. These must be followed carefully to prevent food residues and consequent public health implications. The times listed in TABLE 29 serve only as general guidelines.

CEPHALOSPORINS AND CEPHAMYCINS

The cephalosporins, and the closely related cephamycins, are similar to penicillins in several respects, sharing pharmacologic group features.

Classes and Antibacterial Spectra

Cephalosporins include cephamycins, the latter of which differ from other cephalosporins in that they contain a 7- α -methoxy group, which imparts resistance to extended-spectrum β -lactamases. The early cephalosporins differed mainly with respect to pharmacokinetic characteristics. Whereas penicillins were classified based on source (natural versus semisynthetic) and spectra, cephalosporins are classified by generations (1–4). Later generations are more resistant to β -lactam destruction and are often characterized by extended but variable spectra.

First-generation Cephalosporins:

This group includes cephalothin (no longer marketed in the USA), cephaloridine, cephapirin, cefazolin, cephalixin, cephadrine, and cefadroxil. Cephalosporins in this group are usually quite active against many gram-positive bacteria but are only moderately active against gram-negative organisms. They are ineffective against enterococci. Susceptible gram-negative bacteria include *Escherichia coli* and *Proteus*, *Klebsiella*, *Salmonella*, *Shigella*, and *Enterobacter* spp. Cefazolin is more effective against *E. coli* than cephalixin, the latter of which is minimally susceptible. Although generally less susceptible to β -lactamase destruction than penicillins, they are susceptible to cephalosporinases. They are not as effective against anaerobes as are the penicillins.

Second-generation Cephalosporins:

This group includes cefamandole, cefoxitin (a cephamycin), cefotiam, cefachlor, cefuroxime, and ceforanide. These agents are generally active against both gram-positive and gram-negative bacteria. Moreover, they are relatively resistant to β -lactamases compared with first-generation drugs. They are ineffective against enterococci, *Pseudomonas aeruginosa* (with the frequent exception of cefoxitin), *Actinobacter* spp, and many obligate anaerobes (again, cefoxitin is an exception).

Third- and Fourth-generation Cephalosporins:

The third-generation cephalosporins include ceftiofur, ceftriaxone, cefsulodin, cefotaxime, cefoperazone, moxalactam (not a true cephalosporin), and

TABLE 29 DRUG WITHDRAWAL AND MILK DISCARD TIMES OF PENICILLINS

Penicillin ^a	Species	Withdrawal Time (days)	Milk Discard Time (days)
Procaine penicillin G	Cattle	10 (at label dosage) 30 (at 20,000 IU/kg, bid)	3
	Sheep	9	
	Pigs	7	
Benzathine penicillin G	Cattle	30	
Ampicillin	Cattle	6	
	Preruminant calves	15	
Amoxicillin	Cattle	30	2

^a All administered IM

several others, including cefpodoxime and cefovecin, approved for use in dogs and for use in dogs and cats, respectively. Cefepime is a fourth-generation cephalosporin. The spectrum of third- and fourth-generation cephalosporins varies and should be confirmed based on culture and susceptibility testing before use. The spectrum of veterinary third-generation cephalosporins should not be considered extended in that efficacy often does not include *Pseudomonas* or other problematic coliforms. Ceftiofur has been specifically approved for use in cattle with bronchopneumonia, especially if caused by *Mannheimia haemolytica* or *Pasteurella multocida*. Although it is approved for use in dogs to treat urinary tract infections (injectable), other more convenient drugs are generally used. Cefpodoxime and cefovecin are particularly effective against *Staphylococcus pseudintermedius*, while retaining fair efficacy toward gram-negative organisms such as *E. coli*, *Klebsiella*, and *Proteus*. Some drugs approved for use in people have only moderate activity against gram-positive bacteria (again, enterococci are resistant) but have extensive activity against a wide variety of gram-negative bacteria, including *Pseudomonas* spp, *Proteus vulgaris*, *Enterobacter* spp, and *Citrobacter* spp (eg, cefotaxime, ceftazidime). Third- and fourth-generation cephalosporins were designed to be increasingly resistant to β -lactamases. However, differences in chemical structure have been overcome by the formation of extended-spectrum β -lactamases that target third- and fourth-generation drugs (but not, as a general rule, cephamycins). Ceftiofur is a third-generation cephalosporin with a gram-negative spectrum that is more similar to that of first-generation cephalosporins.

General Properties

The physical and chemical properties of the cephalosporins are similar to those of the penicillins, although the cephalosporins are somewhat more stable to pH and temperature changes. Cephalosporins are weak acids derived from 7-aminocephalosporanic acid. They are used either as the free base form for PO administration (if acid stable) or as sodium salts in aqueous solution for parenteral delivery (sodium salt of cephalothin contains 2.4 mEq sodium/g). Cephalosporins also contain a β -lactam nucleus susceptible to β -lactamase (cephalosporinase) hydrolysis. These β -lactamases may or may not also target penicillins. Modifica-

tions of the 7-aminocephalosporanic acid nucleus and substitutions on the sidechains by semisynthetic means have produced differences among cephalosporins in antibacterial spectra, β -lactamase sensitivities, and pharmacokinetics.

Antimicrobial Activity

Bacterial Resistance: Resistance to the cephalosporins includes mechanisms described in general for β -lactams (see p 2652). Cephalosporins generally are stable against the plasmid-mediated β -lactamases produced by gram-positive bacteria such as *Staphylococcus aureus*. Several types of inducible β -lactamases produced by gram-negative organisms may be mediated by either plasmids or chromosomally and may hydrolyze either or both penicillins and cephalosporins (cross-resistance). Second- and particularly third-generation cephalosporins have greater stability against gram-negative β -lactamases. However, third- and fourth-generation drugs are susceptible to extended-spectrum β -lactamases, the presence of which on susceptibility testing is indicated based on resistance to these drugs but susceptibility to clavulanic acid.

Pharmacokinetic Features

Limited information regarding the pharmacokinetics of cephalosporins in animals is available.

Absorption: Only a few cephalosporins are acid stable and thus effective when administered PO (eg, cephalexin, cephradine, cefadroxil, cefpodoxime, and cefaclor). They are usually well absorbed, and bioavailability values are 75%–90%. There is no information regarding bioavailability of human generic products when used off-label in veterinary patients. The others are administered either IV or IM, with plasma concentrations peaking ~30 min after injection. Ceftiofur is available in a sustained-release form; its duration of action is extended by administration at the base of the ear in food animals.

Distribution: Cephalosporins are distributed into most body fluids and tissues, including kidneys, lungs, joints, bone, soft tissues, and the biliary tract, but in general, the volume of distribution is <0.3 L/kg. However, poor penetration into the CSF, even in inflammation, is a notable feature of the standard cephalosporins. Cephalosporins are substrates for

P-glycoprotein efflux from the CNS. The third-generation cephalosporins (eg, moxalactam) may achieve good penetration into the CSF. The degree of plasma-protein binding is variable (eg, 20% for cefadroxil and 80% for cefazolin). The high degree of protein binding of cefovecin (90% dogs, 99% cats) contributes to its long elimination half-life (5.5 days in dogs, 6.9 days in cats). However, drug concentrations in transudate remain above the MIC_{90} of both *Staphylococcus intermedius* and *E coli* for up to 14 days. Third- or fourth-generation cephalosporins are often able to penetrate the blood-brain barrier and are frequently indicated in bacterial meningitis caused by susceptible pathogens.

Biotransformation: Several cephalosporins (such as cephalothin, cephapirin, ceftiofur, cephacetrile, and cefotaxime) are actively deacetylated, primarily in the liver but also in other tissues. The deacetylated derivatives are much less active, with the exception of ceftiofur. Ceftiofur is metabolized to several active metabolites, including an acetylated metabolite, that can contribute significantly to efficacy. Few of the other cephalosporins are metabolized to any appreciable extent.

Excretion: Most cephalosporins, including cefpodoxime and cefovecin, are renally excreted. Tubular secretion predominates, although glomerular filtration is important in some cases (cephalexin and cefazolin). In renal failure, dosages might be reduced, although the need for doing so is not clear. Biliary

elimination of the newer cephalosporins (eg, cefoperazone) may be significant. Generally, these β -lactam antibiotics maintain effective blood concentrations for only 6–8 hr. Exceptions include ceftiofur, cefpodoxime, and cefovecin.

Pharmacokinetic Values: Plasma half-lives of cephalosporins are quite variable, being as short as 30–120 min, but generally are longer than those of penicillins. For example, the half-life of the approved cephalexin product in dogs is 7.3 hr (9 hr if given with food). Third-generation cephalosporins tend to have longer plasma half-lives in people, but this is not always the case in other animals—substantial species differences exist. A selection of pharmacokinetic values for cephalosporins is listed in TABLE 30 to serve as a guide. Dosage modifications are often required in hepatic and renal disease.

Therapeutic Indications and Dose Rates

First-generation cephalosporins have proved useful, particularly for infections involving *Staphylococcus* spp (eg, oral cephalexin for dermatitis) and for surgical prophylaxis (eg, cefazolin). However, their efficacy appears to be declining because of emerging resistance, including methicillin-resistant organisms. Ceftiofur is approved for use in a variety of food animals. It is approved for bovine respiratory disease principally caused by *Pasteurella* spp and in urinary tract infections in dogs. Use of ceftiofur for treatment of soft-tissue infections in dogs is not recommended, because proper dosages and safety have not

TABLE 30

ELIMINATION, DISTRIBUTION, AND CLEARANCE OF CEPHALOSPORINS

Cephalosporin	Species	Elimination Half-life (min)	Volume of Distribution (mL/kg)	Clearance (mL/kg/min)
Cefazolin	Horses	45	188	5.5
Cefotaxime	Sheep	25	134	9.0
Cefpodoxime	Dog	300	150	—
Cefovecin	Dog	5.5 days	90	—
Cephalexin	Dogs	7.3–9 hr	—	—
Cefadroxil	Dogs	120	—	—
	Cats	150–180	—	—
Ceftiofur	Cattle	~360	—	—

been documented. Cefpodoxime (PO) and cefovecin (SC) also have been approved for use in dogs and in dogs and cats, respectively. Cephalosporins are particularly useful to treat infections of soft tissue and bone due to bacteria that are resistant to other commonly used antibiotics. Cefazolin (IV) has been used prophylactically 1 hr before surgery. More than most penicillins, cephalosporins may penetrate tissues and fluids sufficiently (CSF being an exception for most) to be effective in management of osteomyelitis, prostatitis, and arthritis. Oral cephalosporins can be effective in management of urinary tract infections, except those due to *Pseudomonas aeruginosa*. Cephalexin should be anticipated to be ineffective against *E. coli*. Cephapirin benzathine is used for dry-cow therapy, and cephapirin sodium is used to treat mastitis. Except for cephapirin, extra-label use of cephalosporins is banned in major food animal species.

A selection of general dosages for some cephalosporins is listed in TABLE 31. The dose rate and frequency should be adjusted as needed for the individual animal.

Special Clinical Concerns

Adverse Effects and Toxicity: The approved cephalosporins are relatively nontoxic. IM injections can be painful, and repeated IV administration may lead to local phlebitis. Nausea, vomiting, and diarrhea may occasionally be seen. Hypersensitivity reactions of several forms have been seen, with cross-reactivity to penicillin allergies possible. Superinfection may arise with the use of cephalosporins, and *Pseudomonas* or *Candida* spp are likely opportunistic pathogens.

Interactions: In vitro incompatibilities are quite common for cephalosporin and cephamycin preparations; an exception exists when mixing with weak bases such as aminoglycosides. Potential pharmacokinetic interactions are similar to those of the penicillin group.

Effects on Laboratory Tests: Several laboratory determinations may be altered by the cephalosporins. Alkaline phosphatase, AST, ALT, lactate dehydrogenase, and BUN may be increased. A false-positive Coombs' test and a false-positive urine glucose may occur. Hypermnatremia may be caused by the sodium salts of various cephalosporins.

Drug Withdrawal and Milk Discard Times: Although prolonged tissue residues for most cephalosporins are not anticipated, withdrawal times are not available for most of the cephalosporins because they are not approved for use in food animals in most countries (see TABLE 32). An exception exists for ceftiofur, the withdrawal time of which varies with the product.

AMINOGLYCOSIDES

(Aminocyclitols)

Aminoglycosides are mostly bactericidal drugs that share chemical, antimicrobial, pharmacologic, and toxic characteristics.

Classes

Narrow-spectrum Aminoglycosides: Included in this group are streptomycin and dihydrostreptomycin, which are mainly active against aerobic, gram-negative bacteria.

TABLE 31 DOSAGES OF CEPHALOSPORINS

Cephalosporin ^a	Dosage, Route, and Frequency
Cephalexin	20–60 mg/kg, PO, bid–tid
Cephapirin	30 mg/kg, IM or IV, every 4–6 hr
Cefazolin	20–25 mg/kg, IM or IV, tid–qid
Cefpodoxime	8 mg/kg, SC, every 14 days
Cefovecin	5–10 mg/kg, PO, once to twice daily
Cephalexin	10–30 mg/kg, PO, tid–qid
Cefadroxil	22 mg/kg, PO, bid
Ceftiofur	1.1–2.2 mg/kg/day, IM

^a All for use in small animals, except ceftiofur, which is for use in cattle.

TABLE 32

DRUG WITHDRAWAL AND MILK DISCARD TIMES OF CEPHALOSPORINS

Cephalosporin	Withdrawal Time	Milk Discard Time
Ceftiofur	2–16 days, depending on formulation	
Sodium cephapirin (intramammary)	4 days before slaughter	4 days
Benzathine cephapirin (dry-cow treatment)	42 days after latest infusion	3 days after calving—milk not used for food

Expanded-spectrum Aminoglycosides:

Neomycin, framycetin (neomycin B), paromomycin (aminosidine), and kanamycin have broader spectra than streptomycin that includes many gram-negative aerobic bacteria, as well as synergistic activity toward selected gram-positive organisms. Gentamicin, tobramycin, amikacin (synthesized from kanamycin), sisomicin, and netilmicin are aminoglycosides with extended spectra that include *Pseudomonas aeruginosa*.

Miscellaneous Aminoglycoside

Antibiotics: The chemical structure of apramycin differs somewhat from that of the typical aminoglycosides but is similar enough to be included in this class. The structure of spectinomycin is unusual, but it is fairly comparable to other aminocyclitols with regard to its mechanism of action and antibacterial spectrum.

General Properties

Chemically, the aminoglycoside antibiotics are characterized by an aminocyclitol group, with aminosugars attached to the aminocyclitol ring in glycosidic linkage. Because of minor differences in the position of substitutions on the molecules, there may be several forms of a single aminoglycoside. For example, gentamicin is a complex of gentamicins C₁ and C₂, and neomycin is a mixture of neomycins B and C and fradiomycin. The amino groups contribute to the basic nature of this class of antibiotics, and the hydroxyl groups on the sugar moieties contribute to high aqueous solubility and poor lipid solubility. If these hydroxyl groups are removed (eg, tobramycin), antibiotic activity is markedly increased. Differences in the substitutions on the basic ring structures within the various aminoglycosides account for the relatively minor differences in antimicrobial spectra, patterns of resistance, and

toxicities. Aminoglycosides are typically quite stable. When the water solubility of an aminoglycoside is marginal, it is usually the sulfate salt that is used for PO or parenteral administration. The pK_s of these drugs are generally between 8 and 10, and as a result, they tend to be ionized at physiologic pH, which may limit drug movement, particularly in acidic environments.

Antimicrobial Activity

Mode of Action: Aminoglycosides are more effective against rapidly multiplying organisms, and they affect and ultimately destroy bacteria by several mechanisms. They need only a short contact with bacteria to kill them and, as such, are concentration dependent in their actions. Their main site of action is the membrane-associated bacterial ribosome through which they interfere with protein synthesis. To reach the ribosome, they must first cross the lipopolysaccharide (LPS) covering (gram-negative organisms), the bacterial cell wall, and finally the cell membrane. Because of the polarity of these compounds, a specialized active transport process is required.

The first concentration-dependent step requires binding of the cationic aminoglycoside to anionic components in the cell membrane. The subsequent steps are energy dependent and involve the transport of the polar, highly charged cationic aminoglycoside across the cytoplasmic membrane, followed by interaction with the ribosomes. The driving force for this transfer is probably the membrane potential. These processes are much more efficient if the energy used is aerobically generated. The efficacy of the aminoglycosides is markedly curtailed in an anaerobic environment. Aminoglycosides are associated with a postantibiotic effect in a number of bacteria, principally gram-negative (eg, *E. coli*, *Klebsiella pneumoniae*, *P. aeruginosa*).

The effect generally lasts 2–8 hr after exposure and allows for dosing intervals longer than the half-lives of the drugs.

Several features of these mechanisms are of clinical significance: 1) The antibacterial activity of the aminoglycosides depends on an effective concentration of antibiotic outside the cell. 2) Anaerobic bacteria and induced mutants are generally resistant, because they lack appropriate transport systems. 3) With low oxygen tension, as in hypoxic tissues, transfer into bacteria is diminished. 4) Divalent cations (eg, calcium and magnesium) located in the LPS, cell wall, or membrane can interfere with transport into bacteria because they can combine with the specific anionic sites and exclude the cationic aminoglycosides. 5) Passive movement of aminoglycosides across bacterial cell membranes is facilitated by an alkaline pH; a low pH may increase membrane resistance more than 100-fold. 6) Changes in osmolality also can alter the uptake of aminoglycosides. 7) Some aminoglycosides are transported more efficiently than others and thus tend to have greater antibacterial activity. 8) Synergism is common when aminoglycosides and β -lactam antibiotics (penicillins and cephalosporins) are used in combination. The cell-wall injury induced by the β -lactam compounds allows increased uptake of the aminoglycoside by the bacteria because of easier accessibility to the bacterial cell membrane.

The intracellular site of action of the aminoglycosides is the ribosome, which is irreversibly bound by aminoglycosides, particularly at the 30 S but also the 50 S subunits (which comprise the 70 S subunit). Variability occurs between aminoglycosides with respect to their affinity and degree of binding. The number of steps in protein synthesis that are affected also varies. Spectinomycin cannot induce misreading of the mRNA and often is not bactericidal, in contrast to the other bactericidal members. However, at low concentrations, all aminoglycosides may be only bacteriostatic.

A cell-membrane effect also occurs with aminoglycosides. The functional integrity of the bacterial cell membrane is lost during the late phase of the transport process, and high concentrations of aminoglycosides may cause nonspecific membrane toxicity, even to the point of bacterial cell lysis.

Efficacy of aminoglycosides is enhanced if peak plasma or tissue drug concentrations exceed MIC by 10–12 times. Once-daily dosing has been used to enhance both efficacy and safety.

Bacterial Resistance: Several mechanisms of resistance to the aminoglycoside antibiotics have been described. These may be plasmid or chromosomally mediated.

Impaired transport across the cell membrane is an inherent mechanism of nonplasmid-mediated resistance that occurs in anaerobic bacteria (eg, *Bacteroides fragilis* and *Clostridium perfringens*), because the transport process is active and oxygen-dependent. Facultative anaerobes (eg, enterobacteria and *Staphylococcus aureus*) are more resistant to the aminoglycosides when in an anaerobic environment. Impaired transport can be induced by exposure to sublethal concentrations of these antibiotics. Examples include streptomycin resistance among strains of *P aeruginosa*, low-level aminoglycoside resistance among enterococci, and gentamicin resistance in *Streptococcus faecalis*.

Impaired ribosomal binding may not be a clinically important form of single-step resistance, because generally the drugs bind to multiple sites on the ribosomes. Exceptions include *E coli* strains in which a single-step mutation prevents the binding of streptomycin to the ribosome. The same mechanism has been described in *P aeruginosa*.

Enzymatic modification of aminoglycosides may be either plasmid-encoded or chromosomally mediated. Enzymes occur in both gram-negative and gram-positive bacteria. More than 50 enzymes have been identified, with three major types, each including several subclasses: acetylating enzymes (acetyltransferases), adenylating enzymes (nucleotidyltransferases), and phosphorylating enzymes (phosphotransferases). The susceptibility of each aminoglycoside to specific enzymatic attack varies among each subclass. Although cross-resistance is common, there are differences in susceptibility patterns. Chemical modification stabilizes the drug, which decreases susceptibility to enzymatic destruction. For example, chemically modified kanamycin yields amikacin, which is more resistant to enzymatic hydrolysis.

Other mechanisms of resistance include 1) increased concentration of divalent cations (especially Ca^{2+} and Mg^{2+}), which act to repel ionized drug from the microbe, and 2) increased production by *P aeruginosa* mutants of the outer cell membrane protein, H1, resulting in resistance to gentamicin. Note that efficacy will be reduced in the presence of decreased pH (eg, acidic urine or abscesses), which increases resistance to relatively high concentrations of aminoglycosides.

Antibacterial Spectra: Streptomycin and dihydrostreptomycin (no longer available in the USA) are characterized by narrow spectra, and efficacy is limited by bacterial resistance. Gram-negative bacilli are still susceptible, including strains of *Actinomyces bovis*, *Pasteurella* spp, *E coli*, *Salmonella* spp, *Campylobacter fetus*, *Leptospira* spp, and *Brucella* spp. *Mycobacterium tuberculosis* is also sensitive to streptomycin.

The spectra of neomycin, framycetin, and kanamycin are broader, with clinical use targeting gram-negative organisms, including *E coli* and *Salmonella*, *Klebsiella*, *Enterobacter*, *Proteus*, and *Acinetobacter* spp. Aminoglycosides with spectra that include *Pseudomonas aeruginosa* (gentamicin, tobramycin, amikacin, sisomicin, and netilmicin) are also often highly effective against a wide variety of aerobic bacteria. Because of their efficacy against *P aeruginosa*, aminoglycosides might be considered higher-tier drugs. Selected staphylococci are susceptible, but treatment should be based on synergistic effects, ie, combination with other antimicrobials (eg, β -lactams). With such combination therapy, generally low doses of aminoglycosides are used. Because oxygen is necessary for active transport of drug into the microbe, caution is recommended when treating facultative anaerobes in a low-oxygen environment. Obligate anaerobic bacteria and fungi are not appreciably affected; streptococci are usually only moderately sensitive or quite resistant.

Pharmacokinetic Features

The pharmacokinetic features of the aminoglycosides are similar in most species.

Absorption: Aminoglycosides are poorly absorbed (usually <10%) from the healthy GI tract. However, permeability may be increased in the neonate and in the presence of enteritis and other pathologic changes, allowing absorption to be significantly greater. In the presence of renal failure, toxic (trough) concentrations may accumulate. Aminoglycosides can be administered slowly by bolus IV injection or SC or IM routes. Absorption from IM injection sites is rapid and nearly complete (>90% availability), except in severely hypotensive animals. Blood concentrations usually peak within 30–90 min after IM administration. Absorption after SC injection may be protracted. Absorption

after IP administration can be rapid and substantial. Short dosing intervals, including continuous infusions, are contraindicated for all aminoglycosides. Once-daily therapy is indicated for safety considerations. Serum concentrations of aminoglycosides may reach bactericidal levels after repeated intrauterine infusion, particularly in endometritis.

Distribution: Aminoglycosides are polar at physiologic pH, limiting distribution to extracellular fluids, with minimal penetration into most tissues. Exceptions include the renal cortex of the kidneys and the endolymph of the inner ear, sites at which aminoglycosides increasingly accumulate as ionization increases. The extracellular fluid compartment normally approximates 25% of body weight, but this volume can change substantially, which leads to indirectly proportional changes in the concentration of an aminoglycoside. For example, extracellular fluid space contracts with dehydration and during gram-negative sepsis, causing concentrations to increase, whereas the distribution volume of aminoglycosides increases with congestive heart failure or ascites, causing concentrations to decrease. Concentrations tend to be lower in neonates, which have a large extracellular fluid compartment relative to body weight. Aminoglycosides are not appreciably bound to plasma proteins (usually <20%). Therapeutic concentrations (~10 times the MIC of the infecting microbe) can be achieved in the synovial, pleural, and even peritoneal fluids, especially if inflammation is present. However, effective concentrations are not reached in CSF, ocular fluids, milk, intestinal fluids, or prostatic secretions. Fetal tissue and amniotic fluid concentrations are very low in most species.

Biotransformation, Excretion, and Pharmacokinetic Values: The aminoglycosides are excreted unchanged in the urine by glomerular filtration, with 80%–90% of administered drug recoverable from the urine within 24 hr of IM administration. A variable fraction of filtered aminoglycoside is absorbed onto the brush border of the proximal tubule and loop of Henle cells. Binding is facilitated by ionization. After binding, the drug is transported into the cell, sequestered in lysosomes. Rupture of lysosomes results in release into the cytosol. Excessive accumulation (mainly in the renal cortex) leads to a characteristic tubular cell necrosis. Glomerular filtration rates differ between species and are often

less in neonates, which may explain the greater sensitivity to aminoglycosides in newborn foals and puppies.

Elimination varies with glomerular filtration changes associated with cardiovascular and renal function, age, fever, and several other factors. Half-life also will vary directly and proportionately with the volume of the extracellular fluid compartment. The aminoglycosides have relatively short plasma half-lives (~1 hr in carnivores and 2–3 hr in herbivores). The elimination kinetics often follow a three-compartment model, indicating a “deep” compartment that reflects binding of drug in the renal tubular cell. Approximately 90% of the injected drug, including that within therapeutic concentrations, is excreted unchanged through the kidneys during the β phase of elimination. The remaining deep or γ phase is excreted over a protracted period, probably due to the gradual release of the antibiotic from renal intracellular binding sites (terminal elimination half-life often 20–200 hr). Concentrations in plasma during this phase are generally below what would be considered therapeutic. The

limited selection of pharmacokinetic values for two typical aminoglycosides (see TABLE 33) serves as a basis for any required dosage modifications that may be necessary because of age or renal insufficiency. The best way to alter a dosage regimen of aminoglycosides is to monitor plasma concentrations to assure that 10 times the MIC is achieved at peak concentrations, and concentrations less than target (generally <2 mcg/mL) are achieved before the next dose (“trough” concentrations).

Therapeutic Indications and Dose Rates

Despite their potential to cause nephrotoxicity, the aminoglycosides are commonly used to control local and systemic infections caused by susceptible aerobic bacteria (generally gram-negative). Several aminoglycosides are used topically in the ears and eyes and via intrauterine infusion to treat endometritis. Aminoglycosides occasionally may be infused into the udder to treat mastitis. In general, because of their concentration dependency and potential for

TABLE 33 ELIMINATION, DISTRIBUTION, AND CLEARANCE OF AMINOGLYCOSIDES

Aminoglycoside	Species	Elimination Half-life (min)	Volume of Distribution (mL/kg)	Clearance (mL/kg/min)
Gentamicin	Dogs	75	335	3.10
	Horses	110	190	1.23
	Foals	200	300	1.04
Amikacin	Dogs	60	300	3.50
	Horses	45	207	0.75
	Sheep	115	200	0.70

TABLE 34 DOSAGES OF AMINOGLYCOSIDES

Aminoglycoside	Dosage, Route, and Frequency
Gentamicin	6–12 mg/kg/day, IM or SC
Kanamycin	25–30 mg/kg/day, IM or SC
Streptomycin/dihydrostreptomycin	15–25 mg/kg/day, IM or SC
Amikacin	15–22 mg/kg/day, IM or SC
Netilmicin	6–12 mg/kg/day, IM or SC
Neomycin	15 mg/kg, PO, once to twice daily
	0.5–1 g/day/quarter (intramammary)

nephrotoxicity, aminoglycosides are administered once daily (same total daily dose; "high" dose), thus minimizing the risk of nephrotoxicity. If used at lower doses for synergistic activity against gram-positive organisms, such as staphylococci, lower doses (30%–50% of the higher dose) might be given at more frequent intervals.

A selection of general dosages for some aminoglycosides is listed in TABLE 34. The dose rate and frequency should be adjusted as needed for the individual animal.

If monitoring, two time points (a peak and a second sample 4 hr later) is ideal such that an extrapolated peak concentration can be determined, along with an elimination half-life. The peak should be collected after distribution into tissues is complete, or ~1 hr. The "trough" in this scenario should be collected 2–3 half-lives later (eg, 4–6 hr after dosing) such that concentrations will still be detectable. If a single sample is collected to determine safety, a trough concentration (just before the next dose) is indicated. Trough concentrations generally should be <2 mcg/mL. For efficacy, a 1.5–2 hr peak concentration might be collected; peak concentrations should be 10–12 times the MIC of the infecting organism. For renal function, both a peak and detectable trough (taken well before the next dose, because concentrations may not otherwise be detectable) are indicated so that a half-life, and, if IV administration is used, clearance might be calculated. As a precaution, the following general guidelines may be followed in cases of renal failure in which plasma creatinine values are increased (see TABLE 35).

The treatment interval should be increased in neonates (especially puppies and foals), in renal failure, and in obese animals. Doses may be increased in neonates or pediatric animals, in which the volume of distribution is greater than in adults, and in animals with edema,

hydrothorax, or ascites, provided their renal function is unimpaired.

Special Clinical Concerns

Adverse Effects and Toxicity:

Ototoxicity, neuromuscular blockade, and nephrotoxicity are reported most frequently; these effects may vary with the aminoglycoside and dose or interval used, but all members of the group are potentially toxic. Nephrotoxicity is of major concern and may result in renal failure due to acute tubular necrosis with secondary interstitial damage. Aminoglycosides accumulate in proximal tubular epithelial cells, where they are sequestered in lysosomes and interact with ribosomes, mitochondria, and other intracellular constituents to cause cell injury. The greater the ionization (eg, the more the amine groups and the lower the pH), the greater the active uptake. Kidneys must have a drug-free period to eliminate accumulated drugs. As such, persistence of aminoglycosides in plasma and thus urine is likely to predispose the tubular cells to toxicity, and the risk may be reduced by allowing plasma drug concentrations to drop below recommended concentrations (generally 1–2 mcg/mL) before the next dose. Nonoliguric renal failure is the usual observation; it is generally reversible if damage is not sufficiently extensive to harm the basement membrane, although recovery may be prolonged.

Renal function should be monitored during therapy; however, no indicator of renal disease is sufficiently sensitive to prevent continued damage once nephrotoxicity is detected. Polyuria, decreased urine osmolality, enzymuria, proteinuria, cylindruria, and increased fractional sodium excretion are indicative of aminoglycoside nephrotoxicity. Later, BUN and creatinine concentrations may be increased. Early changes or evidence of nephrotoxicity can

TABLE 35 DOSAGE MODIFICATIONS OF AMINOGLYCOSIDES IN RENAL FAILURE

Increase in Normal Serum or Plasma Creatinine (mg/dL)	Dose and Dosage Interval
<1	Full dose at usual dosage interval
2-fold increase	Full dose at usual dosage interval or increased to 50% plus usual dosing interval (eg, 36 hr)
3- to 4-fold increase	Full dose, doubling usual dosage interval
>4-fold increase	Aminoglycosides contraindicated

be detected in 3–5 days, with more overt signs in 7–10 days. Several factors predispose to aminoglycoside nephrotoxicosis, including age (with young [especially the newborn foal] and old animals being sensitive), compromised renal function, total dose, duration of treatment, dehydration and hypovolemia, aciduria, acidosis, hypomagnesemia, severe sepsis or endotoxemia, concurrent administration of furosemide, and exposure to other potential nephrotoxins (eg, methoxyflurane, amphotericin B, cisplatin, and perhaps some cephalosporins). In renal insufficiency, generally the interval between doses is prolonged (rather than reducing the dose) to minimize toxicity, while avoiding a negative impact on efficacy. Dosing in the morning may decrease toxicity in diurnal animals. The risk of toxicity is less in alkaline urine. Nephroactive drugs, including those that alter renal vascular response (eg, autoregulation) should be avoided or used cautiously (eg, NSAIDs, diuretics). Treatment with *N* acetylcysteine should be considered (*see* ototoxicity, below).

Aminoglycosides can cause ototoxicity, which may manifest as either auditory or vestibular dysfunction. Binding or damage to mitochondria plays a prominent role in ototoxicity. Vestibular injury leads to nystagmus, incoordination, and loss of the righting reflex. The lesion is often irreversible, although physiologic adaptation can occur. Ototoxicity is not unusual in people, but relevance to veterinary patients is not clear. Cats are particularly sensitive to the toxic vestibular effects, although occurrence at therapeutic concentrations after systemic administration is unlikely. However, aminoglycosides should not be administered topically into the ear unless the tympanic membrane is intact. Hearing impairment reflects permanent damage and loss of the hair cells in the organ of Corti. Loss of high-frequency hearing is followed by deafness, which may not be complete if sufficiently low doses or durations were used. Aminoglycosides should be avoided in working dogs that depend on hearing (eg, guide dogs). Factors increasing the risk of vestibular and cochlear damage are the same as for nephrotoxicity but also include preexisting acoustic or vestibular impairment and concurrent treatment with potentially ototoxic drugs. The ototoxic potential is greatest for gentamicin, sisomicin, and neomycin, and least for netilmicin. In people, treatment with *N*-acetylcysteine has decreased the risk of aminoglycoside ototoxicity.

All aminoglycosides, when administered in doses that result in high plasma concentrations, have been associated with muscle weakness and respiratory arrest attributable to neuromuscular blockade. The effect is more pronounced when aminoglycosides are used with other drugs that cause neuromuscular blockade and with gas anesthetics. Neomycin, kanamycin, amikacin, gentamicin, and tobramycin are listed in order of most to least potent for these neuromuscular effects. The effect is due to the chelation of calcium and competitive inhibition of the prejunctional release of acetylcholine in most instances (there are some differences among aminoglycosides). The blockade is antagonized by calcium gluconate and somewhat less consistently by neostigmine.

CNS disturbances rarely include convulsions or collapse after rapid IV administration. Other adverse effects include superinfection when used topically or PO, a malabsorption syndrome due to attenuation of intestinal villous function when used PO in neonates, occasional hypersensitivity reactions, contact dermatitis, cardiovascular depression, and inhibition of some WBC functions (eg, neutrophil migration and chemotaxis and even bactericidal activity at high concentrations).

Interactions: Enhanced nephrotoxicity may become evident with concurrent administration of aminoglycosides and other potentially nephroactive (such as diuretics) or nephrotoxic (such as NSAIDs) agents. Neuromuscular blockade is more likely when aminoglycosides are administered at the same time as skeletal muscle relaxants and gas anesthetics. Aminoglycoside ototoxicity is enhanced by the loop-acting diuretics, especially furosemide. Cardiovascular depression may be aggravated by aminoglycosides when administered to animals under halothane anesthesia. High concentrations of carbenicillin, ticarcillin, and piperacillin inactivate aminoglycosides because of direct interactions both *in vitro* and *in vivo* in the presence of renal failure. Synergistic interactions that enhance antibacterial efficacy have been documented when aminoglycosides are administered with other antimicrobials, particularly β -lactams.

Effects on Laboratory Tests: BUN, serum creatinine, serum transaminases, and alkaline phosphatase values may be increased. Proteinuria is a significant laboratory finding.

Drug Withdrawal and Milk Discard

Times: Note that withdrawal times do not exist for drugs not approved for use in food animals. Regulatory requirements for withdrawal times for food animals and milk discard times vary among countries. These must be followed carefully to prevent food residues and consequent public health implications. The times listed serve only as general guidelines (see TABLE 36).

Miscellaneous Aminocyclitol Antibiotics

Apramycin (administered orally) is used to control enteric gram-negative infections, particularly *E. coli* and salmonellae in calves and piglets. It also is active against *Proteus*, *Klebsiella*, *Brachyspira*, and *Mycoplasma* spp. There is little cross-resistance within the aminoglycosides, and plasmid-mediated resistance is yet to be confirmed. Apramycin is poorly absorbed after administration PO (<10%). It is rapidly absorbed from parenteral injection sites. Plasma concentrations peak within 1–2 hr of IM administration. Apramycin distributes only into the extracellular fluid and is excreted unchanged in the urine (95% within 4 days). The elimination half-life in calves is ~4–5 hr. Apramycin is toxic in cats but considered safe in most other species (3–6 times the recommended oral dose rarely produces toxicity). The oral dose rate is 20–40 mg/kg/day, for 5 days. The parenteral dose rate is 20 mg/kg, bid. The withdrawal time in pigs and calves (in Europe) is 28 days after oral use.

The structure of spectinomycin differs from that of the aminoglycosides, but it also binds to bacterial ribosomes and interferes with protein synthesis. However, the effect is bacteriostatic rather than bactericidal. Spectinomycin can be inactivated by an enzyme coded for by an R factor, but mutant resistance due to diminished ribosomal binding is perhaps more common. It is

active against several strains of streptococci, a wide range of gram-negative bacteria, and *Mycoplasma* spp; most *Chlamydia* spp are resistant. It is poorly absorbed from the GI tract but is rapidly absorbed after IM administration, with blood concentrations peaking within 1 hr. Like aminoglycosides, spectinomycin penetrates tissues rather poorly and distributes principally into extracellular fluid. Metabolic transformation of spectinomycin is limited, and 80% can be recovered unchanged in the urine over 24–48 hr; ~75% is eliminated by glomerular filtration in ~4 hr. At usual doses, no major toxic reactions have been reported. It is administered both PO at 20 mg/kg, bid, and IM at 5–10 mg/kg, bid. Withdrawal time for pigs is usually ~3 wk.

QUINOLONES, INCLUDING FLUOROQUINOLONES

Quinolone carboxylic acid derivatives are synthetic antimicrobial agents. Nalidixic acid and its congener oxolinic acid have been used for treatment of urinary tract infections for years, whereas flumequine has been used successfully in several countries to control intestinal infections in livestock. Many broad-spectrum antimicrobial agents have been produced by modification of the various 4-quinolone ring structures.

Classes

Known generically as quinolones or 4-quinolones, these drugs are derived from several closely related ring structures that have certain common features. Examples of the quinolone carboxylic acids and species in which they are approved are presented in TABLE 37. Nalidixic acid, considered a first-generation drug, is the earliest of the quinolones. In general, subsequent generations are based on spectrum, but this

TABLE 36 DRUG WITHDRAWAL AND MILK DISCARD TIMES OF AMINOGLYCOSIDES

Route	Approximate Withdrawal Time (days)
Oral	20–30 (3 for neonatal pigs)
Parenteral	100–200 (40 for neonatal pigs [often not approved for food animals])
Udder infusion	2–3 ^a (often not approved for food animals)

^a Milk discard time

often reflects similar changes in chemical structure. Subsequent drugs contain a fluorine group and, as such, are referred to as fluoroquinolones. Most veterinary drugs and many human drugs, including ciprofloxacin, are considered second generation. Pradofloxacin is an example of a later-generation drug approved for use in cats (USA) or dogs and cats (European Union).

General Properties

Within the diversity of their various ring structures, the quinolones have a number of common functional groups essential for their antimicrobial activity. For example, the quinolone nucleus contains a carboxylic acid group at position 3 and an exocyclic oxygen at position 4 (hence the term 4-quinolones), which are believed to be the active DNA gyrase binding sites. Various modifications have produced compounds with differing physical, chemical, pharmacokinetic, and antimicrobial properties. For example, the side chain attached to the nitrogen at position 1 affects potency. Replacement of the ethyl group at this position with a bulkier group (eg, the cyclopropyl group of ciprofloxacin and similar drugs) enhances gram-negative and positive spectra. Addition of a fluorine atom at position 6 profoundly enhances the gram-positive spectrum, whereas the addition of a (heterocyclic nitrogen-containing) piperazyl ring at position 7 enhances bacterial penetration and potency, including toward *Pseudomonas aeruginosa*. Substitutions on the piperazyl (eg, ofloxacin and its L isomer, levofloxacin; sparfloxacin) enhance gram-positive penetration, whereas substitutions at position 8 enhance

anaerobic activity (eg, sparfloxacin, pradofloxacin, moxifloxacin). If the substitution is with a methoxy group (rather than a halogen), the risk of phototoxicity is reduced.

The quinolones are amphoteric and, with a few exceptions, generally exhibit poor water solubility at pH 6–8. Although the impact on therapeutic efficacy is not clear, they appear to act as weak bases in that they are much less effective in acidic than in nonacidic urine pH. In concentrated acidic urine, some quinolones form needle-shaped crystals, although this apparently has not been reported with clinical use. Liquid formulations of various quinolones for PO or parenteral administration usually contain freely soluble salts in stable aqueous solutions. Solid formulations (eg, tablets, capsules, or boluses) contain the active ingredient either in its betaine form or, occasionally, as the hydrochloride salt.

Antimicrobial Activity

Mode of Action: The quinolones inhibit bacterial enzyme topoisomerases, including topoisomerase II (otherwise known as DNA gyrase) and topoisomerase IV. Bacterial DNA supercoils and then uncoils during replication. Supercoiling requires transient nicks that are subsequently sealed after DNA polymerase passes. Topoisomerase II allows for single strand nicks in the DNA that support coiling and uncoiling. Topoisomerase IV supports disentanglement of DNA as chromosomes separate. Inhibition of topoisomerases reduces supercoiling, resulting in disruption of the spatial arrangement of DNA, and reduces DNA repair. Mammalian topoisomerase

TABLE 37 QUINOLONES AND SPECIES APPROVALS IN THE USA

Quinolone	Species
Ciprofloxacin	Dogs, cats
Danofloxacin	Dogs, cattle
Difloxacin	Dogs
Enrofloxacin	Dogs, cats, cattle, swine
Marbofloxacin	Dogs, cats
Norfloxacin	Dogs, cats
Orbifloxacin	Dogs, cats
Pradofloxacin	Cats
Sarafloxacin	Voluntarily withdrawn

enzymes fundamentally differ from bacterial gyrase and are not susceptible to quinolone inhibition. The quinolones are usually bactericidal; susceptible organisms lose viability within 20 min of exposure to optimal concentrations of the newer fluoroquinolones. Typically, clearing of cytoplasm at the periphery of the affected bacterium is followed by lysis, rendering bacteria recognizable only as "ghosts."

Quinolones are associated with a postantibiotic effect in a number of bacteria, principally gram-negative (eg, *E coli*, *Klebsiella pneumoniae*, *P aeruginosa*). The effect generally lasts 4–8 hr after exposure.

Efficacy of the fluorinated quinolones depends on concentrations in plasma that exceed the MIC of the infecting organism by 10- to 12-fold. As such, the drugs are concentration dependent. However, efficacy also is correlated to the magnitude of the area under the inhibitory curve (AUC:MIC); as such, efficacy also takes into account elimination half-life.

The fluoroquinolones can have significant antibacterial activity at extraordinarily low concentrations, although efficacy toward some organisms (eg, *E coli*) is bimodal: some isolates are very susceptible (MIC <0.01–0.5 mcg/mL), whereas the MIC for a significant number of other isolates is very high (>64 mcg/mL). In general, MIC for most susceptible microbes, including *E coli*, *Klebsiella*, *Proteus*, *P aeruginosa*, and *Staphylococcus* have increased since the approval of the quinolones in the early 1990s.

Bacterial Resistance: Chromosomal mutational resistance to the original fluoroquinolones was considered to be low in frequency, and plasmid-mediated resistance nonexistent. However, resistance is increasingly being recognized, indicating that therapy based on culture and susceptibility is prudent. In general, cross-resistance should be anticipated among the more closely related members of this class.

Gram-negative bacteria more commonly target DNA gyrase; emerging resistance is more often associated with changes in the GyrA compared to the GyrB subunit. In contrast, the primary target of gram-positive organisms tends to be topoisomerase IV, with resistance mechanisms targeting it, followed by changes in DNA gyrase. Use of the drug selects for resistance. High-level resistance (3–4 times the breakpoint MIC) generally reflects a second-step mutation that leads to changes in the amino acid sequence of subsequent topoisomerase

targets. However, even with this second step of resistance, MIC are often below the resistant breakpoint range on which susceptibility testing is based. With the second increase in MIC, mutations in efflux pump regulators also emerge, causing marked increase in expression. As a result, high-level, multidrug resistance emerges.

Another mechanism of resistance is the combined effect of increased efflux pumps and decreased porins that act in concert to reduce intracellular concentrations. Virulence of refractory mutants may not diminish.

Note that if resistance does emerge to one fluoroquinolone, it is likely to impact all fluoroquinolones. However, resistance may be slower to emerge to newer drugs, including gemifloxacin, trovafloxacin, gatifloxacin, or pradofloxacin, because of larger side chains that facilitate binding to either DNA gyrase or topoisomerase IV.

Antimicrobial Spectra: The fluoroquinolones are active against a wide range of gram-negative organisms and several gram-positive aerobes. This includes *E coli*, *Salmonella*, *Klebsiella*, *Enterobacter*, *Proteus*, and generally *Pseudomonas aeruginosa*. The fluoroquinolones are active against intracellular pathogens, including, eg, *Brucella* spp. Quinolones also have significant activity against *Mycoplasma* and *Chlamydia* spp. Obligate anaerobes tend to be resistant to most quinolones, as are most enterococci (previously group D *Streptococcus* spp (*Enterococcus faecalis* and *Enterococcus faecium*), *Nocardia* and atypical mycobacteria may also be susceptible.

The newer third- and fourth-generation fluorinated quinolones, such as pradofloxacin, are often characterized by an effective anaerobic spectrum.

A synergistic effect has been demonstrated in vitro between quinolones and β -lactams, aminoglycosides, clindamycin, and metronidazole.

Pharmacokinetic Features

Among the few quinolones that have been studied to any degree in domestic animals, pharmacokinetic differences can markedly differ. Because of the physicochemical nature of the group, this is to be expected. A general overview follows, but some diversity should be anticipated.

Absorption: Quinolones are commonly administered PO, although forms of enrofloxacin and ciprofloxacin are available

for IV, IM, and SC (enrofloxacin) administration. Absorption into the blood after IM or SC delivery is rapid; after administration PO, blood concentrations usually peak within 1–3 hr. Bioavailability is often >80% for most quinolones, except for ciprofloxacin and in ruminants with functional forestomachs, in which bioavailability may be as low as 0–20%. The presence of food may delay absorption in monogastric animals, which may impact efficacy. The bioavailability of ciprofloxacin after administration PO in dogs is variable and can be as little as 40%; it is 0–20% in cats and horses. Marbofloxacin oral bioavailability is almost 100%.

Distribution: With few exceptions, the quinolones penetrate all tissues well and quickly. Particularly high concentrations are found in organs of elimination (kidneys, liver, and bile), but concentrations found in prostatic fluid, bone, endometrium, and CSF are also quite notable. Most quinolones also cross the placental barrier. The apparent volume of distribution of most quinolones is large. The degree of plasma-protein binding is extremely variable, from ~10% for norfloxacin to 30% for enrofloxacin in dogs and >90% for nalidixic acid. Fluorinated quinolones as a group accumulate in phagocytic WBCs.

Biotransformation: Some quinolones are eliminated unchanged (eg, ofloxacin), some are partially metabolized (eg, ciprofloxacin, enrofloxacin), and a few are completely degraded. Metabolites are sometimes active; enrofloxacin is de-ethylated to form ciprofloxacin. Characteristically, phase I reactions result in a number of primary metabolites (up to six have been described for some quinolones) that retain some antibacterial action. Conjugation with

glucuronic acid then ensues, followed by excretion. In contrast, only ~10% of marbofloxacin is metabolized.

Excretion: Renal excretion is the major route of elimination for most quinolones. Both glomerular filtration and tubular secretion are involved. Urine concentrations are often high for 24 hr after administration, and crystals may form in concentrated acidic urine. The clinical significance of this finding is unclear. In renal failure, clearance is impaired, and reductions in dose rates are essential. Biliary excretion of parent drug, as well as conjugates, is an important route of elimination in some cases (eg, ciprofloxacin, marbofloxacin, difloxacin, pefloxacin, nalidixic acid). Quinolones appear in the milk of lactating animals, often at high concentrations that persist for some time.

Pharmacokinetic Values: The clearance and volume of distributions of the drugs vary among species, resulting in differences in plasma half-lives. Plasma concentrations attained are usually directly proportional to the dose administered but also vary with volume of distribution and oral bioavailability. Package inserts should be consulted for C_{max} for those drugs approved for use in the target species.

Therapeutic Indications and Dose Rates

Quinolones are indicated for the treatment of local and systemic infections caused by susceptible microorganisms, particularly against deep-seated infections and intracellular pathogens. Therapeutic success has been obtained in respiratory, intestinal, urinary, and skin infections, as well as in bacterial prostatitis, meningoencephalitis, osteomyelitis, and arthritis.

TABLE 38 PHARMACOKINETICS OF SELECTED FLUOROQUINOLONES

Drug	Species	Elimination Half-life (hr)	Volume of Distribution (L/kg)	Clearance (mL/min/kg)
Enrofloxacin	Cats	7		4.3
	Dogs	4.4	3.7	11
	Mares	4–7	2	0.5–4
Marbofloxacin	Dogs	12	2	1.5
Orbifloxacin	Cats	4.5	1.3	
	Dogs	5.4	1.2	

Because of their lipid solubility and ability to accumulate in phagocytic WBCs, quinolones should be considered for use in infections located in tough to penetrate tissues. Therapeutic failure is likely to result with multidrug-resistant organisms; this coupled with their emerging adverse events should cause these drugs to be considered second tier for dogs and cats.

A selection of general dosages for some quinolones is listed in TABLE 39. The dose rate and frequency should be adjusted as needed for the individual animal and the MIC of the infecting organisms. Plasma drug concentrations should approximate 10 times the MIC of the infecting microbe. Higher doses are encouraged unless mitigating circumstances preclude the increase; in such instances, unless the MIC is very low, alternative antimicrobials might be considered. In dogs and cats, use ideally is based on culture and susceptibility testing when possible. Extra-label use of fluoroquinolones is prohibited in food animals.

Special Clinical Concerns

Adverse Effects and Toxicity:

Although adverse effects with the older quinolones (nalidixic and oxolinic acids) were relatively common, the newer ones seem to be well tolerated. However, several adverse effects can limit use in selected species. Retinal degeneration may occur acutely in cats, with the risk greatest for enrofloxacin; because these drugs are concentration dependent, enrofloxacin

probably should not be used in cats. The presence of renal disease may increase this risk. Pradofloxacin may be the least retinotoxic, followed by marbofloxacin and orbifloxacin, but each of these appears to be safe in cats at doses that would be necessary to achieve targeted C_{max} :MIC ratios for susceptible organisms. The mechanism is not known. Quinolones tend to be neurotoxic, and convulsions can occur at high doses. Vomiting and diarrhea rarely develop with fluoroquinolones. Dermal reactions and photosensitization have been described in people, but the occurrence seems low. Hemolytic anemia has also been seen. Administering large doses of quinolones for any length of time during pregnancy has resulted in embryonic loss and maternal toxicity. Because high prolonged dosages in growing dogs have produced cartilaginous erosions leading to permanent lameness, excessive use of quinolones should be avoided in immature animals. Quinolone administration in horses has not yet been extensively studied, but there is some indication that damage to the cartilage in weightbearing joints may be seen.

In 2008, the FDA added a "black-box" warning for seven fluoroquinolones that increased the risk of tendinitis and a tendon rupture.

An emerging toxicity associated with fluoroquinolones is mitotoxicity, ie, damage to mitochondrial topoisomerase or other mitochondrial structures. Mitochondrial effects may not emerge until some time after fluoroquinolone therapy is instituted.

TABLE 39 DOSAGES OF QUINOLONES

Quinolone ^a	Species	Dosage, Route, and Frequency
Nalidixic acid	Cats, dogs	3 mg/kg, PO, qid
Enrofloxacin	Dogs	5–20 mg/kg, PO, once to twice daily 2.5 mg/kg, SC, once, then PO
	Beef cattle (not veal or dairy)	7.5–12.5 mg/kg, SC, once 2.5–5 mg/kg/day, SC
	Pigs	2.5–5 mg/kg/day, PO or IM
	Preruminant calves	2.5–5 mg/kg/day, PO or SC
Marbofloxacin	Cats, dogs	2.75–5.5 mg/kg/day, PO
Difloxacin	Dogs	5–10 mg/kg/day, PO
Orbifloxacin	Cats, dogs	2.5–7.5 mg/kg/day, PO
Pradofloxacin	Cats	7.5 mg/kg/day, PO

^a Extra-label use of fluorinated quinolones in food-producing animals is prohibited in the USA.

Although the entirety of the clinical impact of this toxicity is not known, nor its relevance to veterinary medicine, adverse events ranging from neurologic to musculoskeletal to cardiovascular may ultimately be attributed to this effect.

Interactions: The fluorinated quinolones may be involved in a number of drug interactions. Antacids or other drugs containing multivalent cations and sucralate appear to interfere with the GI absorption of the quinolones. Nitrofurantoin impairs the efficacy of quinolones if used concurrently for urinary tract infections. Quinolones inhibit the biotransformation of methylxanthines, with theophylline being the most clinically relevant, but also including caffeine and theobromine. This is a class effect, with the risk varying among the fluoroquinolones in people. A similar ranking of risk is not available for veterinary medicine. In people, cyclosporine concentrations may also be increased by concurrent administration with fluoroquinolones, leading to prolonged and potentially toxic plasma concentrations.

Effects on Laboratory Tests: AST, ALT, alkaline phosphatase, and BUN may be increased. Urine glucose may be altered, and urinalysis may reveal needle-shaped crystals.

SULFONAMIDES AND SULFONAMIDE COMBINATIONS

Sulfonamides are the oldest and remain among the most widely used antibacterial agents in veterinary medicine, chiefly because of low cost and their relative efficacy in some common bacterial diseases. The synergistic action of sulfonamides with specific diaminopyrimidines renders these drugs much more effective than sulfonamides alone.

Classes

The many available sulfonamides and sulfonamide derivatives can be categorized into several types, based mainly on their indications and duration of action in the body. Probably the most common classification is based on water versus lipid solubility or duration of effect. Although there are many sulfonamide antimicrobials, only a few are used clinically in animals.

Standard Use Sulfonamides: In most species, members of this large group are

administered 1–4 times/day, depending on the drug, to control systemic infections caused by susceptible bacteria. In some instances, administration of the sulfonamide can be less frequent if the drug is eliminated slowly in the species being treated. Sulfonamides included in this class, depending on the species, are sulfathiazole, sulfamethazine (sulfadimidine), sulfamerazine, sulfadiazine, sulfapyridine, sulfabromomethazine, sulfaethoxypyridazine, sulfamethoxypyridazine, sulfadimethoxine, and sulfachlorpyridazine.

Highly Soluble Sulfonamides Used for Urinary Tract Infections: A few very water-soluble sulfonamides, eg, sulfisoxazole (sulfafurazole) and sulfasomidine, are rapidly excreted via the urinary tract (>90% in 24 hr) mostly in an unchanged form; because of this, they are primarily used to treat urinary tract infections.

Poorly Soluble Sulfonamides Used for Intestinal Infections: Some sulfonamide derivatives, such as sulfaguanidine, are so insoluble that they are not absorbed from the GI tract (<5%). Phthalylsulfathiazole and succinylsulfathiazole undergo bacterial hydrolysis in the lower GI tract with the consequent release of active sulfathiazole. Salicylazosulfapyridine (sulfasalazine) is also hydrolyzed in the large intestine to sulfapyridine and 5-aminosalicylic acid, an anti-inflammatory agent that might be used for management of ulcerative colitis in dogs.

Potentiated Sulfonamides: A group of **diaminopyrimidines** (trimethoprim, methoprim, ormetoprim, aditoprim, pyrimethamine) inhibit dihydrofolate reductase in bacteria and protozoa far more efficiently than in mammalian cells. Used alone, these agents are not particularly effective against bacteria, and resistance develops rapidly. However, when combined with sulfonamides, a sequential blockade of microbial enzyme systems occurs with bactericidal consequences. Examples of such potentiated sulfonamide preparations include trimethoprim/sulfadiazine (co-trimazine), trimethoprim/sulfamethoxazole (co-trimoxazole), trimethoprim/sulfadoxine (co-trimoxine), and ormetoprim/sulfadimethoxine. Sulfonamides are used in combination with pyrimethamine to treat protozoal diseases such as leishmaniasis and toxoplasmosis. (See also TABLE 41, p 2679.)

Topical Sulfonamides: Several sulfonamides are used topically for specific purposes. Sulfacetamide is not highly

efficacious but is occasionally used to treat ophthalmic infections. Mafenide and silver sulfadiazine are used on burn wounds to prevent invasion by many gram-negative and gram-positive organisms. Sulfathiazole is commonly included in wound powders for the same purpose.

General Properties

The sulfonamides are derivatives of sulfanilamide, which is the nucleus common to all. The addition or substitution of various functional groups to the amido group or in which various substitutions on other amino groups result in compounds with varying physical, chemical, pharmacologic, and antibacterial properties. Although amphoteric, sulfonamides generally behave as weak organic acids and are much more soluble in alkaline aqueous solutions than in acidic solutions. Those of therapeutic interest have pK_a values of 4.8–8.6. Water-soluble sodium or disodium salts are used for parenteral administration. Such solutions are highly alkaline, somewhat unstable, and readily precipitate with the addition of polyionic electrolytes. In a mixture of sulfonamides (eg, the sulfapyrimidine group), each component drug has its own solubility; therefore, a combination of sulfonamides is more water soluble than a single drug at the same total concentration. This is the basis of triple sulfonamide mixtures used clinically. The N-4 acetylated sulfonamides, except for the sulfapyrimidine group (sulfamethazine, sulfamerazine, sulfadiazine), are less water soluble than their nonacetylated forms. This has bearing in the development of sulfonamide crystalluria. The highly insoluble sulfonamides (phthalylsulfathiazole and succinylsulfathiazole) are retained in the lumen of the GI tract for prolonged periods and are known as “gut-active” sulfonamides. Trimethoprim and ormetoprim are basic drugs.

Antimicrobial Activity

Mode of Action: The sulfonamides are structural analogues of para-aminobenzoic acid (PABA) and competitively inhibit dihydropterate synthetase, an enzyme that facilitates PABA as a substrate for the synthesis of dihydrofolic acid (folic acid). Dihydrofolate is a precursor for formation of tetrahydrofolate (folinic acid), an essential component of the coenzymes responsible for single carbon metabolism in cells. Sulfonamides are antimetabolites that substitute for PABA, resulting in blockade

of several enzymes needed for the biogenesis of purine bases and other metabolic reactions necessary for formation of RNA. Protein synthesis, metabolic processes, and inhibition of growth and replication occur in organisms that cannot use preformed (eg, dietary) folate. The effect is bacteriostatic, although a bactericidal action is evident at the high concentrations that may be found in urine. Diaminopyrimidines such as trimethoprim inhibit dihydrofolate reductase, which is further into the folic acid synthesis pathway. The combination of a sulfonamide and a diaminopyrimidine results in synergistic, bactericidal actions on susceptible organisms; as such, the combination is referred to as a “potentiated” sulfonamide.

The optimal ratio in vitro for the combination of trimethoprim or ormetoprim and a sulfonamide depends on the type of microorganism but is usually ~1:20. However, the commercially available preparations use a ratio of 1:5 because of pharmacokinetic considerations that presumably result in the optimal ratio at the site of infection.

Sulfonamides are most effective in the early stages of acute infections when organisms are rapidly multiplying. They are not active against quiescent bacteria. Typically, there is a latent period before the effects of sulfonamide therapy become evident. This lag period occurs because the bacteria use existing stores of folic acid, folinic acid, purines, thymidine, and amino acids. Once these stores are depleted, bacteriostasis occurs. Bacterial growth can resume when the concentration of PABA increases or when the level of sulfonamide falls below an enzyme-inhibitory concentration. Because of the bacteriostatic nature of sulfonamides, adequate cellular and humoral defense mechanisms are critical for successful sulfonamide therapy when used as sole agents. Even potentiated sulfonamides, which are bactericidal, are time dependent in their antibacterial efficacy.

Although all of the sulfonamides have the same mechanism of action, differences are evident with respect to activity, pharmacokinetic fate, and even antimicrobial spectrum at usual concentrations. The differences are due to the variety of physiochemical characteristics seen among the sulfonamides.

The efficacy of sulfonamides can be reduced radically by excess PABA, folic acid, thymine, purine, methionine, plasma, blood, albumin, tissue autolysates, and endogenous protein-degradation products.

Bacterial Resistance: Resistance to sulfonamides is both chromosomally and plasmid mediated. Altered proteins such that affinity is reduced appears to be the most common mechanism of resistance. For example, in staphylococci, chromosomally mediated resistance reflects mutations in genes encoding for dihydropterate synthetase and plasmid-mediated resistance reflects mutations in dihydrofolate reductases, with the latter causing high-level resistance to trimethoprim. Staphylococci may have acquired some mechanisms of sulfonamide resistance from enterococci. Because sulfonamides act in a competitive fashion, overproduction of PABA can also preclude inhibition of dihydropterate synthetase. Alternate pathways of folic acid synthesis may also contribute to low-level resistance. Cross-resistance between sulfonamides is common. Resistance emerges gradually and is widespread in many animal populations. Plasmid-mediated sulfonamide resistance in intestinal gram-negative bacteria is often linked with ampicillin and tetracycline resistance.

Antimicrobial Spectra: The spectrum of all sulfonamides is generally the same. Sulfonamides inhibit both gram-positive and gram-negative bacteria, *Nocardia*, *Actinomyces* spp, and some protozoa such as coccidia and *Toxoplasma* spp. More active sulfonamides may include several species of *Streptococcus*, *Staphylococcus*, *Salmonella*, *Pasteurella*, and even *Escherichia coli* in their spectra. Strains of *Pseudomonas*, *Klebsiella*, *Proteus*, *Clostridium*, and *Leptospira* spp are most often highly resistant, as are rickettsiae, mycoplasmas, and most *Chlamydia*.

Pharmacokinetic Features

There are notable differences among the many sulfonamides with respect to their pharmacokinetic fate in the various species. The standard classification of short-, medium-, and long-acting sulfonamides used in human therapeutics is usually inappropriate in veterinary medicine because of species differences in disposition and elimination.

Absorption: Sulfonamides may be administered PO, IV, IP, IM, intrauterine, or topically, depending on the specific preparation. Except for the poorly absorbed sulfonamides intended for local treatment of intestinal infections, most are rapidly and completely absorbed from the GI tract of

monogastric animals. Absorption from the ruminoreticulum is delayed, especially if ruminal stasis is present. Therapeutic doses of sulfonamides are usually administered PO except in acute life-threatening infections when IV infusions are used to establish adequate blood concentrations as rapidly as possible. Sulfonamides are frequently added to drinking water or feed either for therapeutic purposes or to improve feed efficiency. A few highly water-soluble preparations may be injected IM (eg, sodium sulfadiazine) or IP (some irritation of the peritoneum can be seen). Absorption is rapid from these parenteral sites. Generally, sulfonamide solutions are too alkaline for routine parenteral use.

Trimethoprim is rapidly absorbed after administration PO (plasma concentrations peak in ~2–4 hr) except in ruminants, in which it tends to be trapped in the ruminoreticulum and appears to undergo a degree of microbial degradation.

Absorption occurs readily from parenteral injection sites; effective antibacterial concentrations are reached in <1 hr, and peak concentrations in ~4 hr.

Distribution: Sulfonamides are distributed throughout all body tissues. The distribution pattern depends on the ionization state of the sulfonamide, the vascularity of specific tissues, the presence of specific barriers to sulfonamide diffusion, and the fraction of the administered dose bound to plasma proteins. The unbound drug fraction is freely diffusible. Sulfonamides are bound to plasma proteins to a greater or lesser extent, and concentrations in pleural, peritoneal, synovial, and ocular fluids may be 50%–90% of that in blood. Sulfadiazine is ≥90% bound to plasma proteins. Concentrations in the kidneys exceed plasma concentrations, and those in the skin, liver, and lungs are only slightly less than the corresponding plasma concentrations. Concentrations in muscle and bone are ~50% of those in the plasma, and those in the CSF may be 20%–80% of blood concentrations, depending on the particular sulfonamide. Low concentrations are found in adipose tissue. After parenteral administration, sulfamethazine is found in jejunal and colonic contents at about the same concentration as in blood. Passive diffusion into milk also occurs; although the concentrations achieved are usually inadequate to control infections, sulfonamide residues may be detected in milk. Trimethoprim and ormetoprim are basic drugs that tend to accumulate in more

acidic environments such as acidic urine, milk, and ruminal fluid.

Trimethoprim diffuses extensively into tissues and body fluids. Tissue concentrations are often higher than the corresponding plasma concentrations, especially in lungs, liver, and kidneys. Approximately 30%–60% of trimethoprim is bound to plasma proteins. The extent of metabolic transformation of trimethoprim has not yet been established, although there is a suggestion that hepatic biotransformation can be extensive, at least in ruminants. This may not be the case in all species; >50% of a dose is excreted unchanged in many instances. Trimethoprim is largely excreted in the urine by glomerular filtration and tubular secretion. A substantial amount may also be found in the feces. Concentrations in milk are often 1–3.5 times higher than those in plasma.

Biotransformation: Sulfonamides are usually extensively metabolized, mainly by several oxidative pathways, acetylation, and conjugation with sulfate or glucuronic acid. Species differences are marked in this regard. The acetylated, hydroxylated, and conjugated forms have little antibacterial activity. Acetylation (poorly developed in dogs) reduces the solubility of most sulfonamides except for the sulfapyrimidine group. The hydroxylated and conjugated forms are less likely to precipitate in urine.

Excretion: Most sulfonamides are excreted primarily in the urine. Bile, feces, milk, and sweat are excretory routes of lesser significance. Glomerular filtration, active tubular secretion, and tubular reabsorption are the main processes involved. The proportion reabsorbed is influenced by the inherent lipid solubility of individual sulfonamides and their metabolites and by urinary pH. Urinary pH, renal clearance, and the concentration and solubility of the respective sulfonamides and their metabolites determine whether solubilities are exceeded and crystals precipitate. This can be prevented by alkalinizing the urine, increasing fluid intake, reducing dose rates in renal insufficiency, and using triple-sulfonamide or sulfonamide-diaminopyrimidine combinations.

Pharmacokinetic Values: There are great differences between the pharmacokinetic values of various sulfonamides in animals, and extrapolation of these values is rarely appropriate; for example, the plasma half-life of sulfadiazine is 10.1 hr in cattle

and 2.9 hr in pigs. The recommended dose rates and frequencies reflect this disparity in elimination kinetics.

The plasma half-life of trimethoprim is quite prolonged in most species; effective concentrations may be maintained for >12 hr, with the result that the frequency of administration is usually 12–24 hr. The elimination rates of trimethoprim in sheep seem to be much shorter than in monogastric species.

Therapeutic Indications and Dose Rates

The sulfonamides are commonly used to treat or prevent acute systemic or local infections. Disease syndromes treated with sulfonamides include actinobacillosis, coccidiosis, mastitis, metritis, colibacillosis, pododermatitis, polyarthritis, respiratory infections, and toxoplasmosis.

Sulfonamides are more effective when administered early in the course of a disease. Chronic infections, particularly with large amounts of exudate or tissue debris present, often are not responsive. In severe infections, the initial dose should be administered IV to reduce the lag time between dose and effect. For drugs with a long elimination half-life, the initial dose should be double the maintenance dose. Adequate drinking water should be available at all times, and urine output monitored. A course of treatment should not exceed 7 days under usual circumstances. If a favorable response is seen within 72 hr, treatment should be continued for 48 hr after remission to prevent relapse and the emergence of resistance. The ability to mount an immune response must be intact for successful sulfonamide therapy.

A selection of general dosages for some sulfonamides is listed in TABLE 40. The dose rate and frequency should be adjusted as needed for the individual animal.

Special Clinical Concerns

Adverse Effects and Toxicity: Adverse reactions to sulfonamides may be due to hypersensitivity or direct toxic effects. Possible hypersensitivity reactions include urticaria, angioedema, anaphylaxis, skin rashes, drug fever, polyarthritis, hemolytic anemia, and agranulocytosis. Keratitis sicca is a recognized adverse effect. The allergic response targets, in part, metabolites of the aryl amine of sulfonamides. Because dogs are deficient in acetylation, they may be at risk of increased formation of phase I metabolites associated with adverse effects.

TABLE 40 DOSAGES OF SULFONAMIDES

Sulfonamide	Species	Dosage, Route, and Frequency
Sulfathiazole	Horses	66 mg/kg, PO, tid
	Cattle, sheep, pigs	66 mg/kg, PO, every 4 hr
Sulfamethazine	Cattle	220 mg/kg/day, PO or IV (initial dose; half for subsequent doses)
Sulfadiazine	All	50 mg/kg, PO, bid
Sulfadimethoxine	All	55 mg/kg/day, PO (initial dose; half for subsequent doses)
Sulfaethoxypyridazine	Cattle	55 mg/kg/day, PO
	Pigs	110 mg/kg/day, PO (initial dose, half for subsequent doses)
Sulfapyridine	Cattle	132 mg/kg, PO, bid (initial dose, half for subsequent doses)
Succinylsulfathiazole	All	160 mg/kg, PO, bid (initial dose; half for subsequent doses)

Crystalluria with hematuria, and even tubular obstruction, is not common in veterinary medicine. Acute toxic manifestations may be seen after too rapid IV administration or if an excessive dose is injected. Clinical signs include muscle weakness, ataxia, blindness, and collapse. GI disturbances, in addition to nausea and vomiting, may occur when sulfonamide concentrations are sufficiently high in the tract to disturb normal microfloral balance and vitamin B synthesis. Sulfonamides depress the cellulolytic function of ruminal microflora, but the effect is usually transient (unless excessively high concentrations are reached). Several adverse effects have been reported after prolonged treatment, including bone marrow depression (aplastic anemia, granulocytopenia, thrombocytopenia), hepatitis and icterus, peripheral neuritis and myelin degeneration in the spinal cord and peripheral nerves, photosensitization, stomatitis, conjunctivitis, and keratitis sicca. Mild follicular thyroid hyperplasia may be associated with prolonged administration of sulfonamides in sensitive species such as dogs, and reversible hypothyroidism can be induced after treatment with high doses in dogs. Several sulfonamides can lead to decreased egg production and growth. Topically, the sulfonamides retard healing of uncontaminated wounds.

Up to 10 times the recommended dose of trimethoprim has been given with no adverse effects. Prolonged administration of trimethoprim at reasonably high concentra-

tions leads to maturation defects in hematopoiesis due to impaired folinic acid synthesis. This effect is readily reversible by supplementation with folinic acid.

Interactions: Sulfonamide solutions are incompatible with calcium- or other polyionic-containing fluids as well as many other preparations. Sulfonamides may be displaced from their plasma-protein-binding sites by other acidic drugs with higher binding affinities. Antacids tend to inhibit the GI absorption of sulfonamides. Alkalinization of the urine promotes sulfonamide excretion, and urinary acidification increases the risk of crystalluria. Some sulfonamides act as microsomal enzyme inhibitors, which may lead to toxic manifestations of concurrently administered drugs such as phenytoin.

Effects on Laboratory Tests: Bilirubin, BUN, bronsluphthalein (BSP®), eosinophils, methemoglobin, AST, and ALT may be increased. Platelet, RBC, and WBC counts are often decreased. Urinalysis may show a change in color, glucose, porphyrins, and urobilinogen. Sulfonamide crystals may also be found.

Regulatory Considerations and Drug Withdrawal and Milk Discard Times: Sulfonamides are among the drugs for which extra-label use restrictions exist in lactating dairy cattle. Currently allowable drugs are sulfadimethoxine, sulfabro-

TABLE 41 DOSAGES OF POTENTIATED SULFONAMIDES

Combination Sulfonamide	Dosage, Route, and Frequency
Trimethoprim/sulfadiazine	15–60 mg/kg/day, PO, IV, or IM
Ormetoprim/sulfadimethoxine	55 mg/kg/day, PO (initial dose; half for subsequent doses)

TABLE 42 DRUG WITHDRAWAL AND MILK DISCARD TIMES OF SULFONAMIDES

Sulfonamide	Species	Withdrawal Time (days)	Milk Discard Time (hr)
Sulfamethazine	Cattle	10 ^a	96
	Pigs	14	
Sulfabromethazine	Cattle	10	96
Triple sulfonamide solution ^b	Cattle	10	96
Sulfadimethoxidine	Cattle	7	60

^a 28 days for slow-release bolus

^b 8% sodium sulfamethazine, 8% sodium sulfapyridine, 8% sodium sulfathiazole

methazine, and sulfathoxy pyridazine. In addition, sulfonamide residues, particularly in swine and poultry, continue to be a focus of detection. Because of adverse effects in people, including allergic reactions, attention must be made to withdrawal times. Regulatory requirements for withdrawal times for food animals and milk discard times vary among countries and may change. These must be followed carefully to prevent food residues and consequent public health implications. There are some prohibitions on use of sulfonamides in the USA, including use in dairy cattle. The times listed in TABLE 42 serve only as general guidelines.

TETRACYCLINES

The tetracyclines are broad-spectrum antibiotics with similar antimicrobial features, but they differ somewhat from one another in terms of their spectra and pharmacokinetic disposition.

Classes

There are three naturally occurring tetracyclines (oxytetracycline, chlortetracycline, and demethylchlortetracycline) and several that are derived semisynthetically (tetracycline, rolitetracycline, methacycline, minocycline, doxycycline, lymecycline, etc). Elimination times permit a further classification into short-acting

(tetracycline, oxytetracycline, chlortetracycline), intermediate-acting (demethylchlortetracycline and methacycline), and long-acting (doxycycline and minocycline). The newest class of tetracycline-related antimicrobials are the glycylcyclines, represented by tigecycline, which contains a bulky side chain compared with minocycline.

General Properties

All of the tetracycline derivatives are crystalline, yellowish, amphoteric substances that, in aqueous solution, form salts with both acids and bases. They characteristically fluoresce when exposed to ultraviolet light. The most common salt form is the hydrochloride, except for doxycycline, which is available as doxycycline hyclate or monohydrate. The tetracyclines are stable as dry powders but not in aqueous solution, particularly at higher pH ranges (7–8.5). Preparations for parenteral administration must be carefully formulated, often in propylene glycol or polyvinyl pyrrolidone with additional dispersing agents, to provide stable solutions. Tetracyclines form poorly soluble chelates with bivalent and trivalent cations, particularly calcium, magnesium, aluminum, and iron. Doxycycline and minocycline exhibit the greatest liposolubility and better penetration of bacteria such as *Staphylococcus aureus* than does the group

TABLE 43 DRUG WITHDRAWAL AND MILK DISCARD TIMES OF POTENTIATED SULFONAMIDES

Combination Sulfonamide	Withdrawal Time (days)	Milk Discard Time (days)
Trimethoprim/sulfadiazine	3	7
Trimethoprim/sulfadoxine	5 (PO), 28 (parenteral)	

as a whole. This may contribute to their efficacy in treatment of gingival diseases that may be associated with bacterial glycolalx. Tigecycline is a glycylcycline derivative of minocycline; its large side chain decreases the risk of resistance.

Antimicrobial Activity

Mode of Action: The antimicrobial activity of tetracyclines reflects reversible binding to the bacterial 30S ribosomal subunit, and specifically at the aminoacyl-tRNA acceptor ("A") site on the mRNA ribosomal complex, thus preventing ribosomal translation. This effect also is evident in mammalian cells, although microbial cells are selectively more susceptible because of the greater concentrations seen. Tetracyclines enter microorganisms in part by diffusion and in part by an energy-dependent, carrier-mediated system responsible for the high concentrations achieved in susceptible bacteria. The tetracyclines are generally bacteriostatic, and a responsive host-defense system is essential for their successful use. At high concentrations, as may be attained in urine, they become bactericidal because the organisms seem to lose the functional integrity of the cytoplasmic membrane. Tetracyclines are more effective against multiplying microorganisms and tend to be more active at a pH of 6–6.5. Antibacterial efficacy is described as time dependent.

Bacterial Resistance: The most common mechanism by which microbes become resistant to tetracyclines is decreased accumulation of drug into previously susceptible organisms. Two mechanisms include 1) impaired uptake into bacteria, which occurs in mutant strains that do not have the necessary transport system, and 2) the much more common plasmid- or transposon-mediated acquisition of active efflux pumps. The genomes for these capabilities may be transferred either by transduction (as in *Staphylococcus aureus*)

or by conjugation (as in many enterobacteria). A second mechanism of resistance is the production of a "protective" protein that acts by either preventing binding, dislodging the bound drug, or altering the negative impact of binding on ribosomal function. Among the tetracyclines, tigecycline is characterized by less resistance due to efflux or ribosomal protection. Rarely, tetracyclines can be destroyed by acetylation. Resistance develops slowly in a multistep fashion but is widespread because of the extensive use of low concentrations of tetracyclines.

Antimicrobial Spectra: All tetracyclines are about equally active and typically have about the same broad spectrum, which comprises both aerobic and anaerobic gram-positive and gram-negative bacteria, mycoplasmas, rickettsiae, chlamydiae, and even some protozoa (amebae). Tetracyclines generally are the drug of choice to treat rickettsiae and mycoplasma. Among the susceptible organisms is *Wolbachia*, a rickettsial-like intracellular endosymbiont of nematodes, including *Diriofilaria immitis*. Strains of *Pseudomonas aeruginosa*, *Proteus*, *Serratia*, *Klebsiella*, and *Trueperella* spp frequently are resistant, as are many pathogenic *Escherichia coli* isolates. Even though there is general cross-resistance among tetracyclines, doxycycline and minocycline usually are more effective against staphylococci.

Pharmacokinetic Features

Absorption: After usual oral dosage, tetracyclines are absorbed primarily in the upper small intestine, and effective blood concentrations are reached in 2–4 hr. GI absorption can be impaired by sodium bicarbonate, aluminum hydroxide, magnesium hydroxide, iron, calcium salts, and (except for the lipid-soluble tetracyclines doxycycline and minocycline) milk and milk products. Oral bioavailability, however, can vary markedly among drugs,

with chlortetracycline being the least and doxycycline the most orally bioavailable. Tetracyclines at therapeutic concentrations should not be administered PO to ruminants: they are poorly absorbed and can substantially depress ruminal microfloral activity. Specially buffered tetracycline solutions can be administered IM and IV. Through chemical manipulation (especially choice of carrier and high magnesium content), the absorption of oxytetracycline from IM sites may be delayed, which produces a long-acting effect. Tetracyclines can also be absorbed from the uterus and udder, although plasma concentrations remain low.

Distribution: Tetracyclines distribute rapidly and extensively in the body, particularly after parenteral administration. They enter almost all tissues and body fluids; high concentrations are found in the kidneys, liver, bile, lungs, spleen, and bone. Lower concentrations are found in serosal fluids, synovia, CSF, ascitic fluid, prostatic fluid, and vitreous humor. The more lipid-soluble tetracyclines (doxycycline and minocycline) readily penetrate tissues such as the blood-brain barrier, and CSF concentrations reach ~30% of the plasma concentrations. Doxycycline is the most extensively distributed. Because tetracyclines tend to chelate calcium ions (less so for doxycycline), they are deposited irreversibly in the growing bones and in dentin and enamel of unerupted teeth of young animals, or even the fetus if transplacental passage occurs (see p 2658). Drug bound in this fashion is pharmacologically inactive. Tetracyclines are bound to plasma proteins to varying degrees (eg, oxytetracycline, 30%; tetracycline, 60%; doxycycline, 90%).

Biotransformation: Biotransformation of the tetracyclines seems to be limited in most domestic animals, and generally about one-third of a given dose is excreted unchanged. Rolitetracycline is metabolized to tetracycline. Doxycycline and minocycline may be more extensively biotransformed than other tetracyclines (up to 40% of a given dose).

Excretion: Tetracyclines are excreted via the kidneys (glomerular filtration) and the GI tract (biliary elimination and directly). Generally 50%–80% of a given dose is recoverable from the urine, although several factors may influence renal elimination, including age, route of administration, urine pH, glomerular

filtration rate, renal disease, and the particular tetracycline used. Biliary elimination is always significant, commonly being ~10%–20%, even with parenteral administration. Doxycycline appears to be eliminated through feces predominantly through intestinal cells, rather than bile. Only ~16% of an IV dose of doxycycline is eliminated unchanged in the urine of dogs. A portion of doxycycline is also renally excreted in active form in some species. For minocycline, bile appears to be the major route of excretion. Tetracyclines are also eliminated in milk; concentrations peak 6 hr after a parenteral dose, and traces are still present up to 48 hr later. Concentrations in milk usually attain ~50%–60% of the plasma concentration and are often higher in mastitic milk. Tetracyclines also are excreted in saliva and tears.

Pharmacokinetic Values: The plasma half-lives of tetracyclines are 6–12 hr and can be longer depending on age (slower elimination in animals <1 mo old), disease, and the tetracycline itself (see TABLE 44). In large animals, daily injections of standard dosages usually are sufficient to maintain effective inhibitory concentrations. Long-acting formulations of oxytetracycline, when injected IM, generally produce plasma concentrations >0.5 mcg/mL for ~72 hr. Tetracyclines usually are administered PO bid-tid (every 12–24 hr for doxycycline and minocycline).

Therapeutic Indications and Dose Rates

The tetracyclines are used to treat both systemic and local infections. However, resistance and their bacteriostatic nature suggest caution with empirical use for bacterial infections, particularly in dogs and cats. Specific conditions include infectious keratoconjunctivitis in cattle, chlamydiosis, heartwater, anaplasmosis, actinomycosis, actinobacillosis, nocardiosis (especially minocycline), ehrlichiosis (especially doxycycline), *Wolbachia*, eperythrozoonosis, and haemobartonellosis. Minocycline and doxycycline are often effective to a somewhat lesser degree against resistant strains of *Staphylococcus aureus*.

In addition to antimicrobial chemotherapy, the tetracyclines are used for other purposes. As additives in animal feeds, they serve as growth promoters. Because of the affinity of tetracyclines for bones, teeth, and necrotic tissue, they can be used to delineate tumors by fluorescence.

TABLE 44 ELIMINATION, DISTRIBUTION, AND CLEARANCE OF TETRACYCLINES

Tetracycline	Species	Elimination Half-life (hr)	Volume of Distribution (mL/kg)	Clearance (mL/kg/min)
Oxytetracycline	Dogs	6	3,000	4.23
	Calves (<3 mo old)	10–13	1,500–2,400	3.45
	Cattle	7–10	800–1,000	3.33
	Horses	8–10	1,100	2.89
Minocycline	Dogs	7	2,000	3.21
Doxycycline	Dogs	7–10	930	1.7
	Cats	5	340	1.0
	Horses	9		

Demethylchlortetracycline has been used to inhibit the action of antidiuretic hormone in cases of excessive water retention. Because of either their metallo-proteinase-inhibiting effects or their binding of calcium, they are used to “stretch” flexor digital tendons in neonatal foals. Finally, they are being used to reduce the risk of adverse events and to enhance killing of adult heartworms and/or microfilaria before adulticide therapy.

A selection of general dosages for some tetracyclines is listed in TABLE 45. The dose rate and frequency should be adjusted as needed for the individual animal.

Special Clinical Concerns

Adverse Effects and Toxicity: Because several diverse effects may result from administration of tetracyclines, caution should be exercised. Superinfection by nonsusceptible pathogens such as fungi, yeasts, and resistant bacteria is always a possibility when broad-spectrum antibiotics are used. This may lead to GI disturbances after either PO or parenteral administration or to “persistent infection” when they are applied topically (eg, in the ear). Severe and even fatal diarrhea can occur in horses receiving tetracyclines, especially if the animals are severely stressed or critically ill.

High doses administered PO to ruminants seriously disrupt microfloral activity in the rumenoreticulum, eventually producing stasis. Elimination of the gut flora in monogastric animals reduces the synthesis and availability of the B vitamins and vitamin K from the large intestine. With prolonged therapy, vitamin supplementation is a useful precaution.

Tetracyclines chelate calcium in teeth and bones; they become incorporated into these structures, inhibit calcification (eg, hypoplastic dental enamel), and cause yellowish then brownish discoloration. At extremely high concentrations, the healing processes in fractured bones is impaired.

Rapid IV injection of a tetracycline can result in hypotension and sudden collapse. This appears to be related to the ability of the tetracyclines to chelate ionized calcium, although a depressant effect by the propylene glycol carrier itself may also be involved. This effect can be avoided by slow infusion of the drug (>5 min) or by pretreatment with IV calcium gluconate.

The IV administration of undiluted propylene glycol-based preparations leads to intravascular hemolysis, which results in hemoglobinuria and possibly other reactions such as hypotension, ataxia, and CNS depression.

Because tetracyclines interfere with protein synthesis even in host cells and therefore tend to be catabolic, an increase in BUN can be expected. The combined use of glucocorticoids and tetracyclines often leads to a significant weight loss, particularly in anorectic animals.

Hepatotoxic effects due to large doses of tetracyclines have been reported in pregnant women and in other animals. The mortality rate is high.

The tetracyclines are also potentially nephrotoxic and are contraindicated (except for doxycycline) in renal insufficiency. Fatal renal failure has been reported in septicemic and endotoxemic cattle given high doses of oxytetracycline. The administration of expired tetracycline

TABLE 45 DOSAGES OF TETRACYCLINES

Tetracycline	Species	Dosage, Route, and Frequency
Tetracycline	Cats, dogs	7 mg/kg, IM or IV, bid 20 mg/kg, PO, tid
Oxytetracycline	Cats, dogs	7 mg/kg, IM or IV, bid 20 mg/kg, PO, tid
	Cattle, sheep, pigs	5–10 mg/kg/day, IM or IV
	Calves, foals, lambs, piglets	10–20 mg/kg, PO, bid-tid
	Horses	5 mg/kg, IV, once to twice daily
Doxycycline	Dogs	5–10 mg/kg/day, PO 5 mg/kg/day, IV
	Before heartworm adulticide therapy	10 mg/kg, PO, bid, for 30 days

products may lead to acute tubular nephrosis.

Swelling, necrosis, and yellow discoloration at the injection site almost inevitably are seen. Phototoxic dermatitis may occur in people treated with demethylchlortetracycline and other analogues, but this reaction is rare in other animals. Hypersensitivity reactions occur; for example, cats may develop a “drug fever” reaction, often accompanied by vomiting, diarrhea, depression, inappetence, fever, and eosinophilia.

The tetracyclines can inhibit WBC chemotaxis and phagocytosis when present in high concentrations at sites of infection. This clearly hinders normal host defense mechanisms and compounds the bacteriostatic activity of tetracyclines. The use of immunosuppressive drugs such as glucocorticoids impairs immunocompetence even further.

Doxycycline administered in tablets has been associated with esophageal erosion in cats. The incidence is reduced if administration is followed by a 5-mL volume of fluid. Doxycycline may be associated with GI upset; this might be reduced by administering the drug with food.

Interactions: Absorption of tetracyclines from the GI tract is decreased by milk and milk products (except for doxycycline and minocycline), antacids, kaolin, and iron preparations. Tetracyclines gradually lose activity when diluted in infusion fluids and exposed to ultraviolet light. Vitamins of the B-complex group, especially riboflavin, hasten this loss of activity in infusion fluids.

Tetracyclines also bind to the calcium ions in Ringer's solution.

Methoxyflurane anesthesia combined with tetracycline therapy may be nephrotoxic. Microsomal enzyme inducers such as phenobarbital and phenytoin may shorten the plasma half-lives of minocycline and doxycycline. Except for minocycline and doxycycline, the presence of food can substantially delay absorption of tetracyclines from the GI tract. The tetracyclines are less active in alkaline urine, and urine acidification can increase their antimicrobial efficacy.

Effects on Laboratory Tests: Tetracyclines may increase amylase, BUN, bromsulphthalein (BSP®), eosinophil count, AST, and ALT. Tetracyclines used in combination with diuretics are often associated with a marked rise in BUN. Cholesterol, glucose, potassium, and prothrombin time may be decreased. A false-positive urine glucose test is also possible.

Drug Withdrawal and Milk Discard Times: Regulatory requirements for withdrawal times for food animals and milk discard times vary among countries. These must be followed carefully to prevent food residues and consequent public health implications. The withdrawal times listed in TABLE 46 serve only as general guidelines.

PHENICOLS

Chloramphenicol is a highly effective and well-tolerated broad-spectrum antibiotic. However, because it causes blood

TABLE 46 DRUG WITHDRAWAL AND MILK DISCARD TIMES OF TETRACYCLINES

Tetracycline	Species	Withdrawal Time (days)
Oxytetracycline ^a	Cattle	15–22
	Pigs	22
	Poultry	5
Oxytetracycline (long acting) ^a	Cattle	28
Chlortetracycline	Cattle	10
	Pigs	1–7

^a Not for use in lactating dairy cows

dyscrasias, it is prohibited for use in food-producing animals in several countries, including the USA and Canada. Thiamphenicol is less effective but safer than chloramphenicol; florfenicol, a thiamphenicol derivative, is significantly more active in vitro than chloramphenicol against many pathogenic strains of bacteria. Florfenicol is approved for use in cattle.

General Properties

Chloramphenicol is a relatively simple neutral nitrobenzene derivative with a bitter taste. It is highly lipid soluble and is used either as the free base or in ester forms (eg, the neutral-tasting palmitate for administration PO and the water-soluble sodium succinate for parenteral injection). Chloramphenicol is a relatively stable compound and is unaffected by boiling, provided that a pH of 9 is not exceeded. The nitrophenol group of chloramphenicol is replaced by a methyl sulfonyl group for thiamphenicol and florfenicol; florfenicol also contains a fluorine molecule. These structural changes improve efficacy, reduce toxicity, and for florfenicol, the fluorine molecule reduces bacterial resistance.

Antimicrobial Activity

Mode of Action: The phenicols inhibit microbial protein synthesis by binding to the 50S subunit of the 70S ribosome and impairing peptidyl transferase activity. Because peptide-bond formation is inhibited, peptides cannot elongate. The effect is usually bacteriostatic but, at high concentrations, chloramphenicol may be bactericidal for some species. Protein synthesis is inhibited in both prokaryotic and eukaryotic (mitochondrial) ribosomes.

Bacterial Resistance: Resistance against chloramphenicol develops slowly and in a stepwise fashion. In clinical

bacterial isolates, high-level plasmid-mediated resistance reflects the production of chloramphenicol acetyltransferase (encoded for by the *cat* gene) and results in acetylation of the molecule, which can no longer bind to the ribosome. Other inactivating enzymes also may be involved. In resistant gram-negative bacteria, chloramphenicol acetyltransferase is a constitutive enzyme; in gram-positive organisms, the enzyme is inducible. The fluorine atom of florfenicol prevents acetylation, thus enhancing the efficacy of this drug. In *Pseudomonas aeruginosa* and in strains of *Proteus* and *Klebsiella* spp, resistance is also nonenzymatic and is based on an inducible permeability block that is both chromosomal and plasmid-mediated. Reduced permeability contributes to low level resistance. Very rarely, resistance may reflect altered ribosomal subunit structure and binding. Resistance to chloramphenicol often develops together with resistance to tetracycline, erythromycin, streptomycin, ampicillin, and other antibiotics because of multiple genes being carried on the same plasmid.

Antimicrobial Spectra: Many genera of gram-positive and gram-negative bacteria and several anaerobes such as *Bacteroides fragilis*, as well as *Rickettsia* and *Chlamydia* spp are susceptible. Chloramphenicol is notable for its anaerobic spectrum. Of special note is the efficacy against many *Salmonella* spp but the resistance of most strains of *P. aeruginosa*.

Pharmacokinetic Features

Absorption: Absorption occurs promptly and rapidly from the upper GI tract when chloramphenicol base is administered PO to nonruminant animals. Blood concentrations usually are maximal in 1–3 hr. Because ruminal microflora

readily reduce the nitro group, chloramphenicol is inactivated in the ruminoreticulum and is not available for absorption. The larger ester forms of chloramphenicol require hydrolysis by lipases to release the antibiotic for absorption from the GI tract; thus, the systemic availability of chloramphenicol is delayed when the palmitate and other ester preparations are used. Generic inequivalence has been seen with oral dosage forms. The presence of food and intestinal protectants does not interfere with absorption of chloramphenicol, although drugs that depress GI motility do. Florfenicol is rapidly absorbed after administration PO, although milk interferes with absorption.

Chloramphenicol sodium succinate may be injected both IV and IM. However, hydrolysis is required in the body because only free chloramphenicol base is active. The kinetics of this hydrolysis reaction may be slow and incomplete, with considerable individual and species variability. The absorption of chloramphenicol base itself from IM injection sites is notably restricted. For example, in horses, the therapeutic blood concentration of 5 mg/mL is achieved at a dosage of 50 mg/kg body wt, IM, after only 6–8 hr. Chloramphenicol base is absorbed after IP injection. Florfenicol is available as an injectable solution intended for IM use.

Distribution: Approximately 40%–60% of chloramphenicol in plasma is reversibly bound to albumin, and the free fraction readily diffuses into almost all tissues (including the brain); highest concentrations are reached in the kidneys, liver, and bile. Substantial concentrations (~50% of plasma values) are also reached in many body fluids such as the CSF and aqueous humor. Milk concentrations are ~50% those of plasma but may be higher in mastitis. Transplacental diffusion is seen in all species, with concentrations of ~75% being reached in the fetus as compared with the dam. Chloramphenicol does not attain effective concentrations in normal synovial fluid but does so in septic arthritis. The blood-prostate barrier is an exception to the extensive intracorporeal distribution of chloramphenicol, and concentrations in the inflamed prostate are low to nil. Approximately 15%–20% of peak serum concentrations are seen within abscesses. Florfenicol also penetrates most body tissues, although penetration of CSF and aqueous humor is less than that of chloramphenicol. Florfenicol does penetrate the milk of lactating cows.

Biotransformation: Unlike many other antibacterial agents, chloramphenicol undergoes extensive hepatic metabolism. Although some nitroreduction and other phase I reactions occur, free chloramphenicol is biotransformed primarily by glucuronide conjugation. Urinary products after administration of chloramphenicol sodium succinate include inactive forms, mainly the unhydrolyzed sodium succinate and the glucuronide; only 5%–15% appears as biologically active chloramphenicol.

There are several clinical concerns with respect to the biotransformation of chloramphenicol. In cats, a characteristic genetic deficiency in glucuronyl transferase activity leads to plasma half-lives that are often considerably longer than those in other species (eg, cats, 5.1 hr; ponies, 54 min), and dosages need to be adjusted accordingly. Phase I metabolism may also be deficient in cats. Very young animals frequently do not have full microsomal enzyme capabilities, and the plasma half-lives of chloramphenicol in the young (<4 wk old) of many species are often much longer than those of adults. Foals appear to be a notable exception to this generalization. Liver disease also prevents chloramphenicol from undergoing normal metabolic degradation, and active antibiotic accumulates in the body.

Excretion: The principal route of excretion of parent drug (minor) and glucuronide is renal. Free chloramphenicol and the chloramphenicol sodium succinate dosage form undergo glomerular filtration (5%–10%), whereas the glucuronide metabolite is eliminated by tubular secretion (90%–95%). Only 5%–15% of chloramphenicol is present in the urine in the active, unchanged form. The biliary route also plays a part in excretion, but enterohepatic cycling is often pronounced, and usually only a small amount of chloramphenicol is recoverable in feces. Enterohepatic cycling prolongs blood concentrations to some degree in herbivores.

Pharmacokinetic Values: The plasma half-life of chloramphenicol varies among species and depends on age in some species. The specific volumes of distribution usually reflect the extensive diffusion into tissues (see TABLE 47). Dose rates and frequencies are typically adjusted for the species and age of the animal. Florfenicol is eliminated by the kidneys.

TABLE 47 ELIMINATION AND DISTRIBUTION OF CHLORAMPHENICOL AND FLORFENICOL

Drug	Species	Elimination Half-life (hr)	Volume of Distribution (mL/kg)
Chloramphenicol	Cats	5.1	2,360
	Dogs	4.2	1,700
	Calves (<1 wk old)	5.0	1,080
	Cattle	3.0	1,580
	Horses	0.9	950
Florfenicol	Cattle	18.3	700

Therapeutic Indications and Dose Rates

Chloramphenicol is used to treat both systemic and local infections. Salmonellosis and *Bacteroides* sepsis have been specific indications, but use of chloramphenicol has decreased in the absence of an easily accessible, commercially available, approved preparation. Florfenicol is approved for use in treatment of bovine respiratory disease.

General dosages for chloramphenicol and florfenicol are listed in TABLE 48. The dose rate and frequency should be adjusted as needed for the individual animal.

Special Clinical Concerns

Adverse Effects and Toxicity: In people, chloramphenicol (but not florfenicol) can produce two distinctive syndromes of bone marrow suppression. One form is characterized by nonregenerative anemia (with or without thrombocytopenia or leukopenia), increased serum iron, bone marrow hypocellularity, cytoplasmic vacuolization of blast cells and lymphocytes, and maturation arrest of erythroid and myeloid precursors. This suppression is dose-dependent and reversible. Daily doses of 50 mg/kg for 3 wk can produce similar effects in cats. Milder hematologic effects are evident in dogs at much higher daily dosages (225 mg/kg). Such blood dyscrasias may also be seen in susceptible neonatal animals given standard adult doses of chloramphenicol. This toxic effect is postulated to be due to interference with mRNA and protein synthesis in rapidly multiplying cells.

The second form of bone marrow suppression is an irreversible aplastic anemia that is not related to dose or

duration and may appear after the drug has been discontinued. Peripheral blood showing pancytopenia may be associated with hypoplastic or aplastic bone marrow. The incidence is ~1:25,000–40,000. The aplastic anemia appears to reflect lack of the nitro group and, as such, does not cause aplastic anemia. Because tissue residues in food animals might induce aplastic anemia in people, use of chloramphenicol in food animals is prohibited in the USA and several other countries. A form of aplastic anemia, apparently a type of hypersensitivity reaction to chloramphenicol, has been recognized in dogs and cats.

GI disturbances can develop in all nonruminant animals treated with oral chloramphenicol. Use in neonatal calves leads to a malabsorption syndrome associated with ultrastructural and functional changes of the small-intestinal enterocytes. Anorexia and depression have been seen in cats treated for >1 wk.

Because chloramphenicol can suppress anamnestic immune responses, animals should not be vaccinated while being treated with this antibiotic. Because of the ability of chloramphenicol to inhibit protein synthesis, excessive topical application on wounds may delay healing.

In both male and female rats, chloramphenicol has adversely affected the structure and functions of the gonads. In large animals, adverse signs are most often associated with propylene glycol-based preparations that, when infused rapidly IV, may result in collapse, hemolysis, and death.

Notwithstanding the severity of the chloramphenicol-associated adverse effects noted above, chloramphenicol is relatively safe, provided overdose is avoided, courses of therapy are limited to 1 wk, the dose is reduced for newborn animals and

TABLE 48 DOSAGES OF CHLORAMPHENICOL AND FLORFENICOL

Drug	Species	Dosage, Route, and Frequency
Chloramphenicol	Cats	45–60 mg/kg, PO, IV, or IM, bid
	Dogs	45–60 mg/kg, PO, IV, or IM, tid-qid
	Horses	50 mg/kg, PO, tid-qid, or IV, every 2–4 hr
Florfenicol	Cattle	20 mg/kg, IM, repeated in 48 hr

for animals with impaired liver function, and there is no evidence of a preexisting bone marrow depression.

Interactions: Chloramphenicol is a potent noncompetitive microsomal enzyme inhibitor that can substantially prolong the duration of action of several drugs administered concurrently. Frank toxic effects are likely if administration is repeated. Examples of such drugs include pentobarbital, codeine, phenobarbital, phenytoin, NSAIDs, and coumarins.

In combination with sulfamethoxypyridazine, chloramphenicol can cause hepatic damage. Chloramphenicol also delays the response of anemia to iron, folic acid, and vitamin B₁₂. It interferes with the actions of many bactericidal drugs, such as the penicillins, cephalosporins, and aminoglycosides, and such combinations should not be used under most circumstances. Aqueous solutions of chloramphenicol sodium succinate should not be mixed with other preparations before administration because of a high incidence of incompatibility.

Chloramphenicol should not be administered concurrently with other antibacterial agents that bind to the 50S ribosomal subunit (eg, the macrolides and lincosamides).

Effects on Laboratory Tests: Chloramphenicol may cause increased alkaline phosphatase concentrations and prothrombin times. WBC and thrombocyte counts may be decreased. Anemia becomes evident in extreme cases. A false glucosuria test is possible.

Drug Withdrawal and Milk Discard Times:

The use of chloramphenicol in food animals is prohibited in several countries including the USA; in others, withdrawal times vary considerably and may be as long as 2 wk. Withdrawal time for florfenicol is 28 days. Florfenicol should not be used in dairy cattle ≤20 mo old, veal calves, calves <1 mo old, or calves on an all-milk diet.

MACROLIDES

The macrolide antibiotics typically have a large lactone ring in their structure and are much more effective against gram-positive than gram-negative bacteria. They are also active against mycoplasmas and some rickettsiae. (See also POLYENE MACROLIDE ANTIBIOTICS, p 2698.)

Classes

Macrolides fall into three classes, depending on the size of the macrocyclic lactone ring. None of the 12-membered ring group is used clinically. Erythromycin and the closely related oleandomycin and troleanomycin belong to the 14-membered ring group. Azithromycin (synthesized from erythromycin) and gamithromycin are 15-ring members, a subclass referred to as azalides. Of the 16-membered ring group, spiramycin, josamycin, tylosin, and tilmicin (synthesized from tylosin), are used clinically. Tulathromycin contains three amine rings and is classified as a triamilide. Ketolides, which include tylosin and spiramycin, are closely related macrolides.

General Properties

A macrolide is actually a complex mixture of closely related antibiotics that differ from one another with respect to the chemical substitutions on the various carbon atoms in the structure and in the aminosugars and neutral sugars. For example, erythromycin is mostly erythromycin A, but B, C, D, and E forms may also be included in the preparation.

The macrolide antibiotics are colorless, crystalline substances. They contain a dimethylamino group, which makes them basic. Although they are poorly water soluble, they do dissolve in more polar organic solvents. Macrolides are often inactivated in basic (pH >10) as well as acidic environments (pH <4 for erythromycin). The multiple functional groups make it possible for them to undergo a large number of chemical reactions. More stable ester forms, eg,

acetylates, estolates, lactobionate, succinates, propionates, and stearates, are commonly used in pharmaceutical preparations.

Antimicrobial Activity

Mode of Action: The antimicrobial mechanism seems to be the same for all of the macrolides. They interfere with protein synthesis by reversibly binding to the 50S subunit of the ribosome. They appear to bind at the donor site, thus preventing the translocation necessary to keep the peptide chain growing. The effect is essentially confined to rapidly dividing bacteria and mycoplasmas. Macrolides are regarded as being bacteriostatic but demonstrate bactericidal activity at high concentrations. Macrolides are significantly more active at higher pH ranges (7.8–8). Macrolides are considered to be time dependent in terms of antimicrobial efficacy.

The macrolides appear to have immunomodulatory effects useful to treat respiratory infections, in particular, those associated with *Pseudomonas aeruginosa*, based on efficacy at doses (concentrations) considered ineffective against susceptible bacteria.

Bacterial Resistance: Lack of cell wall permeability renders most gram-negative organisms inherently resistant to macrolides. There are a few exceptions, and gram-negative forms without cell walls are usually susceptible. Resistance to macrolides in gram-positive organisms results from alterations in ribosomal structure (target site methylation or mutation) and loss of macrolide affinity. Post-translational methylation results in cross-resistance to lincosamides and streptogramins. Macrolide resistance may be intrinsic or plasmid-mediated and constitutive or inducible; it may develop rapidly (erythromycin) or slowly (tylosin) and generally results in cross-resistance between macrolides. Efflux from cells is a second important mechanism of resistance for some members of this class, as is, less frequently, drug inactivation.

Antimicrobial Spectra: Macrolides are active against most aerobic and anaerobic gram-positive bacteria, although there is considerable variation as to potency and activity. In general, macrolides are not active against gram-negative bacteria, but some strains of *Pasteurella*, *Haemophilus*, and *Neisseria* spp may be sensitive. Exceptions include tilmicosin, gamithromycin, and tulathromycin, for which the

spectra are characterized as broader and include *Mannheimia haemolytica* and *Pasteurella multocida*, as well as the above-mentioned gram-negative bacteria. *Helicobacter* also is generally included in the spectrum. Azithromycin, derived from erythromycin, includes *Bordetella* in its spectrum. *Bacteroides fragilis* strains are moderately susceptible to macrolides. Macrolides are active against atypical mycobacteria, *Mycobacterium*, *Mycoplasma*, *Chlamydia*, and *Rickettsia* spp but not against protozoa or fungi. In vitro synergism is seen with cefamandole (against *B. fragilis*), ampicillin (against *Nocardia asteroides*), and rifampin (against *Rhodococcus equi*).

Pharmacokinetic Features

Absorption: Macrolides are readily absorbed from the GI tract if not inactivated by gastric acid. Oral preparations are often enteric-coated, or stable salts or esters (such as stearate, lactobionate, glucoheptate, propionate, and ethylsuccinate) are used. Plasma concentrations peak within 1–2 hr in most cases, although absorption patterns may be erratic because of the presence of food and may depend on the salt or ester used. Absorption from the ruminoreticulum is usually delayed and is unreliable. Erythromycin and tylosin may also be administered IV or IM. Tilmicosin, gamithromycin, and tulathromycin are administered SC, except in swine, for which an oral tilmicosin preparation is available. Absorption after injection is rapid, but pain and swelling can develop at the injection sites.

Distribution: Macrolides become widely distributed in tissues, and concentrations are about the same as in plasma, or even higher in some instances. They actually accumulate within many cells, including macrophages, in which they may be ≥ 20 times the plasma concentration. WBCs will then facilitate distribution to the site of inflammation. This accumulation accounts in part for the long dosing interval that characterizes some macrolides (eg, tilmicosin). With spiramycin, the tissue concentrations remain especially high, even though plasma concentrations are rather low. Macrolides tend to concentrate in the spleen, liver, kidneys, and particularly the lungs. They enter pleural and ascitic fluids and concentrate in the eye but do not distribute to the eye or the CSF (only 2%–13% of plasma concentration unless the meninges are inflamed). They concentrate in the bile and milk. Up to 75% of the dose is bound to

plasma proteins, and they bind to α 1-acid glycoproteins rather than to albumin.

Biotransformation: Metabolic inactivation of the macrolides is usually extensive, but the relative proportion depends on the route of administration and the particular antibiotic. After administration PO, 80% of an erythromycin dose undergoes metabolic inactivation, whereas tylosin appears to be eliminated in an active form.

Excretion: Macrolide antibiotics and their metabolites are excreted mainly in bile (>60%) and often undergo enterohepatic cycling. Urinary clearance may be slow and variable (often <10%) but may represent a more significant route of elimination after parenteral administration. For example, in people, 14% of azithromycin and 20%–40% of clarithromycin is excreted unchanged in urine. The concentration of macrolides in milk often is several times greater than in plasma, especially in mastitis.

Pharmacokinetic Values: Macrolides tend to be characterized by high oral bioavailability, but this is variable among species, drugs, and salts. For example, oral bioavailability for tylosin is 0.35 for the tartrate salt versus 0.14 for the phosphate. For azithromycin, oral bioavailability is 39% in foals 6–10 wk old, 59% in cats, and 97% in dogs. The accumulation of macrolides among different tissues contributes to the large volume of distribution (for azithromycin 12 L/kg in dogs, 23 L/kg in cats, 22 L/kg in foals 6–10 wk old) and long elimination half-life (for azithromycin, 29 hr in dogs, 35 hr in cats, and 20 hr in foals). For tulathromycin, the elimination half-life is 65 hr in calves and 69 hr in pigs 2–3 mo old. Because of these long half-lives, time to steady state may be prolonged, and a loading dose may be indicated for multiple dosing. Tylosin, however, is an exception, with a volume of distribution approximating 1 L/kg and a half-life of 1–2 hr. Another exception is azithromycin, which has a half-life in cats that varies among tissues, reaching >72 hr for some. Effective plasma inhibitory concentrations are maintained for ~8 hr after administration PO and for ~12–24 hr after IM injection. Dosage frequencies are commonly 2–3 times/day, PO, or 1–2 times/day, parenterally.

Therapeutic Indications and Dose Rates

The macrolides are used to treat both systemic and local infections. They are

often regarded as alternatives to penicillins for treatment of streptococcal and staphylococcal infections. General indications include upper respiratory tract infections, bronchopneumonia, bacterial enteritis, metritis, pyodermitis, urinary tract infections, arthritis, and others. Macrolides are indicated for treatment of *Rhodococcus* respiratory tract infections in foals. Formulations to treat mastitis are also available and often have the advantage of a short withholding time for milk. Tilmicosin, gamithromycin, and tulathromycin are approved for use in treatment of bovine respiratory diseases associated with *Mannheimia haemolytica*, *Pasteurella multocida*, and *Histophilus somni*. In swine, tilmicosin phosphate is added to feed or water for control of swine respiratory disease.

A selection of general dosages for some macrolides is listed in TABLE 49. The dose rate and frequency should be adjusted as needed for the individual animal.

Special Clinical Concerns

Adverse Effects and Toxicity: Toxicity and adverse effects are uncommon for most macrolides (except tilmicosin), although pain and swelling may develop at injection sites. Hypersensitivity reactions have occasionally been seen. Erythromycin estolate may be hepatotoxic and cause cholestasis; it may also induce vomiting and diarrhea, particularly when high doses are administered. Horses are sensitive to macrolide-induced GI disturbances that can be serious and even fatal. In pigs, tylosin may cause edema of the rectal mucosa, mild anal protrusion with diarrhea, and anal erythema and pruritus. After 5 mg/kg/day, dogs had a greater tendency to develop ventricular tachycardia and fibrillation during acute myocardial ischemia. Tilmicosin is characterized by cardiac toxicity (tachycardia and decreased contractility). Parenteral (but not oral) administration should be avoided in swine, and extra-label use should be avoided. Cattle have died after IV injection of tilmicosin, and human injury is possible after accidental exposure.

Interactions: Macrolide antibiotics probably should not be used with chloramphenicol or the lincosamides, because they may compete for the same 50S ribosomal binding site, although the in vivo significance of this potential interaction is unclear. Activity of macrolides is depressed in acidic environments. Macrolide preparations for

TABLE 49 DOSAGES OF MACROLIDES

Macrolide	Species	Dosage, Route, and Frequency
Erythromycin	Cattle	8–15 mg/kg, IM, once to twice daily
	Cats	15 mg/kg, PO, tid
	Foals	25 mg/kg, IM, tid
Tylosin	Cattle	10–20 mg/kg, IM, once to twice daily
	Pigs	10 mg/kg, IM, once to twice daily
		7–10 mg/kg, PO, tid
	Cats	10 mg/kg, IM, bid
Tilmicosin	Cattle	10 mg/kg, SC, once
Tulathromycin	Cattle	2.5 mg/kg, SC, once
	Swine	2.5 mg/kg, IM, once
Gamithromycin	Cattle	6 mg/kg, SC, once
Azithromycin	Dogs	5–10 mg/kg, PO, once to twice daily

parenteral administration are incompatible with many other pharmaceutical preparations. Erythromycin and troleandomycin and other macrolides are microsomal enzyme inhibitors that depress CYP3A4 (in people) and thus the metabolism of many drugs. Macrolides also are substrates for and potentially potent inhibitors of P-glycoprotein efflux pumps.

Effects on Laboratory Tests: Alkaline phosphatase, bilirubin, bromsulphthalein (BSP®), total WBC count, eosinophil count, AST, and ALT may increase. Cholesterol concentrations may decrease.

Drug Withdrawal and Milk Discard Times: Regulatory requirements for withdrawal times and milk discard times vary among countries. These should be followed carefully to prevent food residues and consequent public health implications. The withdrawal times listed in TABLE 50 serve only as general guidelines. Tilmicosin is characterized by a 28-day withdrawal time and should not be used in any species other than adult cattle (but not in dairy cows >20 mo old).

STREPTOGRAMINS

The streptogramin antibiotics include two distinct groups. Group A contain a 23-membered unsaturated ring with lactone and peptide bonds, and group B are depsipeptides (lactone-cyclized peptides). These antibiotics are included in the

macrolide-lincosamide-streptogramin (MLS) group. However, whereas the individual A and B components act in a bacteriostatic fashion when used as sole agents, together the affinity for the ribosome is enhanced, causing them to be bactericidal. Streptogramins include virginiamycin. Streptogramins are used to treat vancomycin-resistant staphylococci and *Enterococcus faecium*.

LINCOSAMIDES

General Properties

Lincosamides are derivatives of an amino acid and a sulfur-containing octose. They are monobasic and more stable in salt forms (hydrochlorides and phosphates).

Antimicrobial Activity

Mode of Action: Lincomycin and clindamycin bind exclusively to the 50S subunit of bacterial ribosomes and suppress protein synthesis. Lincosamides, macrolides, and chloramphenicol, although not structurally related, seem to act at this same site. The lincosamides are bacteriostatic or bactericidal depending on the concentration. Activity is enhanced at an alkaline pH. Efficacy is considered time dependent.

Bacterial Resistance: Lincosamides are generally ineffective against facultative anaerobic (but not anaerobic) gram-negative bacteria. Resistance to lincosamides appears slowly, perhaps as a result of

TABLE 50 DRUG WITHDRAWAL AND MILK DISCARD TIMES OF MACROLIDES

Macrolide	Species	Withdrawal Time (days)	Milk Discard Time (hr)
Erythromycin	Cattle	14	36–72
	Pigs	7	
Tylosin	Cattle	21	96
	Pigs	14	
Tilmicosin	Cattle	28	0
Tulathromycin	Cattle	18	
	Swine	5	
Gamithromycin	Cattle	63 ^a	

^a EU withdrawal; withdrawal period for USA (35 days) pending; withdrawal period for Canada is 49 days.

chromosomal mutation. Plasmid-mediated resistance has been found in strains of *Bacteroides fragilis*. Resistance appears to be due to plasmid or chromosomally mediated post-transcriptional methylation of the 50S ribosomal subunit. Cross-resistance occurs with macrolides and streptogramins. Other mechanisms include increased activation of an efflux pump and destruction of the drug.

Antimicrobial Spectra: Lincomycin has a limited spectrum against aerobic pathogens but a fairly broad spectrum against anaerobes. Clindamycin is a more active analogue with somewhat different pharmacokinetic patterns. Many gram-positive cocci, except for enterococci, and *Mycoplasma* are inhibited by lincosamides, but most gram-negative organisms are resistant. Clindamycin is less effective toward ureaplasmas. *Bacteroides* spp and other anaerobes are usually susceptible. *Clostridium difficile* strains appear to be regularly resistant.

Pharmacokinetic Features

Absorption: Lincomycin is incompletely absorbed from the GI tract, especially if administered soon after feeding; plasma concentrations peak within 2–4 hr. Absorption from IM injection sites is good; plasma concentrations peak in 1–2 hr. Approximately 90% of an oral dose of clindamycin is absorbed, and effective plasma concentrations are achieved more rapidly than with lincomycin. Absorption is not significantly affected by the ingestion of food. Clindamycin palmitate is used PO, and

clindamycin phosphate IM; the latter reaches peak plasma concentration in 1–3 hr.

Distribution: Lincosamides are widely distributed in many fluids and tissues, including bone, but significant concentrations are not attained in the CSF even when the meninges are inflamed. They diffuse across the placenta in many species. Approximately 90% of clindamycin is bound to plasma proteins. It also accumulates in polymorphonuclear WBCs and alveolar macrophages such that concentrations exceed those of plasma 50-fold. Clindamycin is able to penetrate glyocalyx, such as that associated with dental tartar.

Biotransformation: After administration PO, ~50% of a dose of lincomycin and 80%–90% of a dose of clindamycin are metabolically altered in the liver. Metabolites often retain activity. Liver disease impairs the biotransformation of lincosamides.

Excretion: Unchanged antibiotic and several metabolites may be excreted in bile and urine. In people, as little as 10% of clindamycin is excreted in the urine. The proportions depend on the route of administration. Concentrations remain high in the feces for some days, and growth of sensitive microorganisms in the large intestine may be suppressed for up to 2 wk. Milk is also an important excretory route.

Pharmacokinetic Values: The elimination half-life of lincosamides is frequently >3 hr, and the apparent volume of distribu-

tion is >1 L/kg. They are usually administered bid. In dogs, clindamycin has an elimination half-life of 3.9 hr and a volume of distribution of 1.4 L/kg.

Therapeutic Indications and Dose Rates

The lincosamides are indicated for infections caused by susceptible gram-positive organisms, particularly streptococci and staphylococci, and for those caused by anaerobic pathogens. Clindamycin is approved for use in cats and dogs for treatment of infected wounds, abscesses, and dental infections. Clindamycin has also been used to treat selected protozoal diseases, including toxoplasmosis, but usually in combination with other antimicrobials.

A selection of general dosages for some lincosamides is listed in TABLE 51. The dose rate and frequency should be adjusted as needed for the individual animal.

Special Clinical Concerns

Adverse Effects and Toxicity: No serious organ toxicity has been reported, but GI disturbances do occur. Clindamycin-induced pseudomembranous enterocolitis (caused by toxigenic *Clostridium difficile*) or disruption of GI flora is a serious adverse reaction in a number of species and can be lethal; thus, clindamycin is contraindicated for use in some in horses, guinea pigs, hamsters, rabbits, chinchillas, and ruminants. Lincosamides are contraindicated in horses, because severe and even fatal colitis may develop. Skeletal muscle paralysis may be seen at high concentrations. Hypersensitivity reactions occasionally are seen. Lincosamides should not be used in neonates because of their limited ability to metabolize drugs.

Interactions: Lincosamides have additive neuromuscular effects with anesthetic

agents and skeletal muscle relaxants. Kaolin/pectin prevents their absorption from the GI tract. They should not be combined with bactericidal agents or with the macrolides.

Effects on Laboratory Tests: Alkaline phosphatase, AST, and ALT may be increased.

Drug Withdrawal Times: In several countries, there is a 2-day withdrawal time for pigs.

MISCELLANEOUS ANTIMICROBIAL AGENTS

A number of antimicrobial agents are used periodically for several diverse purposes. Several of these are discussed below.

POLYMYXINS

This group of polypeptide antibiotics includes polymyxin B and polymyxin E, or colistin. Because of toxicity, these drugs are most commonly used topically, or PO for treatment of intestinal infections. Colistimethate is a form of colistin intended for parenteral administration. Polymyxins are bactericidal; they interact strongly with phospholipids in bacterial cell membranes and radically disrupt their permeability and function. The polymyxins are more effective against gram-negative than gram-positive bacteria. Their rather narrow spectrum includes *Enterobacter*, *Klebsiella*, *Salmonella*, *Pasteurella*, *Bordetella*, *Shigella*, *Pseudomonas* spp, and *Escherichia coli*. Most *Proteus* or *Neisseria* spp are not susceptible. Although intrinsic bacterial resistance to polymyxins is recognized, resistance is uncommon and is chromosome-dependent only. Polymyxins act synergistically when combined with potentiated sulfonamides, tetracyclines,

TABLE 51 DOSAGES OF LINCOSAMIDES

Lincosamide	Species	Dosage, Route, and Frequency
Lincomycin	Cattle	10 mg/kg, IM, bid
	Pigs	10 mg/kg, IM, bid 7 mg/kg, in-feed
	Dogs	20 mg/kg/day, PO
	Cats	10 mg/kg, IM, bid 25 mg/kg, PO, bid
Clindamycin	Dogs, cats	5–10 mg/kg, PO, bid

and some other antibacterials; they also reduce the activity of endotoxins in body fluids and may be beneficial in endotoxemia. Their action is inhibited by divalent cations, unsaturated fatty acids, and quaternary ammonium compounds.

Polymyxins are not absorbed after PO or topical administration; plasma concentrations peak ~2 hr after parenteral administration. Blood concentrations usually are low, because polymyxins bind to cell membranes as well as tissue debris and purulent exudates. The polymyxins undergo renal elimination mostly as degradation products, and their plasma half-lives are 3–6 hr. They are notably nephrotoxic and neurotoxic and, as such, systemic therapy at antimicrobial doses should be avoided. Neuromuscular blockade can be seen at higher concentrations. Intense pain at sites of injection and hypersensitivity reactions also can be expected. Polymyxin B is a potent histamine releaser. The main indication for parenteral use of polymyxins is life-threatening infection due to gram-negative bacilli or *Pseudomonas* spp that are resistant to other drugs. Polymyxins are also used PO against susceptible intestinal infections. Anti-endotoxin binding activity is an additional therapy via slow IV bolus. Topical application is common, eg, for otitis externa.

Recommended dose rates for polymyxins vary considerably. A general guideline is 20,000 U/kg, PO, bid; 5,000 U/kg, IM, bid; 50,000–100,000 U by intramammary infusion; 100,000 U intrauterine in cattle. IV administration of polymyxins is potentially dangerous.

BACITRACINS

Bacitracins are branched, cyclic, decapeptide antibiotics. Bacitracin A is the most active of the group and the main component of the commercial bacitracin preparations used either topically or PO. These antibiotics are bactericidal. They interfere with cell membrane function, suppress cell wall formation by preventing the formation of peptidoglycan strands, and inhibit protein synthesis. Bactericidal activity requires the presence of divalent cations, such as zinc.

The spectrum of bacitracins is described as broad, but it is used primarily to treat gram-positive infections. Resistance is rare. Bacitracins are often used in combination with neomycin and polymyxins to enhance the antibacterial spectrum.

Bacitracins are not appreciably absorbed from the GI tract and are not used systemi-

cally because of their pronounced nephrotoxicity. However, they are used locally in wound powders and ointments, dermatologic preparations, eye and ear ointments, and as feed additives in swine and poultry rations for growth promotion. In antibiotic-associated pseudomembranous colitis caused by *Clostridium difficile* cytotoxin, bacitracin (given PO) is considered an alternative to vancomycin. Hypersensitivity reactions to bacitracins are seen occasionally.

GLYCOPEPTIDES

Vancomycin is a complex glycopeptide that binds to precursors of the peptidoglycan layer in bacterial cell walls. This effect prevents cell wall synthesis and produces a rapid bactericidal effect in dividing bacteria. Its efficacy is time dependent. Vancomycin is active against most gram-positive bacteria but is not effective against gram-negative cells because of their large size and poor penetrability. Resistance to vancomycin does not readily develop. The drug is widely distributed in the body. Excretion (in active form) is via the kidneys; in renal insufficiency, striking accumulations may develop. The plasma half-life in dogs is 2–3 hr. The only indication for use of parenteral vancomycin is serious infection due to methicillin-resistant *Staphylococcus aureus*. Although poorly absorbed, oral vancomycin is used to treat antibiotic-associated enterocolitis, especially if caused by *Clostridium difficile*. Febrile reactions and thrombophlebitis (because of tissue irritation) at injection sites may be seen. Hypersensitivity reactions are seen infrequently. Ototoxicity and nephrotoxicity were fairly common in the past but are rare today because of fewer impurities in the final form.

FOSFOMYCIN

Fosfomycin, a phosphonic acid that contains a carbon-phosphorus bond, is a natural antibiotic produced by *Streptomyces fradiae*. It is a phosphoenolpyruvate analogue that irreversibly inhibits phosphoenolpyruvate transferase, an enzyme that catalyzes the first step of peptidoglycan synthesis of microbial cell walls. Its in vitro spectrum is broad, with potential efficacy toward isolates expressing multidrug resistance, including *Escherichia coli* and methicillin-resistant staphylococci. As a cell wall inhibitor, fosfomycin is bactericidal when present at the site of infection at therapeutic

concentrations. Cell wall inhibition is time dependent, but fosfomycin also exhibits a concentration-dependent effect. Resistance to fosfomycin is uncommon and reflects the FosX or FosA enzyme, which hydrolyzes the drug. The gene for this protein is chromosomally mediated. When resistance occurs, it generally is not associated with multidrug resistance. Studies in people have demonstrated that fosfomycin distributes well to soft tissues, reaching therapeutic breakpoints. Adverse effects of fosfomycin appear to be limited to diarrhea. Approved for human use in the USA as the tromethamine salt, its indication is as a one time (or up to 3 days) treatment of uncomplicated urinary tract infections in people. Fosfomycin has been added to the World Health Organization's list of critically important drugs. Accordingly, its use should be reserved, along with other critically important drugs, to situations in which lower-tier drugs are no longer appropriate.

NOVOBIOCIN SODIUM

Novobiocin is a narrow-spectrum antibiotic that may be bacteriostatic or bactericidal at higher concentrations. It is active mostly against gram-positive bacteria but also against a few gram-negative bacteria. There is a synergistic effect with tetracyclines. Many species of bacteria can develop resistance to novobiocin. Adverse reactions are quite frequent after administration. Its main use is in combination with other agents for treatment of bovine mastitis.

TIAMULIN FUMARATE

Tiamulin hydrogen fumarate is a semisynthetic derivative of pleuromutilin. Tiamulin is active against gram-positive bacteria, mycoplasmas, and anaerobes, including *Brachyspira hyodysenteriae*. It is also clinically effective in treatment of swine dysentery and mycoplasmal arthritis. Tiamulin is well absorbed when administered PO. The dosage is 8.8 mg/kg/day for 3–5 days, in either food or water. The parenteral dosage for mycoplasmal pneumonia in pigs is 15 mg/kg. In poultry, tiamulin interferes with monensin and salinomycin metabolism, and if the drugs are fed together, they become toxic. Generally, however, tiamulin has few adverse effects.

IONOPHORES

Ionophores are lipid-soluble molecules that transport ions across lipid cell membranes.

The subsequent disruption of cell membrane permeability results in antibacterial effects. Monensin is an ionophore antibiotic derived from *Streptomyces* that forms complexes with monovalent cations, including sodium and potassium. The complexes are transported in a nonpolar manner across the bacterial cell membrane. As such, it acts as an Na^+/H^+ antiporter. Monensin blocks intracellular protein transport, resulting in antibacterial and antimalarial effects. Monensin is used extensively in the beef and dairy industries in feed to prevent coccidiosis and improve feed efficiency. Monensin also increases the production of propionic acid and thus prevents bloat.

RIFAMYCINS

Several semisynthetic derivatives (rifamycin SV, rifampin [rifampicin], rifamide) of natural rifamycins have been used as extended-spectrum antibiotics. Rifamycins interfere with the synthesis of RNA in microorganisms by binding to subunits of sensitive DNA-dependent RNA polymerase. They are active against gram-positive organisms, some mycobacteria, a few strains of gram-negative bacteria (mostly cocci; bacilli are more resistant), some anaerobes, and chlamydiae. At high concentrations, they are also active against several viruses. Fungal and yeast infections resistant to rifampin alone often respond when a rifamycin is added to an antifungal agent (eg, amphotericin B). Resistance to rifamycins may develop rapidly as a 1-step process. For this reason, they should be administered in combination with other antimicrobials, such as penicillins, erythromycin, miconazole, and amphotericin B.

The primary use of the rifamycins in people has been to treat tuberculosis. Rifampin has been used in foals to control *Rhodococcus equi* pneumonia. Because rifamycins penetrate tissues and cells to a substantial degree, they are particularly effective against intracellular organisms. Rifampin is readily but incompletely (~40%) absorbed from the GI tract, and plasma concentrations peak within 2–4 hr. Concurrent feeding may reduce or delay absorption. Rifampin may also be administered IM or IV. Approximately 75%–80% of rifampin is bound to plasma proteins. It is widely distributed in body tissues and fluids because of its high lipid solubility. Rifampin is biotransformed to several metabolites, some of which are active, and is primarily excreted in bile (used for cholangitis in

people) and to a lesser degree in urine. Enterohepatic cycling of the parent drug and its main metabolite (desacetylrifampin) commonly occurs. The elimination half-life of rifampin is dose dependent: in horses, it is ~6 hr; in dogs, ~8 hr. The plasma half-life progressively shortens by ~40% during the first 2 wk of treatment because of the induction of hepatic microsomal enzymes; conversely, it is increased with hepatic dysfunction.

Rifampin is usually well tolerated and produces few adverse effects. GI disturbances and abnormalities in liver function (icterus) have been reported in people. Hypersensitivity reactions can also result from rifampin administration, and renal failure is a possible consequence when intermittent dosage schedules are followed. Partial, reversible immunosuppression of lymphocytes develops. Urine, feces, saliva, sputum, sweat, and tears are often colored red-orange by rifampin and its metabolites. CNS depression after IV administration and temporary inappetence are seen in horses. The dose range for rifampin in horses is 10–25 mg/kg/day, PO or parenterally.

NITROFURANS

Nitrofurans are synthetic chemotherapeutic agents with a broad antimicrobial spectrum; they are active against both gram-positive and gram-negative bacteria, including *Salmonella* and *Giardia* spp, trichomonads, amebae, and some coccidial species. However, when compared with other antimicrobial chemotherapeutic agents, their potency is not of particular note. The nitrofurans appear to inhibit a number of microbial enzyme systems, including those involved in carbohydrate metabolism, and they also block the initiation of translation. However, their basic mechanism of action has not yet been clarified. Their primary action is bacteriostatic, but at high doses they are also bactericidal. They are much more active in acidic environments (pH 5.5 is optimal for nitrofurantoin activity). Resistant mutants are rare, and clinical resistance emerges slowly. Among themselves, nitrofurans show complete cross-resistance, but there is no cross-resistance with any other antibacterial agents.

Because of very slight water solubility, the nitrofurans are used either PO or topically. No nitrofuran is effective systemically. They are either not absorbed at all from the GI tract or are so rapidly eliminated that they reach inhibitory concentrations only in the urine. Toxic

signs seen with excessive doses of nitrofuran derivatives include CNS involvement (excitement, tremors, convulsions, peripheral neuritis), GI disturbances, poor weight gain, and depression of spermatogenesis. Various hypersensitivity reactions can also be seen. Some nitrofurans are carcinogenic, and their future use is in doubt.

Nitrofurans are among the drugs for which extra-label use is prohibited in food animals in the USA.

Nitrofurantoin

The mechanism of action of nitrofurantoin is unique. It is reduced by bacterial flavoproteins to reactive intermediates that inhibit bacterial ribosomes and other macromolecules. Protein synthesis, aerobic energy metabolism, DNA and RNA synthesis, and cell wall synthesis are inhibited. Nitrofurantoin is bactericidal in urine at therapeutic doses. Resistance is rare. Nitrofurantoin is used to treat urinary tract infections caused by susceptible bacteria, such as *Escherichia coli*, *Staphylococcus aureus*, *Streptococcus pyogenes*, and *Aerobacter aerogenes*. *Proteus* spp, *Pseudomonas aeruginosa*, and *Streptococcus faecalis* are usually resistant. After administration PO, nitrofurantoin is rapidly and completely absorbed (the macrocrystal form takes longer) and is swiftly eliminated by the kidneys, mainly by tubular secretion (~40% in the unchanged form). Serum concentrations are low, and little unbound drug is available for diffusion into the tissues. The plasma half-life is only ~20 min. Nitrofurantoin is concentrated in acid urine. When the pH reaches ~5, the drug becomes supersaturated without precipitation, and its antibacterial action is maximal. Nitrofurantoin can be administered PO or parenterally. The dosage for dogs and cats is 4.4 mg/kg, PO, tid for 4–10 days. Adverse effects are not common at usual dosages, but nausea, vomiting, and diarrhea can develop. CNS disorders have been seen, and polyneuropathy is a serious effect seen in people. Animals with decreased renal function have a predisposition for polyneuritis. Various manifestations of hypersensitivity reactions can be seen. Yellow discoloration of teeth occasionally has been reported in very young animals.

Nitrofurazone

Nitrofurazone is only slightly soluble in water but, in general, corresponds to nitrofurantoin in terms of its mechanism of action, antimicrobial spectrum, potency,

and physicochemical characteristics. Its main indications include the treatment of bovine mastitis, bovine metritis, and wounds. However, pus, blood, and milk reduce the antibacterial activity. Nitrofurazone is also used as a feed additive (0.05%) to control intestinal bacterial and coccidial infections. The withdrawal time for nitrofurazone in pigs is 5 days.

Furazolidone

This is a nitrofuran with a wide range of antimicrobial activity that includes *Clostridium*, *Salmonella*, *Shigella*, *Staphylococcus* and *Streptococcus* spp, and *E. coli*. It is also active against *Eimeria* and *Histomonas* spp. It is usually administered PO to treat intestinal infections but may also be applied topically. The usual oral dose of furazolidone in calves is 10–12 mg/kg, bid for 5–7 days. Caution should be exercised when treating small calves (eg, Jersey breed) to avoid excessive dose rates, lest neurotoxicity result; signs include head tremors, ataxia, visual impairment, and convulsions.

Miscellaneous Nitrofurans

Nifuraldezone, like furazolidone, is used to control bacterial enteritis in calves. Nifurpazine is used only topically as an antibacterial agent. Furaltadone is used both PO to prevent intestinal infections and directly into the teat to treat mastitis.

NITROIMIDAZOLES

The 5-nitroimidazoles are a group of drugs that have both antiprotozoal and antibacterial activity. Nitroimidazoles with activity against trichomonads and amebae include metronidazole, tinidazole, nimorazole, flunidazole, and ronidazole. Metronidazole and nimorazole are effective in treatment of giardiasis, whereas dimetridazole, ipronidazole, and ronidazole control histomoniasis in poultry. Several nitroimidazoles have activity against trypanosomes. Metronidazole, ronidazole, and other nitroimidazoles are active against anaerobic bacteria. Metronidazole is the compound that has been the most studied and is discussed as the prototype of the group. Extra-label use of nitroimidazoles is prohibited in food animals in the USA.

Metronidazole

Metronidazole has been used for many years in therapeutic management of trichomoniasis, giardiasis, and amebiasis. It is

active against obligate anaerobic bacteria. It is not active against facultative anaerobes, obligate aerobes, or microaerophilic bacteria other than *Campylobacter fetus*. At concentrations readily attained in serum after PO or parenteral administration, metronidazole is active against *Bacteroides fragilis*, *B. melaninogenicus*, *Fusobacterium* spp, and *Clostridium perfringens* and other *Clostridium* spp. It is generally less active against nonsporeforming, gram-positive bacilli such as *Actinomyces*, *Propionibacterium*, *Bifidobacterium*, and *Eubacterium* spp. Metronidazole is also somewhat less active against gram-positive cocci such as *Peptostreptococcus* and *Peptococcus* spp, but the less sensitive strains are usually not obligate anaerobes.

Metronidazole is bactericidal at concentrations equal to or slightly higher than the minimal inhibitory concentration. The precise mode of action is unclear, but reduction in an anaerobic environment yields a compound that then binds to DNA, causing loss of the helical structure, strand breakage, and impairment of DNA function. Only susceptible organisms (bacteria and protozoa) appear to be capable of metabolizing the drug.

The pharmacokinetic pattern of metronidazole generally follows that expected of a highly lipid-soluble basic drug. It is readily but variably absorbed from the GI tract (bioavailability 60%–100%), with serum concentrations peaking within 1–2 hr, and becomes widely distributed in all tissues. Metronidazole penetrates the blood-brain barrier and also attains therapeutic concentrations in abscesses and in empyema fluid. It is only slightly bound to plasma proteins. Biotransformation is quite extensive, and parent drug and metabolites are excreted by both the renal and biliary routes. The elimination half-life in dogs is ~4.5 hr, and in horses, 1.5–3.3 hr.

The principal clinical indications for metronidazole include the treatment of specific protozoal infections (amebiasis, trichomoniasis, giardiasis, and balantidiasis) and anaerobic bacterial infections such as those that may be seen in abdominal abscesses, peritonitis, empyema, genital tract infections, periodontitis, otitis media, osteitis, arthritis, and meningitis, and in necrotic tissue. Metronidazole has been successfully used to prevent infection after colonic surgery. Nitroimidazoles also act as radiosensitizers, and metronidazole has been used as an adjunct to the radiotherapy of solid tumors.

Adverse effects are not commonly associated with metronidazole. High doses

may induce signs of neurotoxicity in dogs, such as tremors, muscle spasms, ataxia, and even convulsions. Reversible bone marrow depression has been reported. The drug should not be used in pregnant animals, particularly during the first trimester, although the evidence for carcinogenicity and mutagenicity is still tenuous. Metronidazole may produce a reddish brown discoloration of the urine due to unidentified pigments.

Recommended dose rates for metronidazole in dogs are 44 mg/kg, PO, followed by 22 mg/kg, qid, for anaerobic infections; 25 mg/kg, PO, bid, for giardiasis; and 66 mg/kg/day, PO, for trichomoniasis. Courses of therapy are generally 5–7 days. Both PO and IV preparations are available.

HYDROXYQUINOLINES

The 8-hydroxyquinolines are a group of synthetic compounds with antibacterial, antifungal, and antiprotozoal activity. The best-known compounds of this class are iodochlorhydroxyquin (clioquinol), diiodohydroxyquin (iodoquinol), broxyquinoline, and hydroxyquinoline. Because they are not absorbed from the GI tract to any degree, their main use has been to treat intestinal infections caused by bacteria or protozoa (such as *Giardia*). Hydroxyquinolines are also used topically for skin infections caused by bacteria and fungi. Hydroxyquinolines are potentially neurotoxic when used for prolonged periods. The dose for a 455-kg horse is 10 g/day, PO, using a decreasing dosage regimen to discontinue medication.

ANTIFUNGAL AGENTS

Pathogenic fungi affecting animals are eukaryotes, generally existing as either filamentous molds (hyphal forms) or intracellular yeasts. Fungal organisms are characterized by a low invasiveness and virulence. Factors that contribute to fungal infection include necrotic tissue, a moist environment, and immunosuppression. Fungal infections can be primarily superficial and irritating (eg, dermatophytosis) or systemic and life threatening (eg, blastomycosis, cryptococcosis, histoplasmosis, coccidioidomycosis). See also DERMATOPHYTOSIS, p 872, and FUNGAL INFECTIONS, p 632. Clinically relevant dimorphic fungi grow as yeast-like forms in a host but as molds in vitro at room temperature; they include *Candida* spp, *Blastomyces dermatitidis*, *Coccidioides immitis*, *Histoplasma capsulatum*, *Sporothrix schenckii*, and *Rhinosporidium*.

Several factors can lead to therapeutic failure or relapse after antifungal therapy. Drug access to fungal targets is often compromised. Host inflammatory response may be the first barrier, followed by location in sanctuaries (brain, eye, etc) as a second barrier for some infections, and the organisms themselves as a third barrier. The fungal cell wall is rigid and contains chitin, which along with polysaccharides, acts as a barrier to drug penetration. The cell membrane contains sterols such as ergosterol, which influences the efficacy

and potential resistance to some drugs. *Cryptococcus* and occasionally *Sporothrix schenckii* produce an external coating or slime layer that encapsulates the cells and causes them to adhere and clump together. Finally, regarding drug access, most infections are located inside host cells, the lipid membrane of which can present a final barrier.

Discontinuing therapy after clinical signs have resolved but before infection is eradicated also leads to therapeutic failure. Therapy should extend well beyond clinical cure. Once drugs reach the site of action, therapeutic success is impeded by the nature of fungal infections. Fungal growth is slow, yet most antifungal drugs work better in rapidly growing organisms. Likewise, most antifungal agents are fungistatic in action, with clearance of infection largely dependent on host response. As such, the duration of therapy is long, and the “get in quick, hit hard, and get out quick” recommendation for antibacterial therapy is not appropriate for antifungal therapy; care must be taken to not discontinue therapy too early. However, longer duration of therapy contributes to another common cause of therapeutic failure: host toxicity. Because both the antifungal target organism and the host cells are eukaryotic, the cellular targets of fungal organisms are often similar to the host structures. Therefore, as a class, antifungal drugs tend to be more

toxic than antibacterial drugs, and the number of antifungal drugs approved for use are markedly fewer than the number of antibacterial drugs. Drugs that can be used locally (including topically) or characterized by distribution to sites of infection (eg, liposomal products) may decrease this risk. The slow growth that characterizes fungal infections means that acquired resistance occurs less commonly than in bacterial infections. Therapeutic failure may also reflect the inability of the immunocompromised host to overcome residual fungal populations inhibited by the drug; those antifungals that are also (positive) immunomodulators may be more effective.

A number of serious systemic fungal diseases are well recognized in several parts of the world (see p 632). Antifungal agents have greatly reduced previously recorded human mortality rates due to systemic mycoses. A relatively narrow selection of drugs is used in these cases.

POLYENE MACROLIDE ANTIBIOTICS

Amphotericin B is the model polyene macrolide antibiotic and is the sole member of this class used systemically. Polyene antifungal antibiotics are large molecules, consisting of a long polyene, lipid-soluble component and a markedly hydrophilic component. Amphotericin B acts as both a weak base and a weak acid, and as such is amphoteric. The polyene macrolides have been isolated from various strains of bacteria; amphotericin B is an antibiotic product of *Streptomyces nodosus*. Amphotericin B, nystatin, and pimaricin (natamycin) are the only polyene macrolide antibiotics used in veterinary medicine. The polyenes are poorly soluble in water and the common organic solvents. They are reasonably soluble in highly polar solvents such as dimethylformamide and dimethyl sulfoxide. In combination with bile salts, such as sodium deoxycholate, amphotericin B is readily soluble (micellar suspension) in 5% glucose. This colloidal preparation has been used for IV infusion. The polyenes are unstable in aqueous, acidic, or alkaline media but in the dry state, in the absence of heat and light, they remain stable for indefinite periods. They should be administered parenterally (diluted in 5% dextrose) as freshly prepared aqueous suspensions. Lack of stability indicates that labeled expiration dates should be adhered to once the product is diluted. Amphotericin B is also prepared as liposomal and lipid-based preparations, enhancing its safety without loss of efficacy.

Antifungal Activity

Mode of Action: The polyenes bind to sterol components in the phospholipid-sterol membranes of fungal cells to form complexes that induce physical changes in the membrane. The number of conjugated bonds and the molecular size of a particular polyene macrolide influence its affinity for different sterols in fungal cell membranes. Amphotericin B has a greater affinity for fungal ergosterol, the major sterol in fungal membranes, than for eukaryotic (host) cell membrane cholesterol. The long polyene structure causes the formation of channels in the fungal cell membrane. The resultant loss of membrane permeability results in the loss of critically important molecules. Potassium ion efflux from the fungal cell and hydrogen ion influx cause internal acidification and a halt in enzymatic functions. Sugars and amino acids also eventually leak from an arrested cell. Fungistatic effects are most often evident at usual polyene concentrations. High drug concentrations and pH values between 6.0 and 7.3 in the surrounding medium may lead to fungicidal rather than fungistatic action.

In addition to these direct effects on susceptible yeasts and fungi, evidence suggests that amphotericin B may also act as an immunopotentiator (both humoral and cell mediated), thus enhancing the host's ability to overcome mycotic infections.

Fungal Resistance: Polyene macrolides are inherently resistant to dermatophytes. Acquired resistance to the polyene antifungal macrolides is rare both clinically and in vitro. *Pythium*, a pseudofungus, is less susceptible, because it contains limited ergosterol in its cell membranes. Resistance has been documented for *Candida* spp, which are among the more rapidly growing fungal organisms. In general, resistance develops slowly and does not reach high levels, even after prolonged treatment.

Antifungal Spectra: The polyene antibiotics have broad antifungal activity against organisms ranging from yeasts to filamentous fungi and from saprophytic to pathogenic fungi, but there are great differences between the susceptibilities of the various species and strains of fungi. They are ineffective against dermatophytes. In vitro susceptibilities (both resistant and highly susceptible) do not always correlate well with the clinical response, which suggests that host factors may also play a role. Many algae and some protozoa

(*Leishmania*, *Trypanosoma*, *Trichomonas*, and *Entamoeba* spp) are sensitive to the polyenes, but these compounds have no significant activity against bacteria, actinomycetes, viruses, or animal cells. Amphotericin B is effective against yeasts (eg, *Candida* spp, *Rhodotorula* spp, *Cryptococcus neoformans*), dimorphic fungi (eg, *Histoplasma capsulatum*, *Blastomyces dermatitidis*, *Coccidioides immitis*), dermatophytes (eg, *Trichophyton*, *Microsporum*, and *Epidermophyton* spp), and molds. It also has been used successfully to treat disseminated sporotrichosis, pythiosis, and zygomycosis, although it may not always be effective. Nystatin is mainly used to treat mucocutaneous candidiasis, but it is effective against other yeasts and fungi. The antimicrobial activity of pimaricin is similar to that of nystatin, although it is mainly used for local treatment of candidiasis, trichomoniasis, and mycotic keratitis.

Preparations: Amphotericin B is available as an IV solution complexed to bile acids but also as several different preparations complexed to lipid mixtures. Because reticuloendothelial cells phagocytize the lipid component, directed delivery to the site of fungal infection is facilitated, reducing renal exposure. Prolonged antifungal activity (compared with nonliposomal preparations) has been documented.

Pharmacokinetic Features

Absorption: The polyene macrolide antibiotics are poorly absorbed from the GI tract. Amphotericin B is usually administered IV or topically and occasionally locally, intrathecally, or intraocularly. Nystatin and piramycin are mostly applied topically. Nystatin is given PO to treat intestinal candidiasis. Absorption is minimal from sites of local application.

Distribution: Amphotericin B is widely distributed in the body after IV infusion. It associates with cholesterol in host cell membranes throughout the body and is subsequently released slowly into the circulation. Penetration into the CSF, saliva, aqueous humor, vitreous humor, and hemodialysis solutions is generally poor. Amphotericin B becomes highly bound to plasma lipoproteins (~95%). Complexing amphotericin B with various lipid-based products alters the distribution.

Biotransformation and Excretion:

The disposition of amphotericin B is not well described in companion animals.

Approximately 5% of a total daily dose of amphotericin B is excreted unchanged in the urine. Over a 2-wk period, ~20% of the drug may be recovered in the urine. The hepatobiliary system accounts for 20%–30% of excretion. The fate of the remainder of amphotericin B is unknown.

Pharmacokinetics: Amphotericin B has a biphasic elimination pattern. The initial phase lasts 24 hr, during which levels fall rapidly (70% for plasma and 50% for urine). The second elimination phase has a 15-day half-life, during which plasma concentrations decline very slowly. Amphotericin B is usually infused IV, every 48–72 hr, until the total cumulative dosage has been reached. The disposition of the various lipid-complexed amphotericin B products is variable. Because of its small size, AmBisome® is characterized by the slowest uptake by reticuloendothelial cells and thus the highest plasma drug concentrations of amphotericin B. However, the amount of free versus complexed amphotericin B is not clear. AmBisome also was able to achieve CNS concentrations and was associated with the least nephrotoxicity in human studies. AmBisome has been studied in Beagles. Achievable amphotericin concentrations were much higher at equivalent doses of AmBisome compared with other products; further, dogs were able to well tolerate 4 mg/kg for 30 days. Amphotericin concentrations accumulate with multiple dosing when administered as AmBisome.

Therapeutic Indications and Dose Rates

Amphotericin B is used principally to treat systemic mycotic infections. Despite its ability to cause nephrotoxicity (see p 2702), amphotericin B remains a commonly used antifungal agent because of its effectiveness. Multiple approaches to delivery have been described in an attempt to minimize nephrotoxicity. In addition, dosing continues until a maximal cumulative dose is reached, with the amount varying with the fungal organism. Nystatin is primarily indicated for treatment of mucocutaneous (skin, oropharynx, vagina) or intestinal candidiasis; pimaricin is mainly used in therapeutic management of mycotic keratitis.

General dosages for some polyene macrolide antibiotics are listed in TABLE 52. The dose rate and frequency should be adjusted as needed for the individual animal.

TABLE 52 DOSAGES OF POLYENE MACROLIDE ANTIBIOTICS

Polyene Macrolide	Dosage, Route, and Frequency
Amphotericin B (0.1 mg/mL in 5% dextrose)	0.1–1 mg/kg, given IV slowly, 3 times/wk Total dose: 4–11 mg/kg
Amphotericin B lipid complex injection (Abelcet®)	1–3 mg/kg, IV, every other day or 3 times/wk Total dose: 12–24 mg/kg
Amphotericin B liposome (AmBisome®)	3–4 mg/kg, IV, every other day or 3 times/wk Total dose: 12–30 mg/kg
Nystatin	50,000–150,000 U, PO, tid (dogs)
Pimaricin (5% ophthalmic solution)	1 drop, instilled into the eye, every 1–2 hr

Special Clinical Concerns

Adverse Effects and Toxicity: Oral administration of nystatin can lead to anorexia and GI disturbances. The IV infusion of amphotericin B can cause an anaphylactoid reaction due to direct mast cell degranulation. A pre-test dose is recommended to detect this reaction, and pretreatment with H₁ antihistamines and short-acting glucocorticoids may be appropriate. Thrombophlebitis may occur with perivascular leakage. The primary toxicity associated with amphotericin B is nephrotoxicity. Within 15 min of IV administration of amphotericin B, renal arterial vasoconstriction occurs and lasts for 4–6 hr. This leads to diminished renal blood flow and glomerular filtration. Because amphotericin B binds to the cholesterol component in the membranes of the distal renal tubules, a change in permeability occurs in these cells, leading to polyuria, polydipsia, concentration defects, and acidification abnormalities. The net result is a distal renal tubular acidosis syndrome. The metabolic acidosis leads to bone buffering, the excessive release of calcium into the circulation, and ultimately nephrocalcinosis due to calcium precipitation in the acidic environment of the distal tubules. Almost every animal treated with amphotericin B develops some degree of renal impairment, which may become permanent depending on the total cumulative dose.

The administration of amphotericin B can lead to a number of other adverse effects, including anorexia, nausea, vomiting, hypersensitivity reactions, drug fever, normocytic normochromic anemia, cardiac arrhythmias (and even arrest), hepatic dysfunction, CNS signs, and thrombophlebitis at the injection site.

A number of adjuvant therapies are used to minimize adverse events of amphotericin

B. Pretreatment with antiemetic and antihistaminic agents prevents the nausea, vomiting, and hypersensitivity reactions. Giving corticosteroids IV also limits severe hypersensitivity reactions. Mannitol (1 g/kg, IV) with each dose of amphotericin B, and sodium bicarbonate (2 mEq/kg, IV or PO, daily) may help prevent acidification defects, metabolic acidosis, and azotemia; however, clinical evidence of efficacy has not been proved. Saralasin (6–12 mcg/kg/min, IV) and dopamine (7 mcg/kg/min, IV) infusions have prevented oliguria and azotemia induced by amphotericin B in dogs. Administering IV fluids or furosemide before amphotericin B prevents pronounced decreases in renal blood flow and glomerular filtration rate. Newer preparations in which amphotericin B is mixed with lipid or liposomal vehicles (particularly liposomes) are safer and have maintained efficacy.

Interactions: Amphotericin B may be combined with other antimicrobial agents with synergistic results. This often allows both the total dose of amphotericin B and the length of therapy to be decreased. Examples include combinations of 5-flucytosine and amphotericin B for treatment of cryptococcal meningitis, minocycline and amphotericin B for coccidioidomycosis, and imidazole and amphotericin B for several systemic mycotic infections. Rifampin may also potentiate the antifungal activity of amphotericin B.

Drugs that should be avoided during amphotericin B therapy include aminoglycosides (nephrotoxicity), digitalis drugs (increased toxicity), curarizing agents (neuromuscular blockade), mineralocorticoids (hypokalemia), thiazide diuretics (hypokalemia, hyponatremia), antineoplastic drugs (cytotoxicity), and cyclosporine (nephrotoxicity).

Effects on Laboratory Tests: Treatment with polyene macrolide antibiotics increases plasma bilirubin, CK, AST, ALT, BUN, eosinophil count, and urine protein, and decreases plasma potassium and platelet count.

IMIDAZOLES

Imidazoles may have antibacterial, antifungal, antiprotozoal, and anthelmintic activity. Several distinct phenylimidazoles are therapeutically useful antifungal agents with wide spectra against yeasts and filamentous fungi responsible for either superficial or systemic infections. The anthelmintic thiabendazole is also an imidazole with antifungal properties. Clotrimazole, miconazole, econazole, ketoconazole, itraconazole, and fluconazole are the most clinically important members of this group. Posaconazole and voriconazole are among the newer drugs; voriconazole is approved for use in people to treat aspergillosis.

Imidazoles generally are poorly soluble in water but can be dissolved in organic solvents such as chloroform, propylene glycol, and polyethoxylated castor oil (preparation for IV use but dangerous in dogs). An exception is fluconazole. Imidazoles are weak dibasic agents. Alterations in side-chain structure determine antifungal activity as well as the degree of toxicity.

Antifungal Activity

Mode of Action: Imidazoles alter the cell membrane permeability of susceptible yeasts and fungi by blocking the synthesis of ergosterol (demethylation of lanosterol is inhibited), the primary cell sterol of fungi. The enzyme targeted is a fungal cytochrome (CYP450). Other enzyme systems are also impaired, such as those required for fatty acid synthesis. Because of the drug-induced changes of oxidative and peroxidative enzyme activities, toxic concentrations of hydrogen peroxide develop intracellularly. The overall effect is cell membrane and internal organelle disruption and cell death. The cholesterol in host cells is not affected by the imidazoles, although some drugs impair synthesis of selected steroids and drug-metabolizing enzymes in the host. Because imidazoles impair synthesis, a lag time to efficacy occurs. This lag time may be prolonged because of the long half-life of these drugs.

Fungal Resistance: Sensitivity to the imidazoles varies greatly between various

strains of yeasts and fungi, but neither natural nor acquired resistance appears to be prevalent.

Antimicrobial Spectra: The antifungal imidazoles also have some antibacterial action but are rarely used for this purpose. Miconazole has a wide antifungal spectrum against most fungi and yeasts of veterinary interest. Sensitive organisms include *Blastomyces dermatitidis*, *Paracoccidioides brasiliensis*, *Histoplasma capsulatum*, *Candida* spp, *Coccidioides immitis*, *Cryptococcus neoformans*, and *Aspergillus fumigatus*. Some *Aspergillus* and *Mucor* spp are only marginally sensitive.

Ketoconazole has an antifungal spectrum similar to that of miconazole, but it is more effective against *C. immitis* and some other yeasts and fungi. Itraconazole and fluconazole are the most active of the antifungal imidazoles. Their spectrum includes dimorphic fungal organisms and dermatophytes. They are also effective against some cases of aspergillosis (60%–70%) and cutaneous sporotrichosis. Clotrimazole and econazole are used for superficial mycoses (dermatophytosis and candidiasis); econazole also has been used for oculomycosis. Thiabendazole is effective against *Aspergillus* and *Penicillium* spp, but its use has largely been replaced by the more effective imidazoles. Voriconazole is approved for human use in treatment of *Aspergillus* but is effective against many other fungal organisms. Posaconazole may be more effective than itraconazole or fluconazole but may be associated with more adverse effects.

Pharmacokinetic Features

Absorption and Distribution:

The imidazoles are rapidly but sometimes erratically absorbed from the GI tract; plasma levels peak within 2 hr after administration PO. Fluconazole is an exception, being close to 100% bioavailable after administration PO. Except for fluconazole, an acidic environment is required for dissolution of the imidazoles, and a decrease in gastric acidity can reduce bioavailability after administration PO. The rate of absorption appears to be increased when the drug is given with meals, but reports are conflicting. Because oral bioavailability can be very poor with noncommercial imidazole products, caution is recommended with compounded products, and monitoring is recommended if a compounded preparation is used.

Imidazoles appear to be widely distributed in the body, with detectable concentrations in saliva, milk, and cerumen. CSF penetration is poor except for fluconazole, which reaches 50%–90% of plasma concentrations. Most imidazoles (except fluconazole) are highly protein bound in the circulation (>95%), most to albumin. The highest concentrations of imidazoles are found in the liver, adrenal glands, lungs, and kidneys.

Biotransformation and Excretion:

Hepatic metabolism is the primary route of elimination. Metabolism of ketoconazole and most other imidazoles by oxidative pathways is extensive. Only ~2%–4% of a dose administered PO appears unchanged in the urine. Itraconazole is metabolized to an active metabolite that may contribute significantly to antimicrobial activity. The biliary route is the major excretory pathway (>80%); ~20% of the metabolites are eliminated in the urine. Fluconazole (in people) is eliminated (≥90%) unchanged in the urine. The kinetics of voriconazole have not yet been evaluated in animals.

Pharmacokinetics: The rate of elimination of ketoconazole appears to be dose dependent—the greater the dose, the longer the elimination half-life. There is also a biphasic elimination pattern, with rapid elimination in the first 1–2 hr, then a slower decline over the next 6–9 hr. Ketoconazole is usually administered bid. The half-life of itraconazole is longer (up to 48 hr in cats), thus allowing treatment once to twice daily. Because of the long half-life and mechanism of action (impaired synthesis of the fungal cell membrane), time to efficacy may take longer than drugs that have more rapid actions (such as amphotericin B).

Therapeutic Indications and Dose Rates

The imidazoles are used to treat systemic fungal diseases, dermatophyte infections

that have not responded to griseofulvin or topical therapy, *Malassezia* infection in dogs, aspergillosis, and sporotrichosis in animals that cannot tolerate or do not respond to sodium iodide. For serious infections, combination with amphotericin B is strongly recommended. Among the imidazoles, fluconazole may be more likely to distribute into tissues that are tough to penetrate. Both itraconazole and fluconazole are generally preferred to other imidazoles for treatment of systemic fungal infections, including aspergillosis and sporotrichosis. Topically applied imidazoles (clotrimazole, miconazole, econazole) are used for local dermatophytosis. Thiabendazole is included in some otic preparations for treatment of yeast infections.

Enilconazole is an imidazole that can be applied topically for treatment of dermatophytosis and aspergillosis. It has been used safely in cats, dogs, cattle, horses, and chickens and is prepared as a 0.2% solution for treatment of fungal skin infections. When infused into the nasal turbinates of dogs with aspergillosis, enilconazole treated and prevented the recurrence of fungal disease. When applied topically to dog and cat hairs, enilconazole inhibits fungal growth in 2 rather than 4–8 treatments, as is necessary with other topically administered antifungal agents.

General dosages for the antifungal imidazoles are listed in TABLE 53. The dose rate and frequency should be adjusted as needed for the individual animal.

Special Clinical Concerns

Adverse Effects and Toxicity: The imidazoles given PO result in few adverse effects, but nausea, vomiting, and hepatic dysfunction can develop. Ketoconazole in particular is associated with hepatotoxicity, especially in cats. Because imidazoles also inhibit CYP450 associated with steroid synthesis, as a result, sex steroids, including testosterone and adrenal steroid (cortisol),

TABLE 53 DOSAGES OF IMIDAZOLES

Imidazole	Dosage, Route, and Frequency
Enilconazole	10 mg/kg in 5–10 mL, bid for 7–14 days
Fluconazole	5–10 mg/kg, PO, once to twice daily
Itraconazole	5–10 mg/kg, PO, once to twice daily
Ketoconazole	5–20 mg/kg, PO, bid (dogs)
Thiabendazole	44 mg/kg/day, PO, or 22 mg/kg, PO, bid

metabolism is inhibited. Adrenal responsiveness to adrenocorticotrophic hormone (ACTH) will be decreased, particularly with ketoconazole. Reproductive disorders related to ketoconazole administration may be seen in dogs. Voriconazole is associated with a number of adverse effects in people, including vision disturbances.

Interactions: Imidazoles, in general, inhibit the metabolism of many drugs. Although ketoconazole has the broadest inhibitory effects, fluconazole followed by itraconazole also inhibit metabolism. Concurrent administration of these drugs with other drugs metabolized by the liver and potentially toxic should be done only with extreme caution. Imidazoles also are substrates for P-glycoprotein transport protein and may compete with other substrates, causing higher concentrations. Many of the substrates for P-glycoprotein are also substrates for CYP450. Rifampin, which is a P-glycoprotein substrate, decreases serum ketoconazole because of microsomal enzyme induction. The absorption of the imidazoles, except for that of fluconazole, is inhibited by concurrent administration of cimetidine, ranitidine, anticholinergic agents, or gastric antacids. The risk of hepatotoxicity is increased if ketoconazole and griseofulvin are administered together. Imidazoles might be used concurrently with other antifungals to facilitate synergistic efficacy.

Effects on Laboratory Tests: Treatment with imidazoles increases AST, ALT, plasma bilirubin, and plasma cholesterol. Adrenal responsiveness is altered.

FLUCYTOSINE

Flucytosine (5-fluorocytosine) is a fluorinated pyrimidine related to fluorouracil that was initially developed as an antineoplastic agent. It should be stored in airtight containers protected from light. Solutions for infusion are unstable and should be stored at 15°–20°C. Usually, it is given PO in capsules.

Antifungal Activity

Mode of Action: Flucytosine is converted by cytosine deaminase in fungal cells to fluorouracil, which then interferes with RNA and protein synthesis. Fluorouracil is metabolized to 5-fluorodeoxyuridylic acid, an inhibitor of thymidylate synthetase. DNA synthesis is then halted. Mammalian

cells do not convert large amounts of flucytosine to fluorouracil and, thus, are not affected at usual dosage levels.

Fungal Resistance: Resistance to flucytosine can develop rapidly even during the course of treatment; this precludes its use as the sole treatment for mycotic infections. The mechanisms of resistance are not completely understood.

Antifungal Spectra: The following are the main organisms usually sensitive to flucytosine: *Cryptococcus neoformans*, *Candida albicans*, other *Candida* spp, *Torulopsis glabrata*, *Sporothrix schenckii*, *Aspergillus* spp, and agents of chromoblastomycosis (*Phialophora*, *Cladosporium*). The other fungi responsible for systemic mycoses and dermatophytes are resistant to flucytosine.

Pharmacokinetic Features

Absorption and Distribution: Flucytosine is rapidly and well absorbed from the GI tract, with plasma levels peaking in 1–2 hr in animals that have received the drug for several days. The drug is widely distributed in the body, with a volume of distribution approximating the total body water. Flucytosine is minimally bound to plasma proteins. There is excellent penetration into body fluids such as the CSF, synovial fluids, and aqueous humor.

Biotransformation and Excretion:

Nearly all (85%–95%) of an oral dose is excreted unchanged. Flucytosine is principally excreted by glomerular filtration (>80%). The clearance of flucytosine is approximately equivalent to that of creatinine. In renal failure, elimination of flucytosine is markedly impaired.

Pharmacokinetics: With normal renal function, the plasma half-life of flucytosine is usually 2–4 hr but may be up to 200 hr with oliguria. Serum levels of 50–100 mcg/mL are usually in the therapeutic range.

Therapeutic Indications and Dose Rates

The more common indications for flucytosine include cryptococcal meningitis, used together with amphotericin B (~30% of isolates develop resistance during the course of treatment); candidiasis (~90% of isolates are usually sensitive); aspergillosis (some strains are sensitive at <5 mcg/mL); chromomycosis (some strains are very

sensitive); and sporotrichosis (some cases may respond).

General dosages for flucytosine are 25–50 mg/kg and 30–40 mg/kg, P.O., tid–qid in dogs and cats, respectively. The dose rate and frequency should be adjusted as needed for the individual animal. Dosage modification is essential in renal failure. Flucytosine serum levels should be monitored if possible.

Special Clinical Concerns

Adverse Effects and Toxicity: Flucytosine is often well tolerated over long periods, but toxic effects may be seen when serum levels are high (>100 mcg/mL). These include GI signs (nausea, vomiting, diarrhea) and reversible hepatic and hematologic effects (increased liver enzymes, anemia, neutropenia, thrombocytopenia). In dogs, erythemic and alopecic dermatitis may be seen but subsides when the drug is discontinued.

Interactions: There is synergistic antifungal activity between amphotericin B and ketoconazole, and the combination may retard the emergence of strains resistant to flucytosine. The renal effects of amphotericin B prolong elimination of flucytosine. If flucytosine is used together with immunosuppressive drugs, severe depression of bone marrow function is possible.

Effects on Laboratory Tests: Treatment with flucytosine increases alkaline phosphatase, AST, ALT, and other liver leakage enzymes, and decreases RBC, WBC, and platelet counts.

GRISEOFULVIN

Griseofulvin is a systemic antifungal agent effective against the common dermatophytes. It is practically insoluble in water and only slightly soluble in most organic solvents. Particle sizes of griseofulvin vary from 2.7 μm (ultramicrosized) to 10 μm (microsized).

Antifungal Activity

Mode of Action: Dermatophytes concentrate griseofulvin through an energy-dependent process. Griseofulvin then disrupts the mitotic spindle by interacting with the polymerized microtubules in susceptible dermatophytes. This leads to production of multinucleate fungal

cells. The inhibition of nucleic acid synthesis and the formation of hyphal cell wall material also may be involved. The result is distortion, irregular swelling, and spiral curling of the hyphae. Griseofulvin is fungistatic rather than fungicidal, except in young active cells.

Fungal Resistance: Dermatophytes can be made resistant to griseofulvin in vitro.

Antifungal Spectra: Griseofulvin is active against *Microsporum*, *Epidermophyton*, and *Trichophyton* spp. It has no effect on bacteria (including *Actinomyces* and *Nocardia* spp), other fungi, or yeasts.

Pharmacokinetic Features

Absorption: Plasma levels peak ~4 hr after administration P.O., but absorption from the GI tract continues over a prolonged period. Absorption is highly variable and influenced by a number of factors. The rates of disaggregation and dissolution in the GI tract limit the bioavailability of griseofulvin; thus, microsized and ultramicrosized particles are usually used. High-fat meals, margarine, or propylene glycol significantly enhance GI absorption of griseofulvin and are indicated if the microsized particles are used.

Distribution: Griseofulvin is deposited in keratin precursor cells within 4–8 hr of administration P.O. Sweat and transdermal fluid loss appear to play an important role in griseofulvin transfer in the stratum corneum. When these cells differentiate, griseofulvin remains bound and persists in keratin, making it resistant to fungal invasion. For this reason, new growth of hair, nails, or horn is the first to become free of fungal infection. As the fungus-containing keratin is shed, it is replaced by normal skin and hair. Only a small fraction of a dose of griseofulvin remains in the body fluids or tissues.

Biotransformation and Pharmacokinetics: Depending on the species, 10%–50% of a griseofulvin dose is excreted almost exclusively as metabolites in the urine, and the remainder in the feces for ~4–5 days after administration. The elimination half-life of griseofulvin is ~24 hr in several species. The drug can be detected in 48–72 hr at the base level of the skin, in 6–12 days in the lower quarter, and in 2–19 days in the middle section of the horny layer.

Therapeutic Indications and Dose Rates

Griseofulvin is used for dermatophyte infections in dogs, cats, calves, horses, and other domestic and exotic animal species. Most dermatophytes are sensitive, but certain species present greater therapeutic challenges than others. Several may require higher dose rates for satisfactory control.

General dosages for griseofulvin are listed in TABLE 54. The dose rate and frequency should be adjusted as needed for the individual animal.

Special Clinical Concerns

Adverse Effects and Toxicity: Adverse effects induced by griseofulvin are rare. Nausea, vomiting, and diarrhea have been seen. Hepatotoxicity has also been reported. Animals with impaired liver function should not be given griseofulvin, because its biotransformation will be reduced and toxic levels may be reached. Idiosyncratic (Type B or Type II adverse reaction) toxicity in cats has been reported. Clinical signs are neurologic, GI, and hematologic. Griseofulvin is contraindicated in pregnant animals (especially mares and queens) because it is teratogenic.

Interactions: Lipids increase GI absorption of griseofulvin. Barbiturates decrease its absorption and antifungal activity. Griseofulvin is a microsomal enzyme inducer and promotes the biotransformation of many concurrently administered drugs. The combined use of ketoconazole and griseofulvin may lead to hepatotoxicity.

Effects on Laboratory Tests: Treatment with griseofulvin increases alkaline phosphatase, AST, and ALT. Proteinuria may be detected.

ALLYLAMINES

The allylamines include terbinafine, naftifine, and the much older thiocarba-

mate tolnaftate. Their mechanism is competitive inhibition of squalene epoxidase, blocking conversion of squalene to lanosterol, leading to squalene accumulation and ergosterol depletion in the cell membrane. Terbinafine has a much higher affinity for fungal than for mammalian squalene epoxidase. Avid uptake of terbinafine into body fat and epidermis presumably enhances treatment for dermatophytes of superficial yeast pathogens of the skin. However, data are emerging to potentially support its use for systemic fungal infections. Terbinafine is also active against yeasts (eg, *Blastomyces dermatitidis*, *Cryptococcus neoformans*, *Sporothrix schenckii*, *Histoplasma capsulatum*, *Candida*, and *Pityrosporum* spp). Terbinafine increasingly is used in combination with other antifungal drugs to enhance efficacy. Effects are fungicidal. The allylamines appear to be more efficacious than griseofulvin for treatment of dermatophyte infections. Efficacy has also been demonstrated against *S schenckii* and *Aspergillus*. Terbinafine may enhance efficacy of other antifungal drugs for a variety of fungal disorders and pythiosis. In contrast to terbinafine, tolnaftate is limited to treatment of dermatophytes. Resistance to the allylamines is rare, but the drugs potentially can be affected by multidrug resistance efflux mechanisms. Terbinafine, available in oral and topical preparations, is well absorbed (80% in people) after PO administration. Fat facilitates absorption. High concentrations occur in the stratum corneum, sebum, and hair. Terbinafine is metabolized by the liver in people; the elimination half-life is sufficiently long to allow once-daily administration, with steady state not occurring for 10–14 days in people. Adverse effects of terbinafine after PO administration are limited to GI and skin signs; hepatobiliary dysfunction is a rare adverse event. Because inhibition of ergosterol synthesis occurs at a step before cytochrome P450 involvement, the allylamines do not affect steroid synthesis as do the imidazoles.

TABLE 54 DOSAGES OF GRISEOFULVIN

Species	Dosage, Route, and Frequency
Dogs, cats	Microsized: 10–30 (up to 130) mg/kg/day, PO, or divided bid-td Ultramicrosized: 5–10 (up to 50) mg/kg/day, PO
Horses, cattle	5–10 mg/kg/day, PO, for 3–6 wk, or longer if required

IODIDES

Sodium and potassium iodide have both been used to treat selected bacterial, actinomycete, and fungal infections, although sodium iodide is preferred. The *in vivo* effects of iodides against fungal cells are not well understood. Iodide is readily absorbed from the GI tract and distributes freely into the extracellular fluid and glandular secretions. Iodide concentrates in the thyroid gland (50 times corresponding plasma level) and to a much lesser degree in salivary, lacrimal, and tracheobronchial glands. Longterm use at high levels leads to accumulation in the body and to iodism.

Clinical signs of iodism include lacrimation, salivation, increased respiratory secretions, coughing, inappetence, dry scaly skin, and tachycardia. Cardiomyopathy has been reported in cats. Host defense systems, such as decreased immunoglobulin production and reduced phagocytic ability of leukocytes, are also impaired. Iodism may also lead to abortion and infertility.

Sodium iodide has been used successfully to treat cutaneous and cutaneous/lymphadenitis forms of sporotrichosis; attempts to control various other mycotic infections with iodides yield equivocal results.

The dosage for sodium iodide (20% solution) is 44 mg/kg/day, PO, for dogs, and 22 mg/kg/day, PO, for cats. The dosage for horses is 125 mL of 20% sodium iodide solution, IV, daily for 3 days, then 30 g, PO, daily for 30 days after clinical remission. The dosage rate for treating actinomycosis and actinobacillosis in cattle is 66 mg/kg, by slow IV, repeated weekly. Potassium iodide should never be injected IV.

TOPICAL ANTIFUNGAL AGENTS

A number of agents that have antifungal activity are applied topically, either on the skin, in the ear or eye, or on mucous membranes (buccal, nasal, vaginal) to control superficial mycotic infections. Concurrent systemic therapy with griseofulvin is often helpful for therapeutic management of dermatophyte infections. The hair should be clipped from affected areas and the nails trimmed to fully expose the lesions before antifungal preparations are applied. Bathing the animal may also be helpful. Isolation or restricted movement of infected animals

is wise, especially when dealing with zoonotic fungi.

Preparations may be used in the form of solutions, lotions, sprays, powders, creams, or ointments for dermal application, or in the form of irrigant solutions, ointments, tablets, or suppositories for intravaginal use. The concentration of active principle in these preparations varies and depends on the activity of the specific agent.

The clinical response to local antifungal agents is unpredictable. Resistance to many of the available drugs is common. Spread of infection and reinfection add to the difficulty of controlling superficial infections. Perseverance is often an essential element of therapy.

Some topical antifungal agents that have been used with success in various conditions and species include iodine preparations (tincture of iodine, potassium iodide, iodophors), copper preparations (copper sulfate, copper naphthenate, cuprimyxin), sulfur preparations (mono-sulfiram, benzoyl disulfide), phenols (phenol, thymol), fatty acids and salts (propionates, undecylenates), organic acids (benzoic acid, salicylic acids), dyes (crystal [gentian] violet, carbolfuchsin), hydroxyquinolines (iodochlorhydroxyquin), nitrofurans (nitrofuraxone, nitrofurfurylmethyl ether), imidazoles (miconazole, tioconazole, clotrimazole, econazole, thiabendazole), polyene antibiotics (amphotericin B, nystatin, pimarin, candicidin, hachimycin), allylamines (naftifine, terbinafine), thiocarbamates (tolnaftate), and miscellaneous agents (acrisorcin, haloprogin, ciclopirox, olamine, dichlorophen, hexetidine, chlorphenesin, triacetin, polynoxylin, amorolfine).

Amorolfine is a topical antifungal agent used to treat onychomycosis and dermatophytosis. It is prepared as a cream or nail lacquer. Amorolfine is a morpholine derivative that appears to interfere with the synthesis of sterols essential for the functioning of fungal cell membranes. *In vitro*, activity has been shown against some yeasts and dimorphic, dematiaceous, and filamentous fungi (*Blastomyces dermatitidis*, *Candida* spp, *Histoplasma capsulatum*, *Sporothrix schenckii*, and *Aspergillus* spp). Despite its *in vitro* activity, amorolfine is inactive when given systemically and thus is limited to topical use in treatment of superficial infections. Its role in treatment of fungal infection in animals is not clear.

ANTI-INFLAMMATORY AGENTS

Inflammation is the complex pathophysiologic response of vascularized tissue to injury. The injury may result from various stimuli, including thermal, chemical, or physical damage; ischemia; infectious agents; antigen-antibody interactions; and other biologic processes. After tissue injury, the process of tissue healing includes three distinct phases: an inflammatory phase, a repair phase, and a remodeling phase. The desired outcome of the inflammatory response is isolation and elimination of the injurious agent to prepare for the repair of tissue damage at the site of injury and restoration of function. Finally, new tissue formed during the repair phase (eg, scar tissue) may be remodeled over several months.

PATHOPHYSIOLOGY OF INFLAMMATION

The initial inflammation phase consists of three subphases: acute, subacute, and chronic (or proliferative). The acute phase typically lasts 1–3 days and is characterized by the five classic clinical signs: heat, redness, swelling, pain, and loss of function. The subacute phase may last from 3–4 days to ~1 mo and corresponds to a cleaning phase required before the repair phase. If the subacute phase is not resolved within ~1 mo, then inflammation is said to become chronic and can last for several months. Tissue can degenerate and, in the locomotor system, chronic inflammation may lead to tearing and rupture. Alternatively, after the subacute inflammatory phase, tissue can repair and be strengthened during the remodeling phase.

From a mechanistic point of view, the acute response to tissue injury occurs in the microcirculation at the site of injury. Initially, there is a transient constriction of arterioles; however, within several minutes, chemical mediators released at the site relax arteriolar smooth muscle, leading to vasodilation and increased capillary permeability. Protein-rich fluid then exudes from capillaries into the interstitial space. This fluid contains many of the components of plasma including albumin, fibrinogen, kinins, complement, and immunoglobulins that mediate the inflammatory response.

The subacute phase is characterized by movement of phagocytic cells to the site of

injury. In response to adhesion, molecules released from activated endothelial cells, leukocytes, platelets, and erythrocytes in injured vessels become sticky and adhere to the endothelial cell surfaces. Polymorphonuclear leukocytes such as neutrophils are the first cells to infiltrate the site of injury. Basophils and eosinophils are more prevalent in allergic reactions or parasitic infections. As inflammation continues, macrophages predominate, actively removing damaged cells or tissue. If the cause of injury is eliminated, the subacute phase of inflammation may be followed by a period of tissue repair. Blood clots are removed by fibrinolysis, and damaged tissues are regenerated or replaced with fibroblasts, collagen, or endothelial cells. During the remodeling phase, the new collagen laid down during the repair phase (mainly type III) is progressively replaced by type I collagen to adapt to the original tissue. However, if inflammation becomes chronic, further tissue destruction and/or fibrosis occurs.

CHEMICAL MEDIATORS OF INFLAMMATION

Biochemical mediators released during inflammation intensify and propagate the inflammatory response (*see* TABLE 55). These mediators are soluble, diffusible molecules that can act locally and systemically. Mediators derived from plasma include complement and complement-derived peptides and kinins. Released via the classic or alternative pathways of the complement cascade, **complement-derived peptides** (C3a, C3b, and C5a) increase vascular permeability, cause smooth muscle contraction, activate leukocytes, and induce mast-cell degranulation. C5a is a potent chemotactic factor for neutrophils and mononuclear phagocytes. The kinins are also important inflammatory mediators. The most important kinin is **bradykinin**, which increases vascular permeability and vasodilation and, importantly, activates phospholipase A_2 (PLA₂) to liberate arachidonic acid (AA). Bradykinin is also a major mediator involved in the pain response.

Other mediators are derived from injured tissue cells or leukocytes recruited to the site of inflammation. Mast cells, platelets,

TABLE 55 ACTIONS OF INFLAMMATORY MEDIATORS

Action	Mediators ^a
Vasodilation, increased vascular permeability	Histamine, serotonin, bradykinin, C3a, C5a, LTC ₄ , LTD ₄ , PGL ₂ , PGE ₂ , PGD ₂ , PGF ₂ , activated Hageman factor, kinonogen fragments, fibrinopeptides
Vasoconstriction	TXA ₂ , LTB ₄ , LTC ₄ , LTD ₄ , C5a
Smooth muscle contraction	C3a, C5a, histamine, LTB ₄ , LTC ₄ , LTD ₄ , TXA ₂ , serotonin, PAF, bradykinin
Mast cell degranulation	C5a, C3a
Stem cell proliferation	IL-3, G-CSF, GM-CSF, M-CSF
Chemotaxis	C5a, LTB ₄ , IL-8, PAF, 5-HETE, histamine, others

^a C = complement, LT = leukotriene, PG = prostaglandin, TX = thromboxane, PAF = platelet activating factor, IL = interleukin, CSF = colony stimulating factor, HETE = hydroxyeicosatetranoate, TNF = tumor necrosis factor

and basophils produce the vasoactive amines serotonin and histamine. **Histamine** causes arteriolar dilation, increased capillary permeability, contraction of nonvascular smooth muscle, and eosinophil chemotaxis and can stimulate nociceptors responsible for the pain response. Its release is stimulated by the complement components C3a and C5a and by lysosomal proteins released from neutrophils. Histamine activity is mediated through the activation of one of four specific histamine receptors, designated H₁, H₂, H₃, or H₄, in target cells. Most histamine-induced vascular effects are mediated by H₁ receptors. H₂ receptors mediate some vascular effects but are more important for their role in histamine-induced gastric secretion. Less is understood about the role of H₃ receptors, which may be localized to the CNS. H₁ receptors are located on cells of hematopoietic origin, and H₁ antagonists are promising drug candidates to treat inflammatory conditions involving mast cells and eosinophils (allergic conditions). **Serotonin** (5-hydroxytryptamine) is a vasoactive mediator similar to histamine found in mast cells and platelets in the GI

tract and CNS. Serotonin also increases vascular permeability, dilates capillaries, and causes contraction of nonvascular smooth muscle. In some species, including rodents and domestic ruminants, serotonin may be the predominant vasoactive amine.

Cytokines, including interleukins 1–10, tumor necrosis factor α (TNF- α), and interferon γ (INF- γ) are produced predominantly by macrophages and lymphocytes but can be synthesized by other cell types as well. Their role in inflammation is complex. These polypeptides modulate the activity and function of other cells to coordinate and control the inflammatory response. Two of the more important cytokines, interleukin-1 (IL-1) and TNF- α , mobilize and activate leukocytes, enhance proliferation of B and T cells and natural killer cell cytotoxicity, and are involved in the biologic response to endotoxins. IL-1, IL-6, and TNF- α mediate the acute phase response and pyrexia that may accompany infection and can induce systemic clinical signs, including sleep and anorexia. In the acute phase response, interleukins stimulate the liver to synthesize acute-phase proteins, including complement components, coagulation factors, protease

inhibitors, and metal-binding proteins. By increasing intracellular Ca^{2+} concentrations in leukocytes, cytokines are also important in the induction of PLA_2 . Colony-stimulating factors (GM-CSF, G-CSF, and M-CSF) are cytokines that promote expansion of neutrophil, eosinophil, and macrophage colonies in bone marrow. In chronic inflammation, cytokines IL-1, IL-6, and TNF- α contribute to the activation of fibroblasts and osteoblasts and to the release of enzymes such as collagenase and stromelysin that can cause cartilage and bone resorption. Experimental evidence also suggests that cytokines stimulate synovial cells and chondrocytes to release pain-inducing mediators.

Lipid-derived autacoids play important roles in the inflammatory response and are a major focus of research into new anti-inflammatory drugs. These compounds include the eicosanoids such as prostaglandins, prostacyclin, leukotrienes, and thromboxane A and the modified phospholipids such as platelet activating factor (PAF). Eicosanoids are synthesized from 20-carbon polyunsaturated fatty acids by many cells, including activated leukocytes, mast cells, and platelets and are therefore widely distributed. Hormones and other inflammatory mediators (TNF- α , bradykinin) stimulate eicosanoid production either by direct activation of PLA_2 , or indirectly by increasing intracellular Ca^{2+} concentrations, which in turn activate the enzyme. Cell membrane damage can also cause an increase in intracellular Ca^{2+} . Activated PLA_2 directly hydrolyzes AA, which is rapidly metabolized via one of two enzyme pathways—the cyclooxygenase (COX) pathway leading to the formation of prostaglandin and thromboxanes, or the 5-lipoxygenase (5-LOX) pathway that produces the leukotrienes.

Cyclooxygenase catalyzes the oxygenation of AA to form the cyclic endoperoxide PGG_2 , which is converted to the closely related PGH_2 . Both PGG_2 and PGH_2 are inherently unstable and rapidly converted to various prostaglandins, thromboxane A_2 (TXA_2), and prostacyclin (PGI_1). In the vascular beds of most animals, PGE_1 , PGE_2 , and PGI_1 are potent arteriolar dilators and enhance the effects of other mediators by increasing small-vein permeability. Other prostaglandins, including $\text{PGF}_{2\alpha}$ and thromboxane, cause smooth muscle contraction and vasoconstriction. Prostaglandins sensitize nociceptors to pain-provoking mediators such as bradykinin and histamine and, in high concentrations, can directly stimulate sensory nerve endings. TXA_2 is a potent

platelet-aggregating agent involved in thrombus formation.

Found predominately in platelets, leukocytes, and the lungs, 5-LOX catalyzes the formation of unstable hydroxyperoxides from AA. These hydroxyperoxides are subsequently converted to peptide **leukotrienes**. Leukotriene B_4 (LTB_4) and 5-hydroxyeicosatetranoate (5-HETE) are strong chemoattractants stimulating polymorphonuclear leukocyte movement. LTB_4 also stimulates the production of cytokines in neutrophils, monocytes, and eosinophils and enhances the expression of C3b receptors. Other leukotrienes facilitate the release of histamine and other autacoids from mast cells and stimulate bronchiolar constriction and mucous secretion. In some species, leukotrienes C_4 and D_4 are more potent than histamine in contracting bronchial smooth muscle.

Platelet activating factor (PAF) is also derived from cell membrane phospholipids by the action of PLA_2 . PAF, synthesized by mast cells, platelets, neutrophils, and eosinophils, induces platelet aggregation and stimulates platelets to release vasoactive amines and synthesize thromboxanes. PAF also increases vascular permeability and causes neutrophils to aggregate and degranulate.

The role of the free radical gas **nitric oxide** (NO) in inflammation is well established. NO is an important cell-signaling messenger in a wide range of physiologic and pathophysiologic processes. Small amounts of NO play a role in maintaining resting vascular tone, vasodilation, and antiaggregation of platelets. In response to certain cytokines (TNF- α , IL-1) and other inflammatory mediators, the production of relatively large quantities of NO is stimulated. In larger quantities, NO is a potent vasodilator, facilitates macrophage-induced cytotoxicity, and may contribute to joint destruction in some types of arthritis.

ANTIHISTAMINES

Antagonists that selectively block specific histamine receptors have been developed. H_1 antagonists block the actions of histamine responsible for increased capillary permeability and wheal and edema formation. However, because histamine is only one component of an incredibly complex inflammatory cascade, antihistamines have very weak anti-inflammatory activity. H_1 antihistamines may be useful to treat immediate hypersensitivity reactions such as anaphylaxis by blocking bronchoconstriction and vasodilation. H_1 antagonists

may be less effective to treat allergic inflammatory diseases, such as atopy, primarily because mediators other than histamine play important roles in such conditions. H_2 (now classified as inverse agonists of the H_2 receptor, such as cimetidine and ranitidine) antagonists are routinely used to block the gastric secretory effects of histamine and have limited anti-inflammatory effects.

CORTICOSTEROIDS

Two classes of steroid hormones, mineralocorticoids and glucocorticoids, are naturally synthesized in the adrenal cortex from cholesterol. (See also THE ADRENAL GLANDS, p 573.)

Mineralocorticoids (aldosterone) are so named because they are important in maintaining electrolyte homeostasis. However, mineralocorticoids also trigger a broader range of functions in nonclassic target cellular sites, including some effects on wound healing after injury. In addition, a chronic and inappropriate (relative to intravascular volume and dietary sodium intake) increase in aldosterone secretion evokes a wound healing response in the absence of tissue injury. This can lead to antialdosterone (eg, spironolactone) drug treatment being recommended to prevent undesired heart remodeling and fibrosis.

Glucocorticoids suppress virtually every component of the inflammatory process; they inhibit PLA_2 , decrease synthesis of interleukins and numerous other proinflammatory cytokines, suppress cell-mediated immunity, reduce complement synthesis, and decrease production and activity of leukocytes. Unsurprisingly then, glucocorticoids are by far the most efficacious anti-inflammatory drugs. They are also the most commonly used anti-inflammatory drugs. However, because their pharmacologic and physiologic effects are so broad, the potential for adverse effects is considerable.

Glucocorticoids play significant roles in carbohydrate, protein, and lipid metabolism; the immune response; and the response to stress. Natural glucocorticoids also have some mineralocorticoid activity and therefore affect fluid and electrolyte balance. While corticosteroids can be highly effective in suppressing or preventing inflammation, their physiologic and pharmacologic mechanisms of action are mediated by the same receptor. This explains why their pharmacologic and physiologic effects are inherently linked, and why supraphysiologic exposure to

corticoids is potentially detrimental to several metabolic, hormonal, and immunologic functions.

All therapeutic corticosteroids have a 21-carbon steroid skeleton, similar to hydrocortisone (cortisol). Modifications to this skeleton selectively alter the degree of anti-inflammatory activity and the metabolic consequences and vary the duration of activity and protein-binding affinity of the resultant compound. The introduction of an additional double bond between C-1 and C-2 of cortisol in all synthetic corticosteroids selectivity increases glucocorticoid and anti-inflammatory activity. However, this single modification does not affect mineralocorticoid activity, resulting in an enhanced glucocorticoid/mineralocorticoid potency ratio, eg, prednisolone is ~4- to 5-fold more selective than cortisol. Additional fluorination at the C-9 position enhances both glucocorticoid and mineralocorticoid activity, as in 9α -fluorocortisol (fludrocortisone) and isoflupredone. Fludrocortisone (administered as fludrocortisone acetate) is 125-fold more potent than cortisol for mineralocorticoid effect and only 10-fold more for glucocorticoid effect. Thus, it is used in small animal medicine for its mineralocorticoid selectivity in the treatment of adrenocortical insufficiency.

Isoflupredone is used as an anti-inflammatory drug in cattle but lacks selectivity for mineralocorticoid effects and increases the risk of severe hypokalemia. When a fluorinated derivative is substituted at the C-16 by an OH radical or a CH_3 group, the new C-16 substituted compound (eg, triamcinolone, dexamethasone, betamethasone) has virtually no mineralocorticoid effect but remains a potent anti-inflammatory glucocorticoid. This last substitution on C-16 yields a new property to these fluorocorticosteroids, enabling them to trigger parturition in various species, including cattle. Dexamethasone and flumethasone (short-acting formulations) can induce parturition when administered after 255 days of gestation in cattle, but induced calving is usually associated with a high incidence of adverse effects, including retained placenta.

Many corticoids are administered as esters. Esterification of the alcohol at C-21 determines the extent of water/lipid solubility and controls the *in vivo* disposition of the compound. Esterification with a monoacid, such as acetic acid, yields water-insoluble drugs (eg, methylprednisolone acetate) that can be used as long-acting formulations when administered by the IM,

SC, or intra-articular route. Other water-insoluble esters are diacetate, terbutate, and pivalate. By contrast, esterification of the same corticoid by a diacid such as succinic acid can yield a hydrosoluble ester, due to the second acid function (as for methylprednisolone sodium succinate) allowing a salt to be formed. Phosphate esters are also hydrosoluble. Solutions of free steroids or of hydrosoluble esters can be administered by the IV or IM route and are often used to treat life-threatening conditions such as heaves or hypersensitivity reaction. Esters may also be used PO, but hydrolysis occurs in the lumen of the digestive tract (pancreatic esterase) and the free active moiety is absorbed; thus, a formulation may be long-acting when administered parenterally but short-acting when given orally (eg, prednisolone acetate).

Nearly all esters are inactive prodrugs and require hydrolyzation to release their active moiety. Hydrolysis by esterases or pseudoesterases may occur either in body fluids such as blood or synovial fluid (acetate) or mainly in liver (succinate). Thus, for a local administration the choice of an appropriate ester is important. Hydrolysis may be only partial; for example, the bioavailability of methylprednisolone (the active moiety) from its hydrosoluble ester, methylprednisolone sodium succinate, is only 50% in dogs after IV administration, which must be considered when determining a dosage regimen.

Substances having a ketone radical in C-11, in lieu of an OH radical required for binding of the corticoid to its cellular receptors, are also prodrugs. Cortisone, prednisone, and methylprednisone are prodrugs of cortisol. These prodrugs are back transformed to their alcohol form in the liver by an 11- β -hydroxylase. There is no reason to administer them locally, because the activity of these prodrugs relies on hepatic metabolic activity. They are not recommended for use in animals with hepatic insufficiency. Prednisone is reported to have poor efficacy for treatment of heaves in horses because it is poorly absorbed, and its active metabolite, prednisolone, is rarely produced. By contrast, prednisolone has good bioavailability and is recommended in horses.

Other structural modifications allow more lipophilic substances to be obtained, such as the introduction of an acetonide between C-16 and C-17 (eg, triamcinolone acetonide). Triamcinolone acetonide, which is not a prodrug of triamcinolone, can be used for intra-articular administration in horses to treat osteoarthritis or as a topical

formulation. Esterification at C-17 (valerate) produces a lipophilic compound with an enhanced topical:systemic potency ratio. Other approaches to achieve local glucocorticoid activity while minimizing systemic effects involve the formation of analogues that are rapidly inactivated after their systemic absorption. Fluticasone propionate, which is not a prodrug, is directly used to treat lung conditions. Similarly, beclomethasone dipropionate (a prodrug) locally yields an active metabolite (beclomethasone 17-monopropionate) that in turn yields beclomethasone, which has very weak anti-inflammatory activity.

Therapeutic corticosteroids are typically classified based on their relative glucocorticoid and mineralocorticoid potency (ie, the relative intensity of drug activity related to its concentration, a property that should not be confused with efficacy) as well as duration of effect (see TABLE 56). Compounds with the most potent glucocorticoid activity are also the most potent suppressors of the hypothalamic-pituitary-adrenal axis (HPAA).

Mode of Action: Glucocorticoids are capable of suppressing the inflammatory process through numerous pathways. They interact with specific intracellular receptor proteins in target tissues to alter the expression of corticosteroid-responsive genes. Glucocorticoid-specific receptors in the cell cytoplasm bind with steroid ligands to form hormone-receptor complexes that eventually translocate to the cell nucleus. There, these complexes bind to specific DNA sequences and alter their expression. The complexes may induce the transcription of mRNA, leading to synthesis of new proteins. Such proteins include lipocortin, a protein known to inhibit PLA₂, and thereby block the synthesis of prostaglandins, leukotrienes, and PAF. Glucocorticoids also inhibit the production of other mediators, including AA metabolites such as those produced via COX activation (both COX-1 and COX-2), cytokines, the interleukins, adhesion molecules, and enzymes such as collagenase.

Physiologic and Pharmacologic Effects:

Peripherally and in the liver, glucocorticoids have important effects on carbohydrate, protein, and lipid metabolism. In the periphery, glucocorticoids stimulate lipolysis and protein breakdown, releasing glycerol and amino acids that act as substrates for gluconeogenesis. As a result, chronic exposure to excessive glucocorticoids may lead to muscle wasting

TABLE 56 RELATIVE POTENCIES OF COMMONLY USED CORTICOSTEROIDS

Compound	Relative Glucocorticoid Activity	Relative Mineralocorticoid Activity	Duration of Effect ^a (Alcohol Form)
Cortisol	1	1	S
Prednisone	5	0.8	I
Prednisolone	5	0.8	I
Methylprednisolone	5	0.5	I
Fludrocortisone	10	125	I
Isoflupredone	25	25	L
Triamcinolone	5	0	I
Triamcinolone acetoneide	30	0	I
Dexamethasone	25	0	L
Betamethasone	25	0	L
Flumethasone	120	0	L

^a S = short (~12 hr), I = intermediate (~24 hr), L = long (~48–72 hr)

and redistribution of body fat typical in animals with hyperadrenocorticism. In the liver, glucocorticoids stimulate hepatic gluconeogenesis and increase the hepatic synthesis and storage of glycogen. It is believed that gluconeogenesis is stimulated through the transcription of enzymes such as glucose-6-phosphatase and phosphoenolpyruvate carboxykinase. Glucocorticoids also decrease glucose uptake in peripheral tissues, including adipose tissue and mammary glands, further contributing to an increase in blood glucose. In dairy cattle, the reduction of milk yield is a major mechanism of the glucose-sparing effect of corticoids. In response to increased blood glucose, there is a compensatory increase in insulin. However, glucocorticoids inhibit the suppression of gluconeogenesis by insulin and cause insulin resistance in peripheral tissues, further contributing to hyperglycemia.

Although not as potent as the mineralocorticoid aldosterone, nonfluorinated glucocorticoids (prednisolone and methylprednisolone) do have some effects on water and electrolyte balance, enhancing potassium excretion and sodium retention primarily due to their activity in the kidneys. Fluorinated corticoids, provided that they are substituted at C-16 as in dexamethasone and triamcinolone, have no mineralocorticoid activity but rather exert a polyuric/polydipsic effect due to an inhibition of antidiuretic hormone

(ADH) secretion and decreased renal sensitivity to ADH. Glucocorticoids can increase renal excretion and decrease the intestinal absorption of calcium, causing depletion of calcium stores. Glucocorticoids also inhibit osteoblasts, stimulate osteoclasts, and increase parathyroid secretion, which could affect bone healing.

A number of mechanisms are responsible for the anti-inflammatory and immunosuppressive actions of glucocorticoids. In homeostasis, glucocorticoids help maintain normal vascular permeability and microcirculation and stabilize cellular and lysosomal membranes. However, in acute inflammation, glucocorticoids decrease vascular permeability and inhibit the migration and egress of polymorphonuclear lymphocytes into tissues. Glucocorticoids suppress cell-mediated immunity by inducing apoptosis in normal lymphoid cells; inhibiting the clonal expansion of T and B lymphocytes; and reducing the number of circulating eosinophils, basophils, and monocytes. In contrast, glucocorticoids inhibit margination of neutrophils and increase the release of mature neutrophils from the bone marrow. Inflamed tissue, phagocytosis, and toxic oxygen-free radical production are inhibited in macrophages and monocytes. In the later stages of inflammation, glucocorticoids inhibit the activity of fibroblasts, reducing fibrosis and the formation of scar tissue. However, they may also slow wound healing.

Glucocorticoids modulate the synthesis and release of a number of chemical mediators of inflammation, including prostaglandins, leukotrienes, histamine, cytokines, complement, and PAF; they also suppress the production of inducible NO synthase and chondrodestructive enzymes such as collagenase.

Glucocorticoids have effects on other hormone systems. All anti-inflammatory glucocorticoid drugs in use today inhibit the HPAA, which can result in clinically significant adverse effects when stopping a prolonged corticoid treatment.

Administration and Pharmacokinetics:

Steroid formulations are available for oral, parenteral, and topical use. Many, including prednisone, prednisolone, methylprednisolone, and dexamethasone are well absorbed when administered PO and are particularly useful when anti-inflammatory treatment is required for a period of one to several weeks. Other preparations are available for parenteral use. The sodium phosphate and succinate salts are highly water soluble, providing a rapid onset of action when given IV. Other injectable formulations include insoluble esters such as methylprednisolone acetate and triamcinolone acetate, which have limited water solubility. The systemic absorption from these preparations is very slow and may result in anti-inflammatory effects and associated HPAA suppression for several weeks. Corticosteroid preparations available for topical or intralesional administration can be effective in treating inflammation of the skin, eyes, or ears. Although controversial, intra-articular administration of glucocorticoids has been used in people and animals, particularly horses, to manage inflammatory joint disease. In horses, for intra-articular administration, triamcinolone acetonide is preferred over methylprednisolone acetate. Glucocorticoids are absorbed systemically from sites of local administration in amounts that may be sufficient to suppress the HPAA.

Following absorption, ~90% of cortisol is reversibly bound to plasma proteins, primarily corticosteroid-binding globulin (CBG) and albumin. Among synthetic corticoids, only prednisolone binds specifically and with high affinity to CBG. Prednisolone can displace cortisol from its CBG binding site, explaining the immediate decrease of plasma cortisol after prednisolone is administered IV, a decrease not associated with HPAA inhibition. Other synthetic corticoids are mainly bound to

albumin. Only the unbound portion is available to exert physiologic and pharmacologic effects and to cross physiologic barriers such as the blood-brain barrier or the udder. Generally, glucocorticoids are metabolized in the liver, where they are reduced and conjugated, forming inactive water-soluble derivatives excreted by the kidney.

Adverse Effects: Adverse effects of glucocorticoids commonly result from the longterm use of supraphysiologic doses to control inflammatory or immunologic disorders. Longterm administration may lead to iatrogenic Cushing syndrome, characterized by polyuria, polydipsia, bilaterally symmetric alopecia, increased susceptibility to infection, muscle atrophy, and redistribution of body fat. The gluconeogenic and insulin antagonistic effects of glucocorticoids may precipitate the onset of diabetes mellitus or exacerbate diabetes in animals with existing disease. Longterm suppression of the HPAA may cause adrenal gland atrophy and resultant iatrogenic secondary hypoadrenocorticism. In affected animals, abrupt discontinuation of glucocorticoid therapy may lead to an Addisonian-like crisis characterized by lethargy, weakness, vomiting, and diarrhea. In severe cases, circulatory shock and death may result.

Glucocorticoids induce glycogen accumulation in hepatocytes, resulting in hepatopathy and hepatomegaly, and stimulate production of the steroid-specific isoenzyme of alkaline phosphatase. Slow turnover of enterocytes and inhibition of protective prostaglandins in the gut due to glucocorticoids may contribute to development of GI ulceration. Furthermore, glucocorticoids potentiate the ulcerogenic effects of NSAIDs. Glucocorticoids reduce collagen synthesis and may lead to thinning and increased fragility of the skin. Alterations in fluid and electrolyte balance may result in sodium and fluid retention and hypokalemic alkalosis. In horses, high doses of glucocorticoids may induce or exacerbate laminitis. Significant mood and behavioral changes have been described in people receiving corticosteroid therapy and may be seen in animals as well.

Although immunosuppression may be a desired effect of glucocorticoid therapy in autoimmune disease, susceptibility to infection may increase, or latent infections may be reactivated. Urinary tract infections are common in animals receiving glucocorticoids for longterm therapy of inflammatory or immunologic disease. In joints,

glucocorticoids may reduce the formation of chondrocyte collagen and synovial fluid and contribute to the development of septic arthritis. Strict aseptic technique must be observed when administering intra-articular injections of steroids.

The adverse effects of longterm (>2 wk) glucocorticoid therapy can be diminished using an alternate-day treatment regimen. Once inflammation has been controlled using daily therapy with a drug that has intermediate duration of activity (eg, oral prednisolone or prednisone), a gradual change to alternate-day therapy can be made.

Therapeutic Uses: Short-acting soluble steroids such as the succinate esters have been routinely used in the treatment of septic shock, but this indication is controversial. The action of corticoids on hemorrhagic and cardiogenic shock is not established, even though product labeling includes this use as an adjunct to fluid therapy. Glucocorticoids are also routinely used in the treatment of cerebral edema, although controlled clinical trials supporting their effectiveness are lacking.

Glucocorticoids are used commonly to treat allergy and inflammation such as pruritic dermatoses and allergic lung and GI diseases. In acute cases of atopic or flea allergy dermatitis, anti-inflammatory dosages (prednisolone, 0.5–1 mg/kg/day) alleviate pruritus and limit self-trauma from scratching until the underlying cause can be addressed. Similar dosages are used in the management of chronic allergic bronchitis and feline asthma. Short-acting corticosteroids have also been used in treatment of acute respiratory distress syndrome in cattle and chronic obstructive pulmonary disease in horses. Historically, corticosteroids have been used to treat several musculoskeletal disorders, including osteoarthritis, myositis, and immune-mediated arthritis. More recently, the NSAIDs have become first-line therapy for musculoskeletal disorders, particularly in the treatment of osteoarthritis in companion animal species. In most inflammatory conditions, glucocorticoids should be used in conjunction with therapies that target the underlying cause.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

The importance of pain management and the use of NSAIDs in animals has increased dramatically in recent decades, with use of

NSAIDs in companion animals being routine. NSAIDs have the potential to relieve pain and inflammation without the myriad potential metabolic, hemodynamic, and immunosuppressive adverse effects associated with corticosteroids. However, all NSAIDs have the potential for other adverse effects that should be considered in overall management of the inflammatory process.

Mode of Action: Generally, the classification NSAID is applied to drugs that inhibit one or more steps in the metabolism of arachidonic acid (AA). Unlike corticosteroids, which inhibit numerous pathways, NSAIDs act primarily to reduce the biosynthesis of prostaglandins by inhibiting cyclooxygenase (COX). In general, NSAIDs do not inhibit the formation of 5-lipoxygenase (5-LOX) and hence leukotriene, or the formation of other inflammatory mediators. The novel NSAID tepoxalin is an exception in that it inhibits both COX and 5-LOX.

The discovery of the two isoforms of COX (COX-1 and COX-2) has led to greater understanding of the mechanism of action and potential adverse effects of NSAIDs. COX-1, expressed in virtually all tissues of the body (eg, gut and kidney), catalyzes the formation of constitutive prostaglandins, which mediate a variety of normal physiologic effects, including hemostasis, GI mucosal protection, and protection of the kidney from hypotensive insult. In contrast, COX-2 is activated in damaged and inflamed tissues and catalyzes the formation of inducible prostaglandin, including PGE₂, associated with intensifying the inflammatory response. COX-2 is also involved in thermoregulation and the pain response to injury. Therefore, COX-2 inhibition by NSAIDs is thought to be responsible for the antipyretic, analgesic, and anti-inflammatory actions of NSAIDs. However, concurrent inhibition of COX-1 may result in many of the unwanted effects of NSAIDs, including gastric ulceration and renal toxicity. Because NSAIDs vary in their ability to inhibit each COX isoform, a drug that inhibits COX-2 at a lower concentration than that necessary to inhibit COX-1 would be considered safer. This concept has propelled the development of the “COX-2 selective” NSAIDs. Although ratios of COX-1:COX-2 inhibition by various NSAIDs in people and animals have been reported, caution is advised when interpreting such ratios, because they vary greatly depending on the selectivity assay used. The COX selectivity of NSAIDs also varies by species; COX selectivity ratios reported for people

cannot be directly extrapolated to other species.

In general, drugs with ratios suggesting preferential activity against COX-2 may have fewer adverse effects due to COX-1 inhibition. In dogs, favorable ratios have been reported for carprofen, meloxicam, deracoxib, firocoxib, and robenacoxib, whereas unfavorable ratios have been reported for aspirin, phenylbutazone, and vedaprofen. COX-1-sparing drugs are associated with less GI ulceration and less platelet inhibition; however, it may be an oversimplification to assume that complete COX-2 inhibition is without potential risk. Recent research has suggested that COX-2 can be induced constitutively in various organs, including the brain, spinal cord, ovary, and kidneys. In dogs, COX-2 mRNA is present in the loop of Henle and the maculae densa and may play an important role in the protective response to hypotension. However, a study that failed to demonstrate COX-2 expression in canine kidneys raised questions regarding its role. COX-2 also appears to be important in the healing of GI ulcers in people, and certain COX-2-specific inhibitors delay ulcer healing experimentally. Although COX-1 plays a primary role in regulating homeostasis, it may play a more significant role in inflammation than originally proposed.

NSAIDs enter the pocket of the COX enzyme, whereupon steric hindrance prevents entry of AA. Aspirin is unusual in that it irreversibly acetylates a serine residue of COX, resulting in a complete loss of COX activity. Thus, the duration of the aspirin effect depends on the turnover rate of COX; activity is lost for the life of the platelet (7–10 days) after aspirin administration, explaining the duration of aspirin's effect on hemostasis. Unlike aspirin, most other NSAIDs (including salicylic acid, an active metabolite of aspirin) are reversible competitive COX inhibitors; their duration of inhibition is primarily determined by the elimination pharmacokinetics of the drug.

Pharmacologic Effects: All NSAIDs, except for acetaminophen (also named paracetamol), are antipyretic, analgesic, and anti-inflammatory. They are routinely used for the relief of pain and inflammation associated with osteoarthritis in dogs and horses and for colic, navicular disease, and laminitis in horses. The use of NSAIDs for the relief of perioperative pain in companion animals is standard practice. In general, NSAIDs provide only symptomatic relief from pain and inflammation and do not significantly alter the course of pathologic

damage. As analgesics, they are generally less effective than opioids and are therefore generally indicated only against mild to moderate pain in people. However, in veterinary medicine, NSAIDs also find use in management of severe pain, optimally in combination with an opioid.

As antipyretics, NSAIDs reduce body temperature in febrile states. Although the beneficial effects of the febrile response usually outweigh the negative effects, NSAID inhibition of PGE₂ activity in the hypothalamus may provide symptomatic relief and improve appetite. In Europe, NSAIDs have been used in conjunction with antibiotics for treatment of acute respiratory diseases in cattle. They may reduce morbidity through their antipyretic and anti-inflammatory effects and prevent development of irreversible lung lesions.

The effects of some NSAIDs on chondrocyte metabolism have been investigated. Some, including aspirin, naproxen, and ibuprofen, are considered chondrotoxic, because they inhibit the synthesis of cartilage proteoglycans. Others, including carprofen and meloxicam, may be considered chondroneutral, or depending on dose, actually stimulate the production of cartilage matrix. The potential beneficial or deleterious effects of NSAIDs on chondrocyte metabolism remain to be clarified.

A therapeutic area in which NSAID use may become important is in the treatment and prevention of cancer. Epidemiologic studies in people show that aspirin use is associated with a significant reduction in the incidence of colon cancer. Newer evidence suggests that the therapeutic effect of NSAIDs on colon cancer is mediated by inhibition of COX-2, which may be upregulated in many premalignant and malignant neoplasms. In veterinary medicine, piroxicam has been shown to reduce the size of tumors such as transitional cell carcinoma in dogs. Specific COX-2 inhibitors may prove useful as a primary or adjunctive therapy in the management of cancer.

Administration and Pharmacokinetics:

Most NSAIDs are weak organic acids that are well absorbed after PO administration. However, food can impair the oral absorption of some NSAIDs (eg, phenylbutazone, meclofenamate, flunixin, and robenacoxib). Several NSAIDs are available as parenteral formulations for IV, IM, or SC administration. Some parenteral formulations are highly alkaline (eg, phenylbutazone) and may cause tissue necrosis if

injected perivascularly. Once absorbed, most NSAIDs are extensively (up to 99%) bound to plasma proteins, with only a small proportion of unbound drug available to be active in the tissues. NSAIDs may also compete for binding sites with other highly protein-bound compounds, leading to some drug displacement; however, this displacement has little therapeutic consequence because it does not affect the concentration of the free drug. Because NSAIDs are highly protein bound and extravasation of protein occurs in inflammation, NSAIDs tend to concentrate in areas of inflammation. Consequently, their duration of action typically exceeds that predicted by elimination half-life.

Most NSAIDs are biotransformed in the liver to inactive metabolites that are excreted either by the kidney via glomerular filtration and tubular secretion or by the bile. Mavacoxib is an exception, mostly being excreted unchanged in the bile. Biotransformation and elimination half-lives vary significantly by species (and in some cases by breed or strain, as is the case for some COX-2 inhibitors in Beagles), so it is not possible to safely extrapolate dosages from one species or animal to another. Some NSAIDs, including naproxen, etodolac, and meclofenamic acid, undergo extensive enterohepatic recirculation in some species, resulting in prolonged elimination half-lives.

Adverse Effects: All NSAIDs have the potential to induce adverse reactions, some of which can be life threatening. Many reactions to NSAIDs are dose-related and are typically reversible with discontinuation of therapy and supportive care.

Vomiting is the most common adverse effect. GI ulceration is the most common life-threatening adverse effect. Loss of GI protective mechanisms results from inhibition of constitutive prostaglandins that regulate blood flow to the gastric mucosa and stimulate bicarbonate and mucus production. This disrupts the alkaline protective barrier of the gut, allowing diffusion of gastric acid back into the mucosa, injuring cells and blood vessels and causing gastritis and ulceration. As organic acids, NSAIDs, especially aspirin, may also cause direct chemical irritation of the GI mucosa. The enterohepatic recirculation of certain NSAIDs may result in high biliary concentrations that increase ulcerogenic potential in the gut. NSAID-induced GI bleeding may be occult, leading to iron-deficiency anemia, or be more severe, resulting in vomiting, hematemesis,

and melena. Horses may develop oral, lingual, or colonic ulceration with accompanying signs of colic, weight loss, and diarrhea.

GI blood loss may be further complicated by impaired platelet function; NSAIDs, by inhibiting COX-1, prevent platelets from forming TXA₂, a potent aggregating agent. Because TXA₂ inhibition causes prolonged bleeding, evaluation of buccal mucosal bleeding time is advised in animals for which surgery is anticipated. Blood dyscrasias after long-term NSAID therapy have been reported in cats, dogs, and horses. Acetaminophen (paracetamol) administration in cats is associated with Heinz body anemia, methemoglobinemia, hepatic failure, and death. Bone marrow dyscrasias associated with phenylbutazone administration have also been reported.

Nephropathies associated with chronic NSAID use are common in people. Animals with underlying renal compromise receiving NSAIDs could experience exacerbation or decompensation of their disease. It is important to maintain hydration and renal perfusion in animals receiving NSAIDs, especially those undergoing anesthesia or surgery and in horses with colic.

Hepatopathies are relatively common in people and animals receiving NSAIDs. NSAID administration routinely induces mild hepatic changes characterized primarily by increases in liver enzymes without clinical signs or hepatic dysfunction. Rare reports of idiosyncratic reactions resulting in hepatic dysfunction or failure have been reported in people (acetaminophen and others), dogs (acetaminophen, carprofen, etodolac), and horses (phenylbutazone). Cytopathic (hepatocellular injury, necrosis), cholestatic, and mixed histopathologic patterns of injury have been documented. NSAIDs should be used with caution in animals with preexisting hepatic disease.

Specific Nonsteroidal Anti-inflammatory Drugs

Based on structure, most NSAIDs can be divided into two broad groups: carboxylic acid and enolic acid derivatives. The main subgroups of enolic acids are the pyrazolones (phenylbutazone) and the oxicams (meloxicam, piroxicam). Carboxylic acid subgroups include the salicylates (aspirin), propionic acids (ibuprofen, naproxen, carprofen, ketoprofen, and vedaprofen), fenemates (tolfenamic and meclofenamic acids), phenylacetic acids (acetaminophen), and aminonicotinic acids (flunixin). The

newer coxib class of selective COX-2 inhibitors includes a diaryl-substituted pyrazole (celecoxib) and a diaryl-substituted isoxazole (valdecoxib), both available for human use. Four NSAIDs of the coxib class, deracoxib, firocoxib, robenacoxib, and mavacoxib have been introduced in veterinary medicine.

Aspirin: By far the most widely used NSAID in people, aspirin is primarily used in veterinary medicine for relief of mild to moderate pain associated with musculoskeletal inflammation or osteoarthritis. The salicylic ester of acetic acid, aspirin (acetylsalicylic acid) is available in several different dosage forms, including bolus (for cattle), oral paste (for horses), oral solution (for poultry), and tablets (for dogs). Enteric-coated products used in human medicine are not recommended in dogs, because gastric retention may lead to erratic plasma exposure. After PO administration, aspirin is rapidly absorbed from the stomach and upper small intestine. Aspirin is subjected to a large, first-pass effect in the liver to yield salicylic acid, its main active metabolite. In addition, the aspirin fraction that gains access to the systemic circulation is also rapidly hydrolyzed to salicylic acid with a half-life of ~15 min. After oral aspirin administration, salicylic acid is considered the main active substance in the systemic circulation. Aspirin primarily inhibits COX-1, whereas salicylic acid has more balanced COX-1/COX-2 activity. In addition, aspirin may irreversibly bind to COX-1 through acetylation of a serine residue near the enzyme active site. Because of this irreversible binding, the anticoagulant activity of aspirin lasts far longer than its anti-inflammatory effect; a single aspirin dose of 20 mg/kg in a horse may prolong bleeding for 48 hr. Depending on its route of administration, aspirin may have different pharmacologic effects. For irreversible platelet COX-1 inhibition (to treat a thromboembolic condition), aspirin given IV is more efficient than aspirin given PO because, for the same dose, aspirin exposure is greater for the IV route of administration.

After absorption, both aspirin and salicylate are widely distributed through most tissues and fluids and readily cross the placental barrier. Approximately 80%–90% of salicylate is bound to plasma proteins. Metabolism and elimination is via hepatic conjugation with glucuronic acid, followed by renal excretion. Cats, which lack glucuronyl transferase, metabolize

salicylates slowly. In addition, salicylate metabolism is saturable and, if overexposure due to an aspirin overdose occurs, plasma salicylate elimination may follow a zero order and slower elimination kinetics. The elimination half-life of salicylic acid in cats approaches 40 hr, whereas it is ~7.5 hr in dogs.

Because aspirin is not approved for veterinary use, definitive efficacy studies have not been performed to establish effective dosages. Recommended dosages in dogs are 10–40 mg/kg, PO, bid-tid. Aspirin has been used for its anticlotting effect in the treatment of laminitis in horses at a dosage of 10 mg/kg/day, PO. In cats, aspirin may be used for its antiplatelet effects in thromboembolic disease at a dosage of 10 mg/kg, PO, every 48 hr, to allow for prolonged metabolism. Adverse effects are common after aspirin administration and appear to be dosage dependent. Even at therapeutic dosages of 25 mg/kg, plain aspirin may induce mucosal erosion and ulceration in dogs. Vomiting and melena may be seen at higher doses. The PGE₁ analogue misoprostol may decrease GI ulceration associated with aspirin and other NSAIDs. Aspirin overdose in any species can result in salicylate poisoning, characterized by severe acid-base abnormalities, hemorrhage, seizures, coma, and death.

Acetaminophen: Acetaminophen (paracetamol) is a para-aminophenol derivative with analgesic and antipyretic effects similar to those of aspirin, but it has weaker anti-inflammatory effects than does aspirin and other NSAIDs. The reason for this anomaly is that acetaminophen's selective COX-2 inhibition is via enzyme reduction; the high levels of peroxides in areas of inflammation are thought to interfere with COX-2 reduction peripherally, whereas the low peroxide levels in the brain and spinal cord account for any centrally mediated analgesia. Acetaminophen does not inhibit neutrophil activation, has little ulcerogenic potential, and has no effect on platelets or bleeding time. The recommended dosage of acetaminophen in dogs is 10–15 mg/kg, PO, tid. Dose-dependent adverse effects include depression, vomiting, and methemoglobinemia. Use in cats is contraindicated because of their deficiency of glucuronyl transferase, which makes them susceptible to methemoglobinemia and centrilobular hepatic necrosis.

Phenylbutazone: One of the earliest NSAIDs approved for use in horses and

Meclofenamic Acid: Meclofenamic acid is a fenamate (anthranilic acid) NSAID available for horses as a granular preparation and for dogs as an oral tablet. The recommended dosage is 2.2 mg/kg/day for

Tolfenamic Acid: Tolfenamic acid is an anthranilic (fenemate) NSAID class approved for use in Europe and other countries. It is used for fever, postoperative pain, and acute and chronic inflammatory conditions in cats, dogs, cattle, and pigs.

Carprofen: Carprofen is an NSAID of the arylpropionic acid class available in the USA in caplet and chewable tablet formulations. An injectable formulation is also available in the USA and Europe. Carprofen is approved by the FDA to manage pain and inflammation associated with osteoarthritis and acute pain associated with soft-tissue and orthopedic surgery in dogs. The recommended dosage is 4.4 mg/kg/day or divided bid, PO. In Europe and other countries, carprofen is

also registered for use in horses and cattle and for short-term therapy in cats. In dogs, oral bioavailability is high (90%), and plasma concentrations peak ~2–3 hr after dosing. The elimination half-life is ~8 hr. As with other NSAIDs, carprofen is highly (99%) protein bound. Elimination is via hepatic biotransformation, with excretion of the resulting metabolites in feces and urine. Some enterohepatic recycling occurs. The exact mechanism of action of carprofen is unclear. Although it has greater selectivity for COX-2 over COX-1, carprofen is considered a weak COX inhibitor. In vitro assays with canine cell lines indicate that it is 129-fold more selective for COX-2, whereas in vitro assays with canine whole blood indicate that it is 7- to 17-fold more selective for COX-2. Equine whole blood assays indicate that it is 1.6-fold more selective for COX-2, and feline whole blood assays indicate it is >5.5-fold more selective for COX-2. Other mechanisms of action, including inhibition of PA_2 , may be responsible for its anti-inflammatory effects. Carprofen has been used extensively in dogs since its introduction, and adverse events have been comparable to those of other NSAIDs (ie, ~2 events/1,000 dogs treated). Approximately one-fourth of the adverse reactions reported were GI signs, including vomiting, diarrhea, and GI ulceration. Renal and hepatic adverse effects are rare, as with other NSAIDs. Potentially serious idiosyncratic hepatopathies, characterized by acute hepatic necrosis, have been reported in some dogs. Approximately one-third of the dogs developing hepatopathies while receiving carprofen were Labrador Retrievers, although a true breed predisposition has not been established. As with any NSAID therapy, clinical laboratory monitoring for hepatic damage is advised, especially in geriatric animals that may be predisposed to more serious complications.

Ketoprofen: Ketoprofen is another propionic acid derivative available in the USA and other countries as a 10% injectable solution for horses, and in Europe and Canada as tablets and a 1% injectable solution for dogs and cats. Ketoprofen is recommended for acute pain (up to 5 days) in both dogs and cats. In horses, it is used for pain and inflammation associated with osteoarthritis and for visceral pain associated with colic. The recommended dosage is 1 mg/kg/day for up to 5 days, IV or PO, in dogs and cats; 2.2 mg/kg/day for up to 5 days, IV, in horses; and 3 mg/kg/day for 1–3 days, IV or IM, in cattle. Ketoprofen is a

potent inhibitor of COX and bradykinin and may also inhibit some lipoxygenases. Its efficacy is comparable to that of opioids in the management of pain after orthopedic and soft-tissue surgery in dogs. After administration PO, ketoprofen is rapidly absorbed and has a terminal half-life in cats and dogs of 2–3 hr. As with other NSAIDs, ketoprofen is metabolized in the liver to inactive metabolites that are eliminated by renal excretion. Adverse effects, including GI upset, are similar to those of other NSAIDs. Other adverse effects, including hepatopathies and renal disease, have been reported in animals. Because of potential antiplatelet effects, care should be exercised when using ketoprofen peri-operatively.

Etodolac: The pyranocarboxylic acid etodolac is approved for use in dogs in the USA. The elimination half-life is ~8–12 hr, allowing dosing at 10–15 mg/kg/day, PO. Extensive enterohepatic recirculation has been reported in dogs, followed by elimination of etodolac and its metabolites in the liver and feces. In in vitro studies, etodolac was more selective in inhibiting COX-2 than COX-1, although in vitro canine whole blood assays have also shown it to be nonselective. Etodolac has been shown to inhibit macrophage chemotaxis and has demonstrated efficacy for the treatment of lameness associated with hip dysplasia. Although the risk of GI ulceration is low at therapeutic doses, administration of three times the label dosage resulted in GI ulceration, vomiting, and weight loss in toxicity studies. GI, hepatic, and renal adverse reactions have been reported after administration of etodolac, similar to those of other NSAIDs.

Vedaprofen: The arylpropionic acid derivative vedaprofen is available in Europe in a gel formulation for horses and dogs and in an injectable formulation for horses. Vedaprofen is indicated for the treatment of pain and inflammation associated with musculoskeletal disorders in dogs (0.5 mg/kg/day) and horses (1 mg/kg, bid) and for the treatment of pain associated with colic in horses (2 mg/kg, IV, as a single injection). After administration PO, vedaprofen is rapidly absorbed. Bioavailability is generally high but may be reduced if the drug is administered with food. The terminal half-life is 10–13 hr in dogs and 6–8 hr in horses. Vedaprofen undergoes extensive biotransformation to hydroxylated metabolites, which are excreted in urine and feces.

Meloxicam: Meloxicam is an oxicam NSAID available as an oral syrup and injectable solution. It is approved for human use in the USA and Canada and for use in dogs in the USA. In Europe and other countries, it is approved for use in dogs, cats, cattle, and horses. A potent inhibitor of prostaglandin synthesis, meloxicam is used for the treatment of acute and chronic inflammation associated with musculoskeletal disease and for the management of postoperative pain. In dogs, a one-time loading dose of 0.2 mg/kg, PO, is recommended, followed by 0.1 mg/kg/day, PO. Once a therapeutic effect is seen, the dosage can be titrated to the lowest possible dose. COX-1:COX-2 ratios reported for meloxicam suggest the drug is COX-2 selective, with *in vitro* canine whole blood assays indicating it is 2.7- to 10-fold more selective for COX-2. Once absorbed, meloxicam is highly protein bound (97%) and has a relatively long elimination half life (>12 hr). GI safety appears to be greater for meloxicam than for nonselective NSAIDs, and meloxicam has been shown to be chondroneutral in rodent studies.

Deracoxib: Deracoxib, the first NSAID of the coxib class approved for use in dogs, is available in a beef-flavored chewable tablet formulation in the USA. Deracoxib has been shown to inhibit COX-2 mediated PGE₂ production. COX-1:COX-2 ratios reported for deracoxib in *in vitro* cloned canine cell assays indicate it is 1,275-fold more selective for COX-2, whereas *in vitro* canine whole blood assays indicate it is 12- to 37-fold selective for COX-2. Deracoxib is indicated for the control of postoperative pain and inflammation associated with orthopedic surgery at a dosage of 3–4 mg/kg/day for up to 7 days, PO, and for the control of pain and inflammation associated with osteoarthritis at a dosage of 1–2 mg/kg/day, PO. Once absorbed, protein binding is >90%, and the elimination half-life is 3 hr.

Firocoxib: Firocoxib is a coxib-class NSAID approved in the USA and Europe for the control of pain and inflammation associated with osteoarthritis and for the control of postoperative pain and inflammation associated with soft tissue and orthopedic surgery in dogs. In Canada, Australia, and New Zealand it is approved for use in osteoarthritis and soft-tissue and orthopedic surgery. It is available in a chewable tablet formulation. After administration PO, firocoxib is rapidly absorbed and then eliminated by hepatic metabolism and fecal excretion. The elimination half-life is ~8 hr,

allowing dosing at 5 mg/kg/day, PO. COX-1:COX-2 ratios from *in vitro* canine whole blood assays indicate it is 384-fold more selective for COX-2. As with other NSAIDs, protein binding is high, at ~96%. GI safety appears to be greater than that of nonspecific NSAIDs.

Robenacoxib: Robenacoxib is a coxib-class highly selective COX-2 inhibitor, structurally related to the human NSAIDs diclofenac and lumiracoxib. Robenacoxib is used for the control of pain and inflammation associated with osteoarthritis, orthopedic and soft-tissue surgery in dogs (approved in Europe), and for musculoskeletal disorders and soft-tissue surgeries in cats (approved in the USA and Europe). Dosage is 2 mg/kg, PO, initially and then 1–2 mg/kg/day thereafter (for up to 6 days in cats). COX-1:COX-2 ratios from *in vitro* canine whole blood assays indicate it is 128-fold more selective for COX-2. As with other NSAIDs, protein binding is high, at ~98%. GI safety appears to be greater than that of nonselective NSAIDs. The elimination half-life is 1 hr after oral administration. Administration with food decreases bioavailability of robenacoxib.

Mavacoxib: Mavacoxib is a coxib-class COX-2 inhibitor approved in Europe and Australia for the control of pain and inflammation associated with degenerative joint disease in dogs. Mavacoxib is structurally related to the human NSAID celecoxib; however, substitution of a methyl group with a single fluorine atom has conferred great resistance to metabolism, resulting in an elimination half-life of 17 days in young Beagle dogs. Unlike the major route of elimination of other NSAIDs, that of mavacoxib is biliary excretion of the parent molecule. In field trials conducted in aged dogs with osteoarthritis, the half-life was found to be even longer at 44 days, and in these older dogs, approximately 1 in 20 exhibited a half-life of >80 days. These population pharmacokinetic studies in target patients were used to optimize the dose regimen. The long half-life means mavacoxib has a unique dose regimen: the initial dose is 2 mg/kg, PO, repeated 14 days later; thereafter, the dosing interval is 1 mo, with the total course not exceeding seven doses (6.5 mo). Food significantly increases bioavailability. COX-1:COX-2 ratios from *in vitro* canine whole blood assays indicate mavacoxib is 128-fold more selective for COX-2. As with other NSAIDs, protein binding is high, at ~98%. GI safety appears to be greater than that of nonselective NSAIDs.

The elimination half-life is 1 hr after oral administration.

Tepoxalin: Tepoxalin is a dual inhibitor of both cyclooxygenases (COX-1 and COX-2) and 5-lipoxygenase (5-LOX). From a mechanistic perspective, its LOX activity (reduction of leukotriene production) may reduce components of inflammation not controlled by COX isoenzyme inhibition. It is available for dogs as an oral tablet. The initial dosage is 20 mg/kg, followed by a maintenance dosage of 10 mg/kg/day. Tepoxalin is rapidly absorbed and reaches peak plasma concentration 2–3 hr after administration. Its plasma half-life is short (2 hr), but it is metabolized to a carboxylic active metabolite (tepoxalin pyrazol acid) that has a long half-life (12–15 hr). The metabolite, tepoxalin pyrazol acid, lacks the LOX activity of the parent molecule. Both tepoxalin and its active metabolite are highly bound to plasma protein (98%–99%). The most commonly reported adverse effects are GI related (eg, diarrhea and vomiting in ~20% of dogs treated for 4 wk).

Other NSAIDs: A large number of prescription and nonprescription NSAIDs are available for human use. However, because of species differences in metabolism, efficacy, and toxicity, many are not recommended for use in animals. For example, in dogs, indomethacin is highly toxic to the GI tract and may result in severe ulceration, hematemesis, and melena at therapeutic doses. Piroxicam undergoes extensive enterohepatic recycling in dogs, resulting in a prolonged plasma half-life. GI ulceration and bleeding and renal papillary necrosis have been seen in dogs receiving piroxicam at dosages of 0.3–1 mg/kg/day.

Ibuprofen is an arylpropionic acid derivative used in dogs as an anti-inflammatory agent. However, dogs are much more sensitive to the development of GI adverse effects from ibuprofen administration than are people. At therapeutic doses, adverse effects seen in dogs include vomiting, diarrhea, GI bleeding, and renal infection. Ibuprofen is not recommended for use in dogs or cats.

Naproxen has been used in horses at a dosage of 5–10 mg/kg, once to twice daily. Bioavailability is lower (~50%) for naproxen than for other NSAIDs, and the elimination half-life is ~5 hr in horses. In dogs, the elimination half-life of naproxen is 35–74 hr, presumably because of extensive enterohepatic recirculation. The pharmacokinetics in dogs also appear to be breed dependent. Because of the prolonged half-life of

naproxen, dogs are extremely sensitive to its adverse effects.

Coxib class drugs, including celecoxib and valdecoxib, developed for use in human medicine are COX-2 selective. In clinical studies, the incidence of GI ulceration in patients receiving valdecoxib or celecoxib was significantly less than that of those receiving naproxen. The use of these drugs in animals has yet to be fully investigated. One pharmacokinetic study with celecoxib in Beagles demonstrated variability in drug elimination between dogs. In that study, one subgroup of Beagles metabolized celecoxib much more rapidly than the other, with elimination half-lives of ~2 and 18 hr, respectively. Until further data are available regarding the pharmacokinetics and safety of these drugs in animals, their use in veterinary medicine is not recommended.

CHONDROPROTECTIVE AGENTS

Polysulfated Glycosaminoglycan:

Polysulfated glycosaminoglycan (PSGAG) is a semisynthetic glycosaminoglycan prepared from bovine tracheal cartilage and composed of a polymeric chain of repeating disaccharide units. The primary glycosaminoglycan in PSGAG is chondroitin sulfate. PSGAG is approved for IM use in dogs and intra-articular and IM use in horses for the control of signs associated with noninfectious degenerative or traumatic arthritis. In horses, the recommended dosage is 500 mg, IM, every 4 days for 28 days, or 250 mg by intra-articular injection once weekly for 5 wk. In dogs, the recommended dosage is 2 mg/lb, IM, twice weekly for up to 4 wk. After IM injection, PSGAG is absorbed into the systemic circulation and eventually incorporated into both healthy and damaged cartilage. The exact mechanism of action is unknown, but in vitro studies show that PSGAG inhibits PGE₂ and catabolic enzymes such as stromelysin, elastase, the metalloproteases, and others. PSGAG also increases the synthesis of hyaluronic acid, proteoglycan, and collagen in vitro. Toxicity associated with administration of PSGAG has been minimal. Because PSGAG is chemically similar to heparin, overdose may inhibit coagulation, and concurrent use of aspirin may prolong bleeding times. The use of PSGAG is contraindicated in septic joints.

Pentosan Polysulfate Sodium:

Pentosan polysulfate sodium (PPS) is a polysulfate ester of xylan, a polymer prepared semisynthetically from beech-

wood plant material. PPS is chemically and structurally similar to heparin and glycosaminoglycan. The compound is approved by the FDA for use as an oral capsule for the treatment of interstitial cystitis in people. An injectable product is available for use in people, dogs, and horses in Australia and other countries. The mechanism of action is unknown. PPS stimulates hyaluronic acid and GAG synthesis in damaged joints, inhibits proteolytic enzymes including metalloproteinases, and scavenges free radicals. PPS may also decrease cytokine activity. In canine models of osteoarthritis, IM administration of PPS significantly decreased overall cartilage damage. Because PPS has a heparin-like structure, coagulopathies may be seen. PPS is given once a week for 4 consecutive weeks, then once every 6 or 12 mo.

Hyaluronan: Hyaluronan (formerly hyaluronic acid), a polydisaccharide of glucuronic acid and glucosamine, is a component of synovial fluid and articular cartilage. In the USA, a purified fraction of the sodium salt of hyaluronic acid extracted from rooster combs is available for treatment of horses with osteoarthritis. Hyaluronan is responsible for the viscosity of the synovial fluid and contributes to its

lubricating function in joint movement. As with other chondroprotective agents, the mode of action is unclear. However, because synovial fluid viscoelasticity is decreased in osteoarthritis, the intra-articular administration of hyaluronan may improve joint lubrication. Hyaluronan inhibits PGE₂ synthesis in vitro and in vivo and may inhibit inflammatory enzymes and reduce pain. Most clinical use has been in horses, in which it appears to have minimal adverse effects.

Orgotein: Orgotein is a water-soluble metalloprotein containing copper and zinc. Found in low concentrations throughout the body, orgotein has superoxide dismutase activity scavenging free oxygen radicals. Orgotein, available as an injectable formulation, has been used for treatment of soft-tissue inflammation in horses and of arthritis in dogs. Although it has been used as an IM or SC injection, orgotein is typically administered as an intra-articular injection, because its large molecular size may limit absorption via other routes. Intra articular administration is effective in cases of acute lameness in horses, although the onset of therapeutic response may be slow (2–6 wk). Reports indicate that orgotein apparently has a wide safety margin.

ANTINEOPLASTIC AGENTS

Antineoplastic chemotherapy is an important component of small animal practice and is routinely used for selected tumors of horses and cattle. Effective use of antineoplastic chemotherapy depends on an understanding of basic principles of cancer biology, drug actions, toxicities, and drug handling safety.

Tumor Growth and Response to Chemotherapy: The fundamental biochemical and genetic differences between cancer cells and healthy cells are areas of intense investigation, because these divergences are not fully understood. None of the empirically developed conventional antineoplastic drugs appears to act on a process entirely unique to cancer cells. Newer therapies that specifically target markers or pathways unique to particular cancers are evolving. However, the mainstay of cancer therapy continues to

be traditional chemotherapy. Clinically useful drugs achieve a degree of selectivity on the basis of certain characteristics of cancer cells that can be used as pharmacologic targets. These characteristics include rapid rate of division and growth, variations in the rate of drug uptake or in the sensitivity of different types of cells to particular drugs, and retention in the malignant cells of hormonal responses characteristic of the cells from which the cancer is derived, eg, estrogen responsiveness of certain breast carcinomas.

Aspects of normal cell growth and the cell cycle provide the rationale for and are of major importance in successful application of antineoplastic chemotherapy. In the S phase, DNA synthesis occurs; the M phase begins with mitosis and ends with cytokinesis; and the G₀ phase is a dormant or nonproliferative phase of the cell cycle. Tumor doubling time is related to the length

of the cell cycle and the growth fraction (the proportion of a population of cells undergoing cell division). Antineoplastic agents can be classified according to a number of schemes relative to effects at different stages of the cell cycle. In the simplest sense, cycle-nonspecific agents are considered to be lethal to cells in all phases of the cell cycle. Cells are killed exponentially with increasing drug levels, and the dose-response curves follow first-order kinetics. Phase-specific agents exert their lethal effects exclusively or primarily during one phase of the cell cycle, usually S or M; the greater the rate of cell division, the more effective the drug. The G_0 phase of the cell cycle is important, not as a target for chemotherapeutic agents, but as a time during which dormant tumor cells can escape or repair the effects of drug therapy.

Principles of Antineoplastic Chemotherapy: The decision to use antineoplastic chemotherapy depends on the type of tumor to be treated, the stage of malignancy, the condition of the animal, and financial considerations. Chemotherapy can be used as an adjuvant to surgery and irradiation and can be administered immediately after or before the primary treatment. Neoadjuvant therapy is administered before surgery or irradiation and is intended to improve the effectiveness of the primary therapy by possibly decreasing tumor size, stage of malignancy, or presence of micrometastatic lesions. Responses to cancer chemotherapy can range from palliation (remission of secondary signs, generally without increase in survival time) to complete remission (in which clinically detectable tumor cells and all signs of malignancy are absent). The percentage and duration of complete remissions are criteria for the success of a particular chemotherapeutic protocol.

Effective clinical use of antineoplastic drugs depends on the ability to balance the killing of tumor cells against the inherent toxicity of many of these drugs to host cells. Because of the narrow therapeutic indices of antineoplastic agents, dosages are frequently calculated based on body surface area (BSA) rather than body mass. However, evidence suggests that small dogs and cats may best be treated based on body weight to avoid overdosage. This is especially true if the primary toxicity is bone marrow suppression. Evidently, BSA does not correlate well with either stem cell number in the bone marrow or resulting hematopoietic toxicity. Correlation is better between body weight and these toxicities. Antineoplastic agents can be administered

by PO, IV, SC, IM, topical, intracavitary, intralesional, intravesicular, intrathecal, or intra-arterial routes. The route chosen depends on the individual agent and is determined by drug toxicity; location, size, and type of tumor; and physical constraints.

Antineoplastic agents are commonly administered in various combinations of dosages and timing; the specific regimen is referred to as a protocol. A protocol may use one or as many as five or six different antineoplastic agents. Selection of an appropriate protocol should be based on type of tumor, grade or degree of malignancy, stage of the disease, condition of the animal, and financial considerations. Preferences of individual clinicians for treatment of specific neoplastic conditions may also vary. Regardless of the protocol chosen, a thorough knowledge of the mechanism of action and toxicities of each therapeutic agent is essential.

Combination antineoplastic chemotherapy offers many advantages. Drugs with different target sites or mechanisms of action are used together to enhance destruction of tumor cells. If the adverse effects of the component agents are different, the combination may be no more toxic than the individual agents given separately. Combinations that include a cycle-nonspecific drug administered first, followed by a phase-specific drug, may offer the advantage that cells surviving treatment with the first drug are provoked into mitosis and, therefore, are more susceptible to the second drug. Another advantage of combination therapy is the decreased possibility of development of drug resistance.

Special considerations associated with administration of antineoplastic drugs include evaluation of the animal's quality of life, medical and nutritional support, control of pain, and psychologic comfort for the owner. Many owners who choose to treat neoplasia in their pets have experienced cancer themselves or have been involved with individuals or family members who have had cancer. Discussion of neoplasia in pets should be handled tactfully and should provide the owners with appropriate information for decision-making.

Resistance to Antineoplastic Agents:

Failure to respond, or resistance, to antineoplastic agents can be seen for several reasons. Pharmacokinetic resistance is seen when the concentration of a drug in the target cell is below that required to kill the cell. This may be due to altered rates of drug absorption, distribu-

tion, biotransformation, or excretion. In addition, marginal blood flow to a tumor may not provide sufficient drug, resulting in inadequate therapeutic drug concentrations and the potential for creation of a population of quiescent, less susceptible cells. Cytokinetic resistance is seen when the tumor cell population is not completely eradicated; this may be a result of dormant tumor cells, dose-limiting host toxicity associated with drug therapy, or the inability to achieve a 100% kill rate even at therapeutic drug dosages. Resistance can also develop via biochemical mechanisms within the tumor cell itself that block transport mechanisms for drug uptake, alter target receptors or enzymes critical to drug action, increase concentrations of healthy metabolites antagonized by the antineoplastic drug, or cause genetic changes that result in protective gene amplification or altered patterns of DNA repair. Acquired multidrug resistance can result from amplification and overexpression of a multidrug resistance gene. This gene encodes a cell transmembrane protein that effectively pumps a variety of structurally unrelated antineoplastic agents out of the cell. As intracellular drug concentrations decline, tumor cell survival and resistance to therapy increase.

Patterns of Toxicity: Conventional antineoplastic agents that act primarily on rapidly dividing and growing cells produce multiple adverse effects or toxicities, including bone marrow or myelosuppression, GI complications, and immunosuppression. Patterns of toxicity may be either acute or delayed. Acute vomiting may develop during administration of an emetogenic drug or within 24 hr after administration of chemotherapy, probably from direct stimulation of the chemoreceptor trigger zone. Several drugs are available aimed at preventing these toxicities, including dolasetron, ondansetron, and maropitant citrate. Dolasetron and ondansetron act as serotonin receptor (5HT₃) antagonists that work centrally on the brain to prevent emesis. Maropitant citrate is an oral or subcutaneous FDA-approved medication for acute nausea/vomiting in veterinary medicine. It works by inhibiting both central and peripheral vomiting pathways by blocking neurokinin-1 receptors to prevent activation of the emetic center.

Administration of oral antiemetics may be indicated for delayed GI toxicities, which can occur 3–5 days after chemotherapy administration. Neurokinin-1 receptor

antagonists are used in human oncology to treat delayed emesis, and there is evidence they may work synergistically or at least in an additive fashion with 5HT₃ inhibitors. In addition to the NK-1 inhibitor maropitant, common antiemetic therapy in veterinary oncology includes metoclopramide, which functions through direct antagonism of central and peripheral dopamine receptors. This drug has the added benefit of stimulating motility of the upper GI tract without stimulating gastric, biliary, or pancreatic secretions. This effect can be useful in dogs that develop ileus secondary to vincristine administration.

Allergic reactions and anaphylaxis may also be of immediate concern with selected drugs and can be treated with antihistamines or corticosteroids as needed. In more severe cases, epinephrine and IV fluids may be indicated.

Other delayed toxicities may develop days to weeks after antineoplastic therapy. Myelosuppression, a common delayed toxicity, can be life-threatening because of the increased risk of infection associated with neutropenia. Less commonly, increased risk of hemorrhage associated with thrombocytopenia and anemia may be seen.

Other important delayed toxicities include tissue damage associated with extravasation of selected drugs, and alopecia caused by hair follicle damage, particularly in nonshedding breeds with continuous hair growth. Adverse effects on spermatogenesis and teratogenesis may be of concern in breeding animals. Unlike in people, chemotherapy-induced stomatitis or ulcerative enteritis are rare events in dogs and cats.

Prevention and management of toxicities are crucial to successful antineoplastic therapy. Collection of an adequate database before treatment can identify potential problems so that contraindicated drugs can be avoided. Several antineoplastic agents should not be used in the presence of specific organ impairment. For example, doxorubicin should not be used in dogs with certain cardiac abnormalities that impair left ventricular function, and cisplatin is contraindicated in animals with impaired renal function.

When a drug is chosen, supportive or preventive therapy aimed at ameliorating toxic adverse effects may be required. Potential cardiotoxicity of doxorubicin may be abrogated with coadministration of dexrazoxane, an iron chelator that inhibits formation of free radicals implicated in myocardial injury. Active diuresis should

accompany administration of nephrotoxic agents (eg, cisplatin). Administration or availability of appropriate antihistamines may be indicated with L-asparaginase and doxorubicin therapy.

The availability of recombinant products is an additional resource to manage myelosuppression and immunosuppression induced by antineoplastic chemotherapy. Recombinant human (rhG-CSF) and canine (rcG-CSF) granulocyte colony-stimulating factors have been used effectively to manage cytopenias induced by chemotherapy and radiation therapy. Administration of rcG-CSF results in a rapid, significant increase in neutrophil numbers that is sustainable as long as the factor is administered. Neutrophil counts drop quickly when therapy is discontinued. Neutrophil phagocytosis, superoxide generation, and antibody-dependent cellular cytotoxicity all increase with G-CSF treatment. Until rcG-CSF is commercially available, longterm (>2–3 wk) or repeated use of recombinant human products should be avoided in dogs and cats, because it can result in anti-factor antibody formation and a subsequent decline in targeted cell numbers.

Prophylactic antibiotics have been shown to reduce hospitalization rates and death in human cancer patients receiving chemotherapy. These are occasionally used in veterinary medicine to reduce the occurrence or severity of hematologic and nonhematologic complications that can result from administration of particular chemotherapy agents.

Safe Handling of Antineoplastic Chemotherapeutic Agents: Most antineoplastic chemotherapeutic agents are potentially toxic as mutagens, teratogens, or carcinogens. Handling of these agents can result in hazardous personal or environmental exposure in several ways.

A common route of exposure is inhalation due to aerosolization during mixing or administration of cytotoxic drugs. This may occur when a needle is withdrawn from a pressurized drug container or on expulsion of air from a drug-filled syringe. Transferring drugs between containers, opening drug-filled glass ampules, or crushing or splitting oral medications may also aerosolize drug residues.

The best way to prepare cytotoxic drugs to avoid aerosolization is in a biologic safety cabinet or hood; a Class II, type A vertical laminar air flow hood exhausted outside the building is recommended. Aerosol exposures can be further decreased through

use of closed system transfer devices that limit escape of air from drug vials into the environment. Administration of chemotherapy should occur in dedicated areas, and meticulous attention to technique should be maintained. Intravenous lines used to administer chemotherapy should be primed with nontoxic solution whenever possible. Disposal of contaminated vials, syringes, needles, and gloves in this area should be anticipated, and the proper puncture-proof chemotherapy waste containers provided.

Personal protection equipment should be used for chemotherapy preparation, administration, cleanup, and disposal. This should include powder-free chemotherapy gloves, nonpermeable gowns, respiratory protection, plastic-backed underpads for the working surface, eye and/or splash protection, shoe covers, and a spill kit.

Another potential route of exposure to antineoplastic agents is by absorption of drug through the skin. This could occur during preparation or administration of drug, cleaning of the drug preparation area, or handling of excreta from animals that have received selected cytotoxic drugs. Conscientious wearing of disposable, powder-free gloves and careful handling of drug-contaminated needles or catheters may avoid most exposures of this type. Re-capping of needles containing drug residues is discouraged to avoid accidental self-inoculation. In addition, use of sprayers and pressure washers to clean cages, kennels, or stalls of treated animals should be avoided to minimize aerosolization of hazardous wastes.

Antineoplastic agents can be inadvertently ingested if food, drink, or tobacco products are allowed in the vicinity of drug preparation areas, treatment areas, or kennels housing treated animals. Any ingestible materials should be restricted to a separate area that is far enough away to avoid any possible contamination with these agents.

All personnel should handle antineoplastic agents with care. Women of child-bearing age should be particularly cautious, and women who are pregnant or breastfeeding should not handle antineoplastic drugs.

A source of exposure to cytotoxic drugs that is commonly overlooked is the handling of body fluids and excreta of treated patients. Uniform guidelines to handle these potentially dangerous substances have not been published. Nevertheless, simple measures can be taken to help minimize exposure of veterinary personnel and pet owners. Collection of biologic samples,

such as blood, urine, or tissue, should be performed before chemotherapy administration. The duration and type of precautionary measures that should be taken after treatment depend on the half-life and routes of elimination of the drug administered. Pet owners and veterinary hospital personnel should be advised to allow dogs to urinate and defecate in a confined area outdoors, away from spaces where people may congregate or children play. A mask should be worn when cleaning litterboxes, and the contents placed in a sealed plastic bag. The use of low-dust kitty litter should be encouraged. Powder-free, disposable gloves should be used when cleaning up urine, feces, or vomitus. Veterinarians are encouraged to contact their local board of health and other federal, state, and local regulatory agencies for regulations regarding disposal of hazardous waste.

Classification of Antineoplastic Chemotherapeutic Agents:

Conventional cytotoxic antineoplastic agents can be grouped by biochemical mechanism of action into the following general categories: alkylating agents, antimetabolites, mitotic inhibitors, antineoplastic antibiotics, hormonal agents, and miscellaneous. The clinically relevant drugs used in veterinary medicine are discussed below, and the indications, mechanism of action, and toxicities of selected agents are summarized in TABLE 57.

ALKYLATING AGENTS

Alkylating agents form highly reactive intermediate compounds that are able to transfer alkyl groups to DNA. Alkylation can result in miscoding of DNA strands, incomplete repair of alkylated segments (which leads to strand breakage or depurination), excessive cross-linking of DNA, and inhibition of strand separation at mitosis. Monofunctional alkylating agents transfer a single alkyl group and usually result in miscoding of DNA, strand breakage, or depurination. These reactions can result in cell death, mutagenesis, or carcinogenesis. Polyfunctional alkylating agents typically cause strand cross-linking and inhibition of mitosis with consequent cell death. Resistance to one alkylating agent often implies resistance to other drugs in the same class and can be caused by increased production of nucleophilic substances that compete with the target DNA for alkylation. Decreased permeation of alkylating agents and increased activity

of DNA repair systems are also common mechanisms of resistance.

Individual alkylating agents are generally cell-cycle nonspecific and can be subgrouped according to chemical structure into nitrogen mustards, ethyleneamines, alkyl sulfonates, nitrosoureas, and triazene derivatives.

Nitrogen Mustards: The most common subgroup of alkylating agents used is the nitrogen mustard group. Mechlorethamine hydrochloride is the prototype of the nitrogen mustards and is commonly used in veterinary medicine to treat lymphoma in conjunction with other chemotherapeutics. Because of the highly unstable nature and extremely short duration of action of mechlorethamine, its use is somewhat limited in veterinary medicine. Derivatives of mechlorethamine commonly used for various neoplasias include cyclophosphamide, chlorambucil, and melphalan.

Cyclophosphamide is a cyclic phosphamide derivative of mechlorethamine that requires metabolic activation by the cytochrome P450 oxidation system in the liver. Cyclophosphamide is given PO or IV, and dose-limiting leukopenia associated with bone marrow suppression is the primary toxicity. However, among the alkylating chemotherapy agents, the myelosuppressive effect of cyclophosphamide is considered relatively sparing of platelets and progenitor cells. Sterile hemorrhagic cystitis may result from aseptic chemical inflammation of the bladder urothelium caused by acrolein, a metabolite of cyclophosphamide. Prevention of this toxicity is key to its management. Specifically, concurrent administration of a diuretic, such as furosemide, may be used when cyclophosphamide is given as a single dose to provide a dilutional effect. In addition, cyclophosphamide may be given in the morning so that patients can be provided several opportunities to urinate throughout the day to minimize contact time of acrolein with the bladder lining. In patients with evidence of sterile hemorrhagic cystitis, cyclophosphamide use should be discontinued. Although the signs may be self-limiting, treatment with fluids, NSAIDs, methylsulfonylmethane (MSM), and intravesicular DMSO may be considered. Mesna is a drug that binds and inactivates the urotoxic metabolites of cyclophosphamide within the bladder. Mesna coadministered with fluid diuresis is recommended when ifosfamide (an analogue of cyclophosphamide) or high-dose cyclophosphamide is used.

TABLE 57

MECHANISMS OF ACTION, INDICATIONS, AND TOXICITIES OF SELECTED ANTINEOPLASTIC AGENTS

Drug	Mechanism of Action	Major Indications	Toxicities
ALKYLATING AGENTS			
Cyclophosphamide	Undergoes hepatic biotransformation to active metabolites that alkylate DNA; alkylation leads to miscoding of DNA and cross-linking of DNA strands	Lymphoma, mammary adenocarcinoma, sarcomas, lymphocytic leukemia	Nausea, vomiting (infrequent), moderate to severe myelosuppression, sterile hemorrhagic cystitis
Melphalan	Alkylates DNA causing miscoding and cross-linking of DNA strands	Multiple myeloma	Nausea, vomiting, anorexia, moderate myelosuppression (may be more myelosuppressive in cats)
Chlorambucil	Alkylates DNA causing miscoding and cross-linking of DNA strands; slowest-acting alkylating agent	Chronic lymphocytic leukemia, small-cell lymphoma	Nausea, vomiting, mild to moderate myelosuppression
Lomustine (CCNU)	Alkylates DNA causing miscoding and cross-linking of DNA strands; inhibits both DNA and RNA synthesis; not cross-resistant with other alkylating agents	Lymphoma, mast cell tumor, histiocytic sarcoma, CNS neoplasias, multiple myeloma	Nausea, vomiting, moderate to severe myelosuppression (may be delayed for 4–6 wk), hepatotoxicity, nephrotoxicity, pulmonary toxicity
Streptozotocin	Inhibits DNA synthesis; high affinity for pancreatic β cells	Insulinoma	Severe, potentially fatal nephrotoxicity (if given without diuresis) and hepatotoxicity, nausea (immediate and delayed), vomiting, mild myelosuppression
Dacarbazine (DTIC)	Undergoes hepatic biotransformation to active metabolites that alkylate DNA; inhibits RNA synthesis	Lymphoma, sarcomas	Severe acute nausea, vomiting, phlebitis, moderate myelosuppression, hepatotoxicity, anecdotal reports of pleural effusion in cats
Ifosfamide	Analogue of cyclophosphamide; undergoes hepatic biotransformation to active metabolites that alkylate DNA; alkylation leads to miscoding of DNA and cross-linking of DNA strands	Various sarcomas	Nausea, vomiting, myelosuppression, sterile hemorrhagic cystitis, possible nephrotoxicity

(continued)

TABLE 57

MECHANISMS OF ACTION, INDICATIONS, AND TOXICITIES OF
SELECTED ANTINEOPLASTIC AGENTS (continued)

Drug	Mechanism of Action	Major Indications	Toxicities
ANTIMETABOLITES			
Methotrexate	Inhibition of dihydrofolate reductase that is required for formation of tetrahydrofolate, a necessary cofactor in thymidylate synthesis; thymidylate essential for DNA synthesis and repair	Lymphoma	Nausea, vomiting, moderate myelosuppression, GI ulceration, hepatotoxicity, pulmonary toxicity
5-Fluorouracil	Pyrimidine analogue; interferes with DNA synthesis and may be incorporated into RNA to cause toxic effects	Carcinomas (systemic); cutaneous carcinomas (topical)	Systemic: nausea, vomiting, moderate myelosuppression, neurotoxicity, GI ulceration, hepatotoxicity Topical: local irritation, pain, hyperpigmentation Cannot be given to cats (fatal neurotoxicity)
Cytarabine	Pyrimidine analogue; incorporates into DNA causing steric hindrance and inhibition of DNA synthesis	Lymphoma (including CNS), leukemias; no activity in solid tumors	Nausea, vomiting, moderate myelosuppression, neurotoxicity, hepatotoxicity
Gemcitabine	Pyrimidine analogue; incorporates into DNA, causing steric hindrance and inhibition of DNA synthesis	Limited efficacy seen in lymphoma and various carcinomas	Mild nausea, vomiting, mild to moderate myelosuppression, pulmonary toxicity, nephrotoxicity
ANTIBIOTIC ANTINEOPLASTICS			
Doxorubicin	Intercalates and binds to DNA, disrupting helical structure and DNA template; inhibits RNA and DNA polymerases; causes DNA topoisomerase II-mediated chain scission; generates free radicals that cause DNA scission and cell membrane damage	Lymphoma, leukemias, multiple myeloma, osteosarcoma, hemangiosarcoma, and various other sarcomas and carcinomas	Nausea, vomiting, moderate myelosuppression, hemorrhagic colitis, severe cutaneous reactions if extravasated; red urine (not hematuria), transient ECG changes and arrhythmias, nephrotoxicity, anaphylactoid reactions Cumulative dose-related congestive heart failure in dogs; cumulative nephrotoxicity in cats

(continued)

TABLE 57

MECHANISMS OF ACTION, INDICATIONS, AND TOXICITIES OF
SELECTED ANTINEOPLASTIC AGENTS (continued)

Drug	Mechanism of Action	Major Indications	Toxicities
Mitoxantrone	Topoisomerase II-mediated chain scission; DNA aggregation, oxidation, and strand breakage	Lymphoma, various carcinomas	Nausea, vomiting, moderate to severe myelosuppression, diarrhea, bluish discoloration to sclera; less severe adverse effects than others in this group
Bleomycin	Mixture of glycopeptides; generates oxygen radicals that cause chain scission and fragmentation of DNA	Carcinomas	Nausea, vomiting, myelosuppression, fever, allergic reactions including anaphylaxis, hyperpigmentation, skin ulceration, pneumonitis, pulmonary fibrosis
Dactinomycin (Actinomycin D)	Intercalates and binds to DNA, disrupting helical structure and DNA template; inhibits RNA and DNA polymerases; causes DNA topoisomerase II-mediated chain scission; generates free radicals that cause DNA scission and cell membrane damage	Lymphoma, various sarcomas	Nausea, vomiting, moderate to severe myelosuppression, phlebitis; severe tissue reaction if extravasated
MITOTIC INHIBITORS			
Vinblastine	Binds to tubulin, leading to disruption of mitotic spindle apparatus and arrest of cell cycle	Lymphoma and leukemias, mast cell tumors	Mild nausea, vomiting, severe myelosuppression, neurotoxicity with high doses, inappropriate secretion of antidiuretic hormone
Vincristine	Binds to tubulin, leading to disruption of mitotic spindle apparatus and arrest of cell cycle	Lymphoma and leukemias, transmissible venereal cell tumors, various sarcomas	Mild to moderate nausea, vomiting, mild to moderate myelosuppression, severe tissue reaction if extravasated, cumulative peripheral neuropathy, constipation, paralytic ileus, inappropriate secretion of antidiuretic hormone

(continued)

TABLE 57

**MECHANISMS OF ACTION, INDICATIONS, AND TOXICITIES OF
SELECTED ANTINEOPLASTIC AGENTS** (continued)

Drug	Mechanism of Action	Major Indications	Toxicities
Vinorelbine	Binds to tubulin, leading to disruption of mitotic spindle apparatus and arrest of cell cycle	Primary lung tumors, limited efficacy in mast cell tumors	Mild nausea, vomiting, myelosuppression
Paclitaxel	Binds to tubulin, stabilizing microtubule polymer and arresting mitosis	Mammary carcinoma, squamous cell carcinoma	Myelosuppression, nausea, vomiting, hypersensitivity (when Cremor EL is used as vehicle)
MISCELLANEOUS			
Cisplatin	Reacts with proteins and nucleic acids; forms cross-links between DNA strands and between DNA and protein; disrupts DNA synthesis	Osteosarcoma, carcinomas, and mesothelioma	Intense nausea, vomiting, mild to moderate myelosuppression, potentially fatal nephrotoxicity if not given with diuresis, anaphylaxis, ototoxicity, peripheral neuropathy, hyperuricemia, hypermagnesemia Cannot be given to cats (fulminant pulmonary edema)
Carboplatin	Reacts with proteins and nucleic acids; forms cross-links between DNA strands and between DNA and protein; disrupts DNA synthesis	Osteosarcoma, carcinomas	Mild nausea, vomiting, diarrhea, moderate to severe myelosuppression
L-Asparaginase	Inhibits protein synthesis by hydrolyzing tumor cell supply of asparagine	Acute lymphoid leukemias and lymphoma	Hypersensitivity reactions, anaphylaxis especially after repeated doses, alteration in coagulation parameters, hepatotoxicity, pancreatitis (people), potential inhibition of immune responsiveness (B and T cells)
Mitotane (o,p'DDD)	Destroys adrenal zona fasciculata and zona reticularis	Pituitary hyperadrenocorticism, palliation of adrenal cortical tumors	Nausea, vomiting, anorexia, diarrhea, adrenal insufficiency, CNS depression, dermatitis

(continued)

TABLE 57

MECHANISMS OF ACTION, INDICATIONS, AND TOXICITIES OF SELECTED ANTINEOPLASTIC AGENTS (continued)

Drug	Mechanism of Action	Major Indications	Toxicities
Hydroxyurea	Inhibits conversion of ribonucleotides to deoxyribonucleotides by destroying ribonucleoside diphosphate reductase	Polycythemia vera, granulocytic and basophilic leukemia, thrombocythemia, investigational for meningiomas	Nausea, vomiting, mild myelosuppression, alopecia, sloughing of claws, dysuria
Procarbazine	Mechanism is unclear; inhibits DNA, RNA, and protein synthesis, perhaps through alkylation	Lymphoma, as part of MOPP chemotherapy protocol; brain tumors	Nausea, vomiting, myelosuppression, diarrhea
HORMONES			
Prednisone	Lympholytic; inhibits mitosis in lymphocytes	Lymphoma, mast cell tumors, multiple myeloma, palliative treatment of brain tumors	Sodium retention, GI ulceration, protein catabolism, muscle wasting, delayed wound healing, suppression of hypothalamic-pituitary-adrenal axis, immunosuppression

Chlorambucil, the slowest-acting nitrogen mustard, achieves effects gradually and often can be used in animals with compromised bone marrow. It can cause bone marrow suppression, which is usually mild; however, periodic monitoring is recommended with long-term administration. This drug is given PO and is most commonly used in treatment of chronic, well-differentiated cancers; it is considered ineffective in rapidly proliferating tumors.

Melphalan, an L-phenylalanine derivative of mechlorethamine, is given PO or IV and is primarily used in veterinary medicine to treat multiple myeloma.

Other Alkylating Agents: Of the other subgroups of alkylating agents, several have limited but specific uses. **Triethylenethiophosphoramide** (thiotepa), an ethylenimine, has been reported as an intravesicular treatment for transitional cell carcinoma of the bladder or as an intracavitary treatment for pleural and peritoneal effusions. **Busulfan**, an alkyl sulfonate, is used specifically in treatment of chronic myelocytic leukemia and polycythemia vera. **Streptozotocin**, a naturally occurring

nitrosourea, is used for palliation of malignant pancreatic islet-cell tumors or insulinomas. Other nitrosoureas, such as **carmustine** and **lomustine**, readily cross the blood-brain barrier and have been useful in management of lymphoma (including epitheliotropic cutaneous lymphoma), mast cell tumors, histiocytic sarcomas, and CNS neoplasias. **Dacarbazine** (DTIC), a triazine derivative, has been used either in combination with doxorubicin or as a single-agent treatment for relapsed canine lymphoma and soft-tissue sarcomas.

Temozolomide is an oral imidazotetrazine derivative of dacarbazine and belongs to a class of chemotherapeutic agents that enter the CSF and do not require hepatic metabolism for activation. In people, it is used for refractory malignant gliomas and malignant melanomas. There have been reports in the veterinary literature of its use as a substitute for dacarbazine (DTIC).

ANTIMETABOLITES

Antimetabolites resemble normal cellular substances and so can subvert normal metabolic pathways in a toxic manner.

Three subgroups of antimetabolites are used: folic acid, pyrimidine, and purine analogues.

Folic Acid Analogues: The prototype folic acid analogue is methotrexate, an inhibitor of dihydrofolate reductase, the enzyme that catalyzes conversion of folic acid to tetrahydrofolate. Tetrahydrofolate deficiency blocks reactions requiring folate coenzymes, disrupting both DNA and RNA synthesis. Methotrexate is an S phase-specific drug that must be actively transported across cell membranes. It can be given PO, IV, IM, or intrathecally. Methotrexate is excreted in the urine, and at high doses may precipitate in renal tubules. Folinic acid can be used to bypass the metabolic blockade produced by folic acid analogues and thus result in rescue of treated cells. Because tumor cells appear less efficient at transport of folinic acid, some degree of selectivity is achieved in the rescue. Resistance to methotrexate may develop due to impaired transport of the drug into cells, production of altered forms, or increased concentrations of dihydrofolate reductase.

Pyrimidine Analogues: Two pyrimidine analogues, 5-fluorouracil and cytarabine, are commonly used.

5-Fluorouracil must be converted to an active 5-fluoro-2'-deoxyuridine-5'-phosphate form to bind the enzyme thymidylate synthetase and block or inhibit DNA and RNA synthesis. This drug is considered S phase-specific. It is used IV but is also available for topical use. Metabolism is via the liver, and the drug readily enters CSF. Occasional CNS reactions have been reported in dogs. Severe irreversible neurotoxicity and sudden death have been described in cats. In people, neurotoxicity is related to deficiency in the enzyme dihydropyrimidine dehydrogenase, but this has not been investigated in veterinary species. Resistance may develop by decreased activation of the drug or acquisition of altered thymidylate synthetase that is not inhibited.

Cytarabine (cytosine arabinoside) is an analogue of 2'-deoxycytidine and must be activated by conversion to a 5'-monophosphate nucleotide. The nucleotide analogue, AraCTP, inhibits DNA synthesis by substitution of arabinose for deoxyribose in the sugar moiety of DNA; cytarabine may also inhibit DNA repair enzymes. This drug is S phase-specific, and its effectiveness in hematopoietic neoplasms is directly proportional to exposure of cells to the drug; continuous infusion or repeated

injections are usually required. Inhibition of conversion to AraCTP or increased degradation of AraCTP can account for development of resistance.

Gemcitabine is another nucleoside analogue of cytidine which, unlike cytarabine, has activity against solid tumors. The drug requires active carrier transport into the cytoplasm where it is terminally activated via phosphorylation; consequently, serum levels may not predict intracellular concentrations. By acting as a counterfeit nucleotide, coupled with the ability to inhibit multiple enzymes needed for pyridine biosynthesis and DNA repair, gemcitabine is capable of self-potential and synergism with other agents, particularly alkylators. Gemcitabine has also been used as a radiation sensitizer.

Purine Analogues: Two purine analogues, **6-mercaptopurine** (6-MP) and **6-thioguanine** (6-TG), are rarely used in veterinary medicine. In people, these drugs are occasionally used for acute leukemias or other autoimmune disorders.

MITOTIC INHIBITORS

Vinca Alkaloids: The vinca alkaloids are large, complex molecules derived from the periwinkle plant. Binding to tubulin, the major component of cellular microtubules, accounts for the antineoplastic effects of these drugs. Vinca alkaloids inhibit microtubule polymerization and increase microtubule disassembly. The mitotic spindle apparatus is disrupted, and segregation of chromosomes in metaphase is arrested. These effects account for the primary M-phase action of vinca alkaloids, although other antitubulin effects related to cytoskeletal maintenance and protein trafficking may be seen. The two drugs of importance in this class are **vincristine** and **vinblastine**. Both are given IV, and both cause severe local vesication if injected perivascularly. Drug extravasation may cause severe tissue reactions and promote exacerbation of self-trauma. The vinca alkaloids are metabolized primarily in the liver but may be partially excreted in an unchanged form in the urine. Although vinca alkaloids are related structurally, resistance to one does not imply resistance to all drugs in this category. Vincristine use is limited by neurologic toxicity that may include a slowly reversible sensorimotor peripheral neuropathy and muscle weakness. In comparison, the dose-limiting toxicity associated with vinblastine is related to myelosuppression

and leukopenia; neurologic toxicity develops only at high doses.

Vinorelbine is a second-generation semisynthetic vinca alkaloid that is derived from vinblastine but with broader antitumor efficacy. According to studies in the veterinary literature, this drug may have efficacy in canine primary lung and cutaneous mast cell tumors.

Taxanes: **Paclitaxel** and **docetaxel** are antimicrotubule agents extracted from the Pacific and European yew trees, respectively. Taxanes bind to tubulin subunits, enhance microtubule polymerization, and inhibit microtubule depolymerization. Formation of stable microtubule bundles disrupts tubulin equilibrium and blocks normal progression through metaphase, and mitosis is arrested. These agents are actively used in human medicine, but hypersensitivity reactions related to the vehicle Cremophor EL have limited the drug's utility in veterinary medicine. A new water-soluble, micellar formulation of paclitaxel has received conditional approval by the FDA for treatment of canine mammary carcinoma and squamous cell carcinoma. Myelosuppression and GI effects (diarrhea, mucosal ulceration, and emesis) have been reported in dogs treated with paclitaxel.

ANTINEOPLASTIC ANTIBIOTICS

The antineoplastic antibiotics are products of *Streptomyces*. The important drugs in this group include actinomycin D (dactinomycin), doxorubicin, mitoxantrone, and bleomycin. Drugs less commonly used include daunorubicin, mithramycin, and mitomycin.

Actinomycin A was the first *Streptomyces* antibiotic isolated and was followed by related antibiotics, including actinomycin D. **Actinomycin D** binds with double-stranded DNA and blocks the action of RNA polymerase, which prevents DNA transcription. Actinomycin D is considered cell-cycle nonspecific and is given IV but does not cross the blood-brain barrier. Resistance may develop because of decreased cellular uptake of the drug. Occasionally, it is used as a substitute for doxorubicin in dogs with questionable cardiac function or for those dogs that have exceeded the cumulative cardiotoxic dose of doxorubicin.

The anthracycline antibiotics, particularly **doxorubicin**, have become important antineoplastic antibiotics. These drugs intercalate and bind to DNA between base pairs on adjacent strands. This causes the

DNA helix to uncoil, which destroys the DNA template and inhibits RNA and DNA polymerases. Scission of DNA is thought to be mediated by either the enzyme topoisomerase II or by generation of free radicals. Intracellular interactions of anthracycline antibiotics result in the formation of semiquinone radical intermediates capable of generating hydrogen peroxide and hydroxyl radicals. Considered cell-cycle nonspecific because of the damage associated with radical formation, these drugs probably have their maximal effect during the S phase of the cell cycle. The anthracycline antibiotics are given IV; they are severe vesicants if administered perivascularly and may cause a severe, delayed phlebitis. Administration of a free radical scavenger, dexrazoxane, may limit the extent of tissue damage seen with extravasation of this drug. The anthracycline antibiotics are metabolized in the liver to a variety of less active and inactive products.

Doxorubicin toxicity can be manifested in a variety of acute and delayed reactions. Acute effects include hypersensitivity reactions (from nonspecific histamine release), extravasation injury, or transient cardiac arrhythmias. Delayed toxicities can be severe, with the major problem in dogs being cumulative, dose-related cardiac toxicity associated with binding of the drug to cardiac DNA and free radical damage to myocardial membranes. A nonspecific decrease in cardiac fibrils occurs, which leads to congestive heart failure unresponsive to digitalis. Because the cardiotoxic effects of doxorubicin are related to the peak plasma concentrations (rather than area under the curve), slow IV administration over 15–30 min is recommended to help lessen cardiac injury. Myocardial damage from doxorubicin also can be prevented by coadministration of dexrazoxane, at 10 times the dose of doxorubicin. In cats, cumulative doses of doxorubicin can result in nephrotoxicity and should be avoided or used judiciously in cats with preexisting renal insufficiency.

Dose-limiting toxicities of doxorubicin include severe myelosuppression and GI upset. Also, if doxorubicin is used in conjunction with radiation therapy, damage by radiation may be augmented. This radiation sensitization effect may necessitate reduction in radiation or drug dosages, or both. Because of the significant toxicity associated with use of doxorubicin, newer-generation drugs specifically aimed at reduction of cardiac toxicity have been developed and are available in human

medicine. Two of these, idarubicin and epirubicin, have been studied, but neither is in common use in veterinary medicine.

A pegylated liposomal encapsulated form of doxorubicin, called doxorubicin HCL liposome injection, has been used effectively in both human and veterinary medicine. The liposomal formulation results in a longer drug circulation time and reduced myelosuppression and cardiotoxicity. In dogs, the dose-limiting toxicity of liposomal doxorubicin is a cutaneous reaction called palmar-plantar erythrodysesthesia. In cats, a delayed nephrotoxicity is the dose-limiting toxicity of both conventional and liposomal doxorubicin.

Mitoxantrone, an anthracenedione related to the anthracycline antibiotics, has shown promise in veterinary medicine for treatment of lymphoma and various carcinomas. The mechanism of action of mitoxantrone is similar to that of the anthracyclines, but most adverse effects are less severe than those of doxorubicin. An exception is myelosuppression, which is more profound with mitoxantrone than doxorubicin.

Bleomycin is actually a mixture of bleomycin glycopeptides that differ only in their terminal amine moiety. The cytotoxic action of these glycopeptides depends on their ability to cause chain scission and fragmentation of DNA molecules. Cells accumulate in the G_2 phase of the cell cycle, which accounts for the classification of bleomycin as a G_2 and M phase-specific agent. Bleomycin may also affect DNA repair enzymes. Given IV or SC, bleomycin does not cross the blood-brain barrier; a large portion is excreted via the kidneys. Bleomycin has minimal myelosuppressive and immunosuppressive activities but does have an unusual delayed pulmonary toxicity. Pulmonary toxicity, which is cumulative, may begin as a nonspecific pneumonitis that progresses to pulmonary fibrosis. Dangers from pulmonary complications are especially important in older animals with preexisting pulmonary disease.

HORMONAL AGENTS

Hormonal therapy for neoplasia commonly involves use of glucocorticoids. Direct antitumor effects are related to their lympholytic properties; glucocorticoids can inhibit mitosis, RNA synthesis, and protein synthesis in sensitive lymphocytes. Glucocorticoids are considered cell-cycle nonspecific and are often used in chemotherapeutic protocols after induction by

another agent. Unfortunately, resistance to a given glucocorticoid may develop rapidly and typically extends to other glucocorticoids. Toxic effects of glucocorticoid therapy can include peptic ulceration, glucose intolerance, polydipsia and polyuria, immunosuppression, pancreatitis, osteopenia, hypokalemia, cataracts, and muscle wasting. Prednisone and prednisolone are commonly used to treat lymphoreticular neoplasms in combination with other drugs. Because they readily enter the CSF, dexamethasone, prednisone, and prednisolone are especially useful in treatment of leukemias and lymphomas of the CNS.

Indirect benefits of glucocorticoid therapy in cancer include symptomatic improvements in appetite and attitude, suppression of noninfectious fevers, management of hypercalcemia of malignancy (after a definitive diagnosis has been made), and relief of edema associated with spinal cord and brain tumors. However, evidence from several sources suggests that treatment of certain lymphomas with prednisone may increase resistance of neoplastic cells to subsequent cycles of antineoplastic chemotherapy through induction of MDR-1-related P-glycoprotein expression.

MISCELLANEOUS ANTINEOPLASTIC AGENTS

Several drugs used as antineoplastics do not fall into any of the categories mentioned thus far. These include L-asparaginase, cisplatin, mitotane (o,p'DDD), hydroxyurea, etoposide, and procarbazine.

L-Asparaginase is an enzyme derived from *Escherichia coli* that catalyzes hydrolysis of asparagine. Because some tumor cells have poor expression of asparagine synthetase and are unable to produce the amino acid asparagine, treatment with this drug deprives these cells of exogenously supplied asparagine and ultimately limits protein synthesis. Because protein synthesis is active in the G_1 phase of the cell cycle, L-asparaginase is considered to be a G_1 phase-specific drug. Preferred routes of administration for L-asparaginase include IM and SC. Anaphylaxis on repeated administration of L-asparaginase may occur as a result of host anti-asparaginase antibody production; pretreatment of animals with antihistamine helps to prevent this acute toxic reaction. Anti-asparaginase antibody production may also account for development of tumor resistance, as can a decreased tumor cell requirement for

asparagine. A related drug, pegaspargase, is modified from L-asparaginase by covalent modification with monomethoxypolyethylene glycol. The conjugated drug produces fewer hypersensitivity reactions than does L-asparaginase.

Cisplatin (cis-diamine-dichloroplatinum) functions primarily as a bifunctional alkylator but is included in the miscellaneous category because of its unusual structure. It is a platinum ion complexed to two chloride ions and two ammonium molecules. Cisplatin causes inter- and intrastrand DNA cross-linking that disrupts DNA helices and prevents DNA synthesis. Cisplatin is cell-cycle nonspecific and has been used both for its direct antitumoral and radiation-sensitizing effects. It is administered by IV drip in combination with aggressive saline diuresis. Excretion is prolonged, with up to 50% of a dose still present in the body 5 days after administration. Extreme, dose-limiting, proximal tubular renal necrosis typifies the delayed adverse effects of cisplatin along with other responses that may include ototoxicity, moderate bone marrow suppression, peripheral neuropathy, and renal potassium and magnesium wasting. Cisplatin causes fatal pulmonary edema in cats and must not be used in this species.

Because of the extreme toxic adverse effects of cisplatin, newer generation derivatives such as **carboplatin** and others have been developed. Carboplatin is effective as an adjunct to surgery for treatment of osteosarcoma. Nausea and vomiting are less severe than with cisplatin, and carboplatin is not considered nephrotoxic. It is, however, myelosuppressive, with neutropenia being the dose-limiting toxicity. Carboplatin is excreted through the kidneys; consequently, dogs or cats with evidence of compromised renal function require dose adjustments to avoid excessive toxicity. Carboplatin is considered safe for administration to cats.

Mitotane (o,p'DDD), a derivative of the insecticides DDT and DDD, causes selective destruction of normal and neoplastic adrenal cortical cells. Mitotane may act by inhibiting production of steroids induced by adrenocorticotrophic hormone, which causes atrophy of the inner zones of the adrenal cortex. Mitotane is administered PO, and plasma concentrations can be detected for several weeks.

Hydroxyurea, a simple hydroxylated derivative of urea, is most commonly used in treatment of polycythemia vera. Hydroxyurea inhibits ribonucleoside diphosphate reductase (RNDR), limits the

conversion of ribonucleotides to deoxyribonucleotides, and blocks DNA synthesis. Cells are arrested in the G₁-S interface. Mechanisms of resistance include amplification of the RNDR gene or development of RNDR with reduced sensitivity to hydroxyurea. Loss of claws has been associated with hydroxyurea use in animals.

Epipodophyllotoxins are semisynthetic glycosides of podophyllotoxin derived from the mandrake plant. Although these toxins bind tubulin, their mechanism of action is unrelated to disruption of microtubules. Instead, they are thought to stimulate DNA cleavage mediated by topoisomerase II. Of the two drugs in this class, etoposide and teniposide, the former has been used primarily in treatment of testicular carcinoma.

Procarbazine is considered to function as an alkylating agent but is included in the miscellaneous category because the exact mechanism of action is not known. It is typically used as part of the MOPP protocol that includes mechlorethamine, vincristine (trade name Oncovin®), procarbazine, and prednisone for dogs with lymphoma. This drug is metabolized and activated in the liver. GI toxicity and myelosuppression are the primary concerns associated with the MOPP protocol.

Biologic Response Modifiers in Cancer Therapy:

In recent years, a number of alternative modes of cancer therapy have become increasingly available in veterinary medicine. These novel forms of therapy work in myriad ways, including enhanced immune recognition, altered blood vessel formation, or by exploitation of specific pathways that are aberrant or overexpressed in neoplastic cells. The widespread use of these newer therapies alone or in combination with conventional chemotherapy has transformed the approach to treatment of many cancer patients.

NSAIDs represent one class of biologic response modifiers that work by inhibiting frequently overexpressed COX-2 enzyme activity present in many tumor types. Several studies have proposed that these drugs may work by reducing cell proliferation, increasing apoptosis, inhibiting angiogenesis, and modulating immune function. Piroxicam has been the drug most researched in dogs, but any of the newer NSAIDs with more COX-2 selective inhibition (such as deracoxib or meloxicam) theoretically may yield equal or improved effects. (See also NONSTEROIDAL ANTI-INFLAMMATORY DRUGS, p 2714.) The clinical usefulness of COX-2 inhibitors has

been demonstrated in canine transitional cell carcinoma, squamous cell carcinoma, and other tumor types in dogs and cats. NSAIDs are often combined in antiangiogenic protocols.

Metronomic or antiangiogenic dosing of chemotherapy is a novel or nontraditional way to administer chemotherapy that consists of the administration of low doses of oral chemotherapy agents at very short intervals, often daily. This treatment approach targets the tumor neovasculature by leveraging the exquisite sensitivity of endothelial progenitor cells and immature endothelium to modest doses of alkylating agents. Studies indicate that antiangiogenic factors, such as thrombospondin-1, increase during metronomic chemotherapy. In addition, antitumor immunosuppression mediated through T regulatory cells may be mediated by metronomic protocols. Disease stabilization is considered a successful outcome of low-dose chemotherapy, because direct cytotoxicity to neoplastic cells is not the intent of metronomic chemotherapy. Preliminary studies in the veterinary literature suggest this is a promising alternative to maximally tolerated doses of conventional chemotherapy, particularly in a microscopic disease setting, and has the added benefit of limited adverse effects.

Targeting of specific pathways that are aberrant or dysregulated in cancers has yielded novel therapies in a variety of human cancers. An example of such a target is the receptor tyrosine kinases (RTKs), which mediate processes involved in tumor growth, progression, and metastasis. These drugs are competitive inhibitors of ATP, and so prevent receptor phosphorylation and subsequent downstream signal transduction. Mutations in *c-kit*, an RTK gene involved in mast cell differentiation and proliferation, has been reported in approximately a quarter of canine mast cell tumors. Toceranib has been approved by the FDA, and biologic response rates of 70%–90% have been reported in dogs that have mast cell tumors with recognized *c-kit* mutations. Moreover, toceranib has activity against other members of the split-kinase family of RTKs, such as vascular endothelial growth factor receptor, platelet-derived growth factor, and others. Preliminary evidence indicates that toceranib has activity against a variety of carcinomas and metastatic osteosarcoma, leading to tumor regression or more often to prolonged disease stabilization. Recent reports indicate that dosages of toceranib ranging from 2.4–2.9 mg/kg, PO, every 48 hr (below

the label dosage of 3.25 mg/kg, PO, every 48 hr) result in sufficient target inhibition with substantially reduced toxicity.

Development of a therapeutic vaccine to stimulate active immunity against cancer has long been a goal in both human and veterinary oncology. This became a reality with introduction of a canine melanoma vaccine. The vaccine exploits the immune response induced by human tyrosinase, an enzyme in the pathway of melanin formation. The vaccine contains a human tyrosinase gene inserted into a bacterial plasmid, which is administered transdermally. The antibodies and T-cell responses produced by xenogeneic tyrosinase cross-react with the tyrosinase overexpressed on canine melanoma cells. Initial studies reported prolonged survival in dogs with advanced stage oral malignant melanoma treated with radiation therapy or surgery of the primary tumor, followed by vaccine administration.

Passive immunotherapy using monoclonal antibodies has grown substantially in human oncology in recent years. Monoclonal antibodies may attach to specific antigens on cancer cells, thereby either marking the cancer cells for destruction by the immune system or impairing functional pathways within the neoplastic cells. Furthermore, monoclonal antibodies may be conjugated to other antineoplastic agents (such as chemotherapy agents, radionuclides, or other toxins) to allow for more targeted delivery of cytotoxic therapy to cancer cells while sparing normal tissues. The introduction of anti-CD20 monoclonal antibodies in human oncology has revolutionized the treatment of B-cell lymphoma with significantly improved outcomes versus chemotherapy alone. In veterinary medicine, anti-CD20 and anti-CD52 monoclonal antibodies have received either USDA or conditional approval to treat canine B-cell and T-cell lymphoma, respectively. The mechanisms by which these antibodies work is not fully understood, but several potential mechanisms include antibody-dependent cell-mediated cytotoxicity, complement-dependent cytotoxicity, and direct signaling leading to inhibition of proliferation or to apoptosis. Field studies of each of these antibodies are underway.

Biologic response modifiers aimed at enhancing innate antitumor defense mechanisms of the host has been an area of active investigation. Nonspecific immunomodulators, including intact bacteria or bacterial cell components, acemannan, IL-2, IL-12, interferon alpha, levamisole, and

cimetidine, have been reported with variable efficacy to enhance immune responsiveness and improve outcomes after surgery or antineoplastic chemotherapy. Liposome-encapsulated muramyl tripeptide phosphatidylethanolamine (L-MTP-PE) is perhaps the best studied nonspecific immunomodulator in veterinary medicine. This synthetic bacterial wall component has been used effectively with chemotherapy to confer a survival advantage in dogs with splenic hemangiosarcoma and osteosarcoma.

Development of immunomodulators such as lymphokines and cytokines (eg, interleukins, interferon, and tumor necrosis factor) for clinical use in cancer patients has not been fully realized, largely because of toxicity. Consequently, these agents are not commonly used in veterinary medicine.

Blocking angiogenesis is an attractive form of anticancer therapy, because tumors must develop their own vascular supply if they are to grow beyond a few millimeters in diameter. Various drugs, such as angiostatin, thrombospondin-1, and matrix metalloproteinase inhibitors, have been investigated with varying results. Specific angiogenesis inhibitors for veterinary patients are not yet commercially available. At present, metronomic chemotherapy combinations are the most practical approach to antiangiogenic therapy in clinical cases.

ANCILLARY ANTINEOPLASTIC AGENTS

Supplementary agents are occasionally used in veterinary oncology to either enhance the effect of certain chemotherapy treatments or support the well-being of the patient. Drugs in this category include antiemetic therapy, prophylactic antibiotics, COX-2 inhibitors (NSAIDs), and various pain medications.

Bisphosphonates are frequently used in veterinary oncology for a variety of reasons, including to treat bone pain from primary bone tumors or bone metastasis, and to effectively treat hypercalcemia of malignancy. Bisphosphonates belong to a class of drugs that directly inhibit osteoclast activity and the subsequent resorption of bone. In people, these drugs are used for various conditions that are characterized by bone resorption and bone fragility, such as osteoporosis. In addition to their inhibitory effects on osteoclasts, bisphosphonates are believed to exert direct cytotoxic effects on some cancer cells. These effects include

induction of apoptosis, inhibition of new blood vessel formation, and reduction of tumor cell adhesion to bone matrix.

Retinoids are a class of compounds structurally related to vitamin A. In preclinical studies, all-trans retinoic acid (tretinoin), 13-cis retinoic acid (isotretinoin), and the aromatic retinoids etretinate and acitretin have preventive and therapeutic effects on carcinogen-induced premalignant and malignant lesions in both human and veterinary medicine. Isotretinoin and etretinate have been used with limited therapeutic success in superficial squamous cell carcinoma and cutaneous lymphoma. In people, dramatic therapeutic effects have been observed in treatment of acute promyelocytic leukemia with tretinoin. The mechanism of action of retinoids is thought to occur through modulation of cell proliferation and differentiation. Retinoids vary in their capacity to induce differentiation and to inhibit proliferation in a variety of human and veterinary cell lines.

TREATMENT OF CANINE LYMPHOMA

Lymphoma is the canine tumor most frequently treated with chemotherapy. It is the most common hematopoietic neoplasia of dogs (see p 40) and cats and is also among the most responsive to chemotherapy. Four antineoplastic agents, vincristine, cyclophosphamide, doxorubicin, and prednisone, form the basis for many lymphoma treatment protocols. Treatments based on these four drugs are often abbreviated as CHOP (cyclophosphamide, hydroxydaunorubicin [doxorubicin], Oncovin® [a trade name of vincristine], and prednisone) protocols. One commonly used CHOP protocol in veterinary medicine is shown in TABLE 58; nearly 40 protocols for management of lymphoma in dogs have been published.

The most common recommendation in veterinary oncology is to use a discontinuous chemotherapy protocol, as opposed to maintenance or continual chemotherapy. Discontinuous chemotherapy in dogs appears to have the same or similar remission and survival duration as a traditional maintenance protocol. For this treatment approach, all chemotherapy is discontinued for patients in a complete remission at the end of the treatment protocol. At the first signs of recurrence of lymphoma, reinduction using the original chemotherapy protocol should be used. Studies have suggested that dogs receiving a

TABLE 58

CHOP MULTIDRUG CHEMOTHERAPY FOR TREATMENT OF CANINE LYMPHOMA

Drug	Dosage	Schedule
L-Asparaginase	10,000 IU/m ² , SC	Wk 1
Vincristine	0.5–0.7 mg/m ² , IV	Wk 1, 3, 6, 8, 11, 13, 16, and 18
Cyclophosphamide	250 mg/m ² , IV or PO	Wk 2, 7, 12, and 17
Doxorubicin	30 mg/m ² , IV, for dogs >10 kg; 1 mg/kg for dogs <10 kg	Wk 4, 9, 14, and 19
Prednisone	2 mg/kg/day, PO	For first week, then 1.5 mg/kg/day, PO, for 7 days, then 1 mg/kg/day, PO, for 7 days, then 0.5 mg/kg/day, PO, for 7 days, then discontinue.

discontinuous protocol were more likely to achieve a second remission when they relapsed than dogs that received longterm or maintenance chemotherapy. If reinduction fails, then use of rescue protocols should be considered.

Other lymphoma protocols include a non-doxorubicin-based combination protocol (COP) or a protocol consisting of single-agent doxorubicin administered every 3 wk. These protocols are generally

well tolerated, less expensive, and easy to administer but are considered to be less effective than a CHOP-based protocol.

CHOP-based chemotherapy protocols provide the basis for most lymphoma chemotherapy protocols in cats, although there is currently no consensus treatment protocol recommended for this species. In general, fewer studies document the clinical effectiveness of various CHOP combinations in cats than in dogs.

ANTISEPTICS AND DISINFECTANTS

Antiseptics and disinfectants are nonselective, anti-infective agents that are applied topically. Their activity ranges from simply reducing the number of microorganisms to within safe limits of public health interpretations (sanitization), to destroying all microorganisms (sterilization) on the applied surface. In general, antiseptics are applied on tissues to suppress or prevent microbial infection. Disinfectants are germicidal compounds usually applied to inanimate surfaces. Sometimes the same compound may act as an antiseptic and a disinfectant, depending on the drug concentration, conditions of exposure, number of organisms, etc. To achieve maximal efficiency, it is essential to use the proper concentration of the drug for the purpose intended. The logic that “if a little is good, twice as much is better” is not only uneconomical but often has toxicologic implications.

Topical anti-infective agents are extensively used in surgery for antisepsis of the surgical site and surgeon's hands and to disinfect surgical instruments, apparel, and hospital premises. Other common uses are as disinfectants for home and farm premises, food processing facilities, in water treatment, in public health sanitation, and as antiseptics in soaps, teat dips, dairy sanitizers, etc. Antiseptics also have been used to treat local infections. However, in most cases, systemic chemotherapeutic agents are preferred, because they often penetrate better into the foci of infection and are less likely than the topical anti-infectives to lose their potency when in contact with body fluids and debris in the infected area.

Ideally, antiseptics and disinfectants should have a broad spectrum and potent germicidal activity, with rapid onset and long-lasting effect. They should not be

prone to development of resistance in target microorganisms. They should withstand a range of environmental factors (eg, pH, temperature, humidity) and must retain activity even in the presence of pus, necrotic tissue, soil, and other organic material. High lipid solubility and good dispersibility increase their effectiveness. Antiseptic preparations should not be toxic to the host tissues and should not impair healing. Disinfectants should be nondestructive to applied surfaces. They should be readily biodegradable, not accumulate in the environment, or react with other chemicals to produce toxic residues. Offensive odor, color, and staining properties should be absent or minimal.

Most of these compounds exert their antimicrobial effect by denaturation of intracellular protein, alteration of cellular membranes (often through extraction of membrane lipids), or enzyme inhibition. Although most classes of antiseptics and disinfectants have been in use for decades, the emergence of microbial resistance to some agents, especially in the hospital environment, has led to continued research into the development of new compounds.

ACIDS AND ALKALIES

Acids: Hydrogen ion is bacteriostatic at pH ~3–6 and bactericidal at pH <3. Strong mineral acids (HCl, H₂SO₄, etc) in concentrations of 0.1–1 N have been used as disinfectants; however, their corrosive action limits their usefulness. Un-ionized weak organic acids can readily penetrate and disrupt bacterial cell membranes. Acids are used as food preservatives (eg, benzoic acid), antiseptics (eg, boric acid, acetic acid), fungicides (eg, salicylic acid, benzoic acid), spermatocides (eg, acetic acid, lactic acid), and cauterizing agents (strong mineral acids).

Acetic acid, 1%, can be used in surgical dressings. At 5%, it is bactericidal to many bacteria and has been used to treat otitis externa produced by *Pseudomonas*, *Candida*, *Malassezia*, or *Aspergillus* spp. Skin and hides that have been contaminated by anthrax spores can be disinfected with 2.5% HCl.

Alkalies: Hydroxyl ion also exerts antimicrobial activity. At a pH >9, it inhibits most bacteria and many viruses. Hydroxides of sodium and calcium are used as disinfectants. Their irritant or caustic property usually precludes their application on tissues.

A 2% solution of soda lye (contains 94% sodium hydroxide [NaOH]) in hot water is used as a disinfectant against many common pathogens, such as those causing fowl cholera and pullorum disease. It is a potent caustic and must be handled with care.

Calcium oxide (CaO), ie, lime (hydrated or air-slaked lime), soaked in water produces Ca(OH)₂. Aqueous suspensions of slaked lime are used to disinfect premises.

ALCOHOLS

Primary aliphatic alcohols are germicidal. Their potency increases but water solubility decreases with chain length until amyl alcohol (6 carbons) is reached. Antimicrobial effect is related to their lipid solubility (damages bacterial membranes) and their ability to coagulate cytoplasmic proteins. However, they do not destroy bacterial spores. Ethyl alcohol (ethanol) and isopropyl alcohol (isopropanol) are the most widely used alcohols. They can be used in concentrations of 30%–90% in aqueous solutions; best results are usually obtained with 70% ethanol or 50% isopropanol. Higher concentrations tend to be less effective. Isopropanol is slightly more potent than ethanol because of its greater depression of surface tension. "Rubbing alcohol" is a mixture of alcohols, with isopropanol as its principal ingredient. It is used as a skin disinfectant and rubefacting. Alcohol-based hand rinses have rapid-acting antiseptic effects. This makes them useful in minimizing the transmission of transient flora acquired from infected patients and reducing nosocomial diseases.

BIGUANIDES

Chlorhexidine is the most popular antiseptic of this group. It has potent antimicrobial activity against most gram-positive and some gram-negative bacteria but not against spores. A 0.1% aqueous solution is bactericidal against *Staphylococcus aureus*, *Escherichia coli*, and *Pseudomonas aeruginosa* in 15 sec. However, it is relatively ineffective against other gram-negative organisms, spores, fungi, and most viruses. Nosocomial infections by *Pseudomonas* spp have developed from the use of contaminated chlorhexidine solutions in which the bacteria persisted. In susceptible organisms, chlorhexidine disrupts the cytoplasmic membrane. Its activity is unaffected or enhanced by alcohols, quaternary ammonium compounds, and alkaline

pH, and is somewhat depressed by high concentrations of organic matter (pus, blood, etc), hard water, and contact with cork. It is incompatible with anionic compounds, including soap.

Chlorhexidine is one of the most commonly used surgical and dental antiseptics. A 4% emulsion of chlorhexidine gluconate is used as a skin cleanser, a 0.5% (w/v) solution in 70% isopropanol as a general antiseptic, and a 0.5% solution in 70% isopropanol with emollients as a hand rinse. Chlorhexidine soaps have good residual activity, which may be advantageous when applied as a presurgical scrub for prolonged surgical procedures. Chlorhexidine-alcohol mixtures are particularly effective in that they combine the antiseptic rapidity of alcohol with the persistence of chlorhexidine. Because of its antiseptic properties and low potential for systemic or dermal toxicity, chlorhexidine has been incorporated into shampoos, ointments, skin and wound cleansers, teat dips, and surgical scrubs. A 1% chlorhexidine acetate ointment is used as a topical antiseptic in treatment of external wounds in dogs, cats, and horses. Contact dermatitis has been reported in up to 8% of human patients after repeated topical exposure. Little data are available on hypersensitivity reactions in animals.

OXIDIZING AGENTS

Peroxides: These compounds generally exert a short-acting germicidal effect on most organisms through release of nascent oxygen, which irreversibly alters microbial proteins. Most have little or no action on bacterial spores. Nascent oxygen is rendered inactive when it combines with organic matter.

Hydrogen peroxide solution (3%) liberates oxygen when in contact with catalase present on wound surfaces and mucous membranes. One mL of 3% hydrogen peroxide liberates 10 mL of oxygen at standard temperature and pressure. The effervescent action mechanically helps remove pus and cellular debris from wounds and is useful to clean and deodorize infected tissue. The antimicrobial action is of short duration and is limited to the superficial layer of the applied surface because there is no penetration of the tissue. However, the use of hydrogen peroxide in partially closed spaces, such as operative wounds, may result in oxygen embolization due to dissection of gas under pressure into tissues. Although its

usefulness as an antiseptic is limited, hydrogen peroxide is finding increased application as a disinfectant in water treatment and food processing facilities and for sterilization of dental and surgical instruments.

Accelerated hydrogen peroxide formulations are synergistic blends of 0.5%–2% hydrogen peroxide with anionic and nonionic surfactants and stabilizers that possess broad-spectrum antimicrobial activity. They are effective against bacteria, spores, mycobacteria, viruses, and fungi, with short contact times. Accelerated hydrogen peroxide formulations are nonirritating to eyes and skin and are biodegradable, decomposing to water and oxygen with no active chemical residues. They have become leading disinfectants in human hospitals and dental clinics. A disadvantage is the potential to damage soft metals, such as brass, copper, and aluminum, and carbon-tipped instruments.

Peracetic acid and the combination of peracetic acid (0.23%) and hydrogen peroxide (7.35%) have been recognized as useful sterilants and antiseptics, combining the broad antimicrobial spectrum and lack of harmful decomposition products of hydrogen peroxide with greater lipid solubility and freedom from inactivation by tissue catalase and peroxidase. They can be used over wide temperature (0°–40°C) and pH (3–7.5) ranges and are not affected by organic matter. They are effective against bacteria, yeasts, fungi, and viruses at concentrations of 0.001%–0.003% and are sporicidal at 0.25%–0.5%. Consequently, peracetic acid products have been accepted worldwide in the food industry, including meat and poultry processing plants and dairies, and are replacing traditional disinfectants for some medical devices. Solutions of 0.2% peracetic acid applied to compresses effectively reduce microbial populations in severely contaminated wounds.

Sodium perborate, used in antiseptic solutions and in mouthwashes, acts by decomposing into sodium metaborate and hydrogen peroxide, which then gradually liberates oxygen.

Benzoyl peroxide slowly releases oxygen to act as an antiseptic. However, it can cause skin irritation. It also has keratolytic and antiseborrheic activity, which makes it useful in treating pyoderma in dogs.

Potassium peroxymonosulfate is a broad-spectrum disinfectant with increasing use in barns and kennels. A 1% solution in water is highly effective against bacteria,

viruses, and fungi, maintaining good activity in the presence of organic matter.

Potassium permanganate has broad antimicrobial properties, but its intense purple color in solution, which stains tissues and clothing brown, is a disadvantage. It is an effective algicide (0.01%) and virucide (1%) for disinfection, but concentrations $>1:10,000$ tend to irritate tissues. Old solutions turn chocolate brown and lose their activity.

Halogens and Halogen-containing Compounds:

Iodine and chlorine are among the oldest topical antimicrobial agents. They owe their activity to high affinity for protoplasm, where they are believed to oxidize proteins and interfere with vital metabolic reactions.

Iodine: Elemental iodine is a potent germicide with a wide spectrum of activity and low toxicity to tissues. A solution containing 50 ppm iodine kills bacteria in 1 min and spores in 15 min. It is poorly soluble in water but readily dissolves in ethanol, which enhances its antibacterial activity.

Iodine tincture contains 2% iodine and 2.4% sodium iodide (NaI) dissolved in 50% ethanol; it is used as a skin disinfectant. Strong iodine tincture contains 7% iodine and 5% potassium iodide (KI) dissolved in 95% ethanol; it is more potent but also more irritating than tincture of iodine. Iodine solution contains 2% iodine and 2.4% NaI dissolved in aqueous solution; it is used as a nonirritant antiseptic on wounds and abrasions. Strong iodine solution (Lugol's solution) contains 5% iodine and 10% KI in aqueous solution.

Iodophores (eg, povidone-iodine and poloxamer-iodine) are combinations of iodine with a solubilizing agent or carrier; they are more stable and water soluble than older formulations. They slowly release iodine as an antimicrobial agent and are widely used as skin disinfectants, particularly before surgery. They do not sting or stain. Iodophores are nontoxic to tissues (although contact dermatitis can result from repeated exposure) but may be corrosive to metals. They are effective against bacteria, viruses, and fungi but less so against spores. Iodophor solutions retain good antibacterial activity at pH <4 , even in the presence of organic matter, and often change color when the activity is lost. Phosphoric acid is often mixed with iodophores to maintain an acidic medium. They have been used in teat dips to control mastitis, as dairy sanitizers, and as a general antiseptic or disinfectant for various dermal and mucosal infections.

Chlorine: Chlorine exerts a potent germicidal effect against most bacteria, viruses, protozoa, and fungi through formation of undissociated hypochlorous acid (HOCl) in water at acid to neutral pH. It is effective against most organisms at a concentration of 0.1 ppm, but much higher concentrations are required in the presence of organic matter. Alkaline pH ionizes chlorine and decreases its activity by reducing its penetrability. Chlorine has a strong acid smell. It is irritating to the skin and mucous membranes, including the respiratory tract, and can cause severe bronchospasms and acute lung injury. It is widely used to disinfect water supplies and inanimate objects (eg, utensils, bottles, pipelines) in dairies, creameries, and milk houses. Chlorine dioxide has recently replaced chlorine as a disinfectant for drinking water in some jurisdictions, because it forms fewer by-products.

Inorganic chlorides include sodium hypochlorite solutions (bleach). A 2%-5% NaOCl solution is a commonly used and effective disinfectant. Calcium hypochlorite is used as a disinfectant.

Organic chlorides contain chlorine weakly bonded to nitrogen, which is slowly released for germicidal activity. They are generally less irritant, more stable, and more convenient to use than hypochlorite solutions.

METALS

Inorganic mercuric bichloride, one of the early antiseptics, was later replaced by the less irritant and less toxic organic mercurials, eg, merbromin, thimerosal (49% mercury), nitromersol, and phenylmercuric nitrate. At moderate concentrations, the organic mercurials are bacteriostatic and act by inhibiting bacterial enzymes through their affinity for sulfhydryl groups. This effect can be reversed by sulfur-containing compounds, eg, cysteine or glutathione. Mercurials are not effective against spores. Use of mercurial antiseptics or disinfectants has decreased, partly because of their environmental persistence and contaminant potential. Repeated application of topical mercurials can result in significant absorption and systemic toxicity.

Silver compounds can have caustic, astringent, and antibacterial effects. Silver ions combine with sulfhydryl, amino, phosphate, and carboxyl groups, and thus precipitate proteins, in addition to interfering with essential metabolic activities of microbial cells.

A 0.1% aqueous silver solution is bactericidal and somewhat irritating, whereas a 0.01% solution is bacteriostatic. A 0.5% solution is sometimes applied as a dressing on burns to reduce infection and induce rapid eschar formation. Colloidal silver compounds, which release silver ions slowly, are bacteriostatic and have a more sustained effect. They do not irritate the tissues and have little astringent or caustic effect. They are generally used as mild antiseptics and in ophthalmic preparations.

PHENOLS AND RELATED COMPOUNDS

Phenolic compounds used as antiseptics or disinfectants include pure phenol and substitution products with halogens and alkyl groups. They act to denature and coagulate proteins and are general protoplasmic poisons.

Phenol (carbolic acid) is one of the oldest antiseptic agents. It is bacteriostatic at concentrations of 0.1%-1% and is bactericidal/fungicidal at 1%-2%. A 5% solution kills anthrax spores in 48 hr. The bactericidal activity is enhanced by EDTA and warm temperatures; it is decreased by alkaline medium (through ionization), lipids, soaps, and cold temperatures. Concentrations >0.5% exert a local anesthetic effect, whereas a 5% solution is strongly irritating and corrosive to tissues. Oral ingestion or extensive application to skin can cause systemic toxicity, manifested primarily by CNS and cardiovascular effects; death may result.

Phenol has good penetrating power into organic matter and is mainly used for disinfection of equipment or organic materials that are to be destroyed (eg, infected food and excreta). Because of its irritant and corrosive properties and potential systemic toxicity, it is not used much as an antiseptic currently, except to cauterize infected areas, eg, the infected umbilicus of neonates. It is also incorporated into cutaneous applications for pruritus, stings, bites, burns, etc, because of its local anesthetic and antibacterial properties to relieve itching and control infections.

Cresol (cresylic acid) is a mixture of ortho-, meta-, and paracresols and their isomers. It is a colorless liquid; however, after exposure to light and air, it turns pink, then yellowish, and finally dark brown. A 2% solution of either pure or saponated cresol "lysol" in hot water is commonly used as a disinfectant for inanimate objects.

Hexachlorophene (a trichlorinated *bis*-phenol) has a strong bacteriostatic action against many gram-positive organisms (including staphylococci) but only a few gram-negative ones. It is used widely in medicated soaps. Frequent washings every day with hexachlorophene soaps lead to sufficient retention of residue on the skin to provide prolonged bacteriostatic action. Washing with other soaps promptly removes these residues. Repeated exposure of skin to high concentrations of hexachlorophene may lead to sufficient absorption of the antiseptic to cause spongiform degeneration of the white matter in the brain, cerebral edema, and nervous disorders. To prevent such neurotoxicity, products containing >0.75% hexachlorophene are available only by prescription. Accidental oral ingestion of hexachlorophene results in acute poisoning.

Pine tar is a viscid blackish brown liquid, used primarily for antiseptic bandaging of wounds of the hoof and horn. Pine tar contains phenol derivatives that provide antimicrobial properties.

Chloroxylenols are broad-spectrum bactericides with more activity against gram-positive than gram-negative bacteria. They are active in alkaline pH; however, contact with organic matter diminishes their activity. Streptococci are more susceptible than staphylococci. **Parachlorometaxylenol (PCMX)** and **dichlorometaxylenol (DCMX)** are the two most commonly used members of this group. DCMX is more active than PCMX. Strong solutions of these compounds can cause irritation and have a disagreeable odor. A 5% chloroxylenol (eg, PCMX) solution (in α -terpineol, soap, alcohol, and water) is diluted with water (1:4) for skin sterilization and (1:25 to 1:50) for wound cleansing and irrigation of the uterus and vagina. PCMX is also combined with hexachlorophene to enhance its antibacterial spectrum and to prevent contamination by gram-negative organisms.

REDUCING AGENTS

Formaldehyde is a gas, whereas **glutaraldehyde** is an oil at room temperature. However, both are readily soluble in water. Their solutions are irritating or caustic to tissues, causing coagulation necrosis and protein precipitation, but have potent germicidal properties against all organisms, including spores. Their solutions do not lose appreciable antimicrobial properties in the presence of organic matter and are

noncorrosive to metals, paints, and fabric. Both are used as disinfectants. **Formalin** contains 37% formaldehyde gas in aqueous solution with variable amounts of methyl alcohol to prevent polymerization. A 1%–10% solution of formaldehyde is commonly used as a disinfectant. **Glutaral** (glutaraldehyde), a 1%–2% alkaline solution (pH 7.5–8.5) in 70% isopropanol, is a more potent germicide than 4% formaldehyde, effective against all microorganisms, including viruses and spores. It is often used to sterilize surgical and endoscopic instruments and plastic and rubber apparatus. It is a known sensitizer, causing occupational contact dermatitis, as well as bronchial and laryngeal mucous membrane irritation.

Orthophthaldehyde (OPA) is an aromatic aldehyde similar to glutaraldehyde but with several potential advantages. Typical 0.55% solutions have excellent stability over a wide pH range (3–9), are less toxic and irritating to eyes and nasal passages, and have a barely perceptible odor. They are compatible with most materials, including flexible endoscopes. OPA solutions are faster acting than glutaraldehyde against mycobacteria but have somewhat less sporicidal activity. A potential disadvantage of OPA is that it stains proteins (including unprotected skin) gray, so it must be handled with caution.

Sulfur dioxide, as a gaseous fumigant, is produced by burning sulfur in closed spaces. For maximal effect, the surface should be moist, because the gas dissolves in water to form sulfurous acid, which is bactericidal. However, this reducing effect of the acid can also corrode metals, rot fabrics, and bleach dyes.

SURFACE-ACTIVE COMPOUNDS

Surfactants lower the surface tension of an aqueous solution and are used as wetting agents, detergents, emulsifiers, antiseptics, and disinfectants. As antimicrobials, they alter the energy relationship at interfaces. Based on the position of the hydrophobic moiety in the molecule, surfactants are classified as anionic or cationic.

Anionic Surfactants: Soaps are dipolar anionic detergents with the general formula RCOONa/K , which dissociate in water into hydrophilic K^+ or Na^+ ions and lipophilic fatty acid ions. Because NaOH and KOH are strong bases (whereas most fatty acids are weak acids), most soap solutions are alkaline (pH 8–10) and may irritate sensitive

skin and mucous membranes. Soaps emulsify lipoidal secretions of the skin and remove, along with most of the accompanying dirt, desquamated epithelium and bacteria, which are then rinsed away with the lather. The antibacterial potency of soaps is often enhanced by inclusion of certain antiseptics, eg, hexachlorophene, phenols, carbanilides, or potassium iodide. They are incompatible with cationic surfactants.

Cationic Surfactants: Cationic detergents are a group of alkyl- or aryl-substituted quaternary ammonium compounds (eg, benzalkonium chloride, benzathonium chloride, cetylpyridinium chloride) with an ionizable halogen, such as bromide, iodide, or chloride. The major site of action of these compounds appears to be the cell membrane, where they become adsorbed and cause changes in permeability. The activity of older quaternary ammonium compounds is reduced by hard water and by porous or fibrous materials (eg, fabrics, cellulose sponges) that adsorb them. They are also inactivated by anionic substances (eg, soaps, proteins, fatty acids, phosphates). Therefore, they are of limited value in the presence of blood and tissue debris. However, newer dialkyl quaternary ammonium compounds (fourth generation, including dodecyl dimethyl ammonium bromide, dioctyl dimethyl ammonium bromide, etc) purportedly remain active in hard water and are tolerant of anionic residues. Fifth-generation quaternaries are mixtures of the fourth generation with the second generation and demonstrate greater biocidal activity under conditions of high soil load, making them useful disinfectants in barns and footbaths. Quaternary ammonium compounds are effective against most bacteria, enveloped viruses, some fungi (including yeasts), and protozoa but not against nonenveloped viruses, mycobacteria, and spores. Aqueous solutions of 1:1,000 to 1:5,000 have good antimicrobial activity, especially at slightly alkaline pH, and are commonly used for disinfection of noncritical instruments and hard surface cleaning. When applied to skin, they may form a film under which microorganisms can survive, which limits their reliability as antiseptics. Concentrations >1% are injurious to mucous membranes.

Octenidine dihydrochloride is a cationic surfactant used increasingly in Europe as an alternative to quaternaries, chlorhexidine, and iodophores for skin, mucous membrane, and wound antiseptics.

OTHER ANTIBACTERIAL AGENTS

The antibacterial activity of **dyes** was first reported in 1913. Interestingly, the discovery of sulfonamides as chemotherapeutic agents ensued from the antibacterial activity observed in the dye prontosil.

Azo dyes (eg, scarlet red and phenazopyridine HCl) are most active in an acidic medium and are effective against gram-negative organisms. Scarlet red is often used as a 5% ointment on sores, ulcers, and wounds. Pyridium is often incorporated as an analgesic with sulfonamides to treat urinary tract infections.

Acridine dyes (eg, acriflavine, proflavine, aminacrine) are more active against gram-positive bacteria. Their activity is enhanced in alkaline medium and antagonized by hypochlorites. Impregnated bandages and gauze and acriflavine jelly have been used extensively for treatment of burns.

VAPOR-PHASE DISINFECTANTS

Alkylating agents such as formaldehyde, ethylene oxide, and propylene oxide are broad-spectrum biocides active against bacteria, viruses, and fungi, including spores.

Ethylene and propylene oxides are highly reactive gaseous fumigants used to sterilize animal feed, human food, surgical equipment that cannot be autoclaved (eg, endoscopes, gloves, syringes, catheters, tubing, implantable devices), laboratory equipment, etc. Both are noncorrosive. However, ethylene oxide has better penetrability than propylene oxide and, therefore, is more commonly used. For this application, ethylene oxide is mixed with chlorofluorocarbons or carbon dioxide and sold in gas cylinders.

Other gaseous disinfectants (eg, formaldehyde, sulfur dioxide, methylbromide) have been used infrequently because of their toxic or corrosive properties.

ANTIVIRAL AGENTS

The conventional approach to control of viral diseases is to develop effective vaccines, but this is not always possible. The objective of antiviral activity is to eradicate the virus while minimally impacting the host and to prevent further viral invasion. However, because of their method of replication, viruses present a greater therapeutic challenge than do bacteria.

Viruses comprise a core genome of nucleic acid surrounded by a protein shell or capsid. Some viruses are further surrounded by a lipoprotein membrane or envelope. Viruses cannot replicate independently and, as such, are obligate intracellular parasites. The host's pathways of energy generation, protein synthesis, and DNA or RNA replication provide the means of viral replication. Viral replication occurs in five sequential steps: host cell penetration, disassembly, control of host protein and nucleic acid synthesis such that viral components are made, assembly of viral proteins, and release of the virus.

Drugs that target viral processes must penetrate host cells; further, because viruses often assume direction of cell division, drugs that negatively impact a virus are also likely to negatively impact

normal pathways of the host. For these reasons, particularly compared with antibacterial drugs, antiviral drugs are characterized by a narrow therapeutic margin. Nephrotoxicity is emerging as an adverse reaction to antiviral drugs in human medicine. Therapy is further complicated by viral latency, ie, the ability of the virus to incorporate its genome in the host genome, with clinical infection becoming evident without reexposure to the organism. In vitro susceptibility testing must depend on cell cultures, which are expensive. More importantly, in vitro inhibitory tests do not necessarily correlate with therapeutic efficacy of antiviral drugs. Part of the discrepancy between in vitro and in vivo testing occurs because some drugs require activation (metabolism) to be effective.

Only a few antiviral drugs are reasonably safe and effective against a limited number of viral diseases, and most of these have been developed in people. Few have been studied in animals, and widespread clinical use of antiviral drugs is not common in veterinary medicine. The advent of human immunodeficiency virus (HIV) and the development of the cat as a model of HIV infection has somewhat increased the animal knowledge base. Only a selection

of the more promising agents and their purported attributes are briefly discussed.

Most antiviral drugs interfere with viral nucleic acid synthesis or regulation. Such drugs generally are nucleic acid analogues that interfere with RNA and DNA production. Other mechanisms of action include interference with viral cell binding or interruption of virus uncoating. Some viruses contain unique metabolic pathways that serve as a target of drug therapy. Drugs that simply inhibit single steps in the viral replication cycle are virustatic and only temporarily halt viral replication. Thus, optimal activity of some drugs depends on an adequate host immune response. Some antiviral drugs may enhance the immune system of the host.

TABLE 59 lists the dosage rates for some commonly used antiviral drugs.

Pyrimidine Nucleosides: A variety of pyrimidine nucleosides (both halogenated and nonhalogenated) effectively inhibit the replication of herpes simplex viruses with limited host-cell toxicity. The exact mechanism of action of these compounds appears to reflect substitution of pyrimidine for thymidine, causing defective DNA molecules. Idoxuridine is effective for treatment of herpesvirus infection of the superficial layers of the cornea (herpesvirus keratitis) and of the skin but is toxic when administered systemically.

Trifluridine, also an analogue of deoxythymidine, is currently the agent of choice for treatment of herpesvirus keratitis in people. The other antiviral pyrimidine nucleosides have not been used clinically to any notable extent.

Purine Nucleosides: Certain purine nucleosides have proved to be effective antivirals and are used as systemic agents.

VIDARABINE

Vidarabine, or araA, is used topically for ocular herpesvirus and systemically for herpetic encephalitis and neonatal herpesviral infections. This drug is an adenosine derivative that is phosphorylated by cellular enzymes to a triphosphate compound that inhibits many viral and human DNA polymerases and thus DNA synthesis. Herpesviral enzymes are ~20-fold more susceptible to the drug than host DNA. Vidarabine is administered IV in large volumes of fluid and is rapidly inactivated. It may produce bone marrow suppression and CNS adverse effects when high blood levels are reached. An ophthalmic solution also is available.

ACYCLOVIR

Acyclovir (acycloguanosine) and its L-valyl ester prodrug valacyclovir, represent a new generation of antiviral agents, mainly because of the unique mechanism of action. This purine nucleoside is phosphorylated more efficiently by virus-induced thymidine kinase than host thymidine kinase. Once activated to the triphosphate form, it is a better substrate and inhibitor of viral, versus host, DNA polymerase. Binding to DNA polymerase is irreversible. Once acyclovir is incorporated into viral DNA, the DNA chain is terminated.

Acyclovir is relatively safe (probenecid renders the drug safer) and is useful against a variety of infections caused by DNA viruses, especially the herpesvirus family. However, resistance is increasing. Acyclovir is unable to eliminate latent infections. It is available as an ophthalmic ointment, a topical ointment and cream, an IV preparation, and various oral formulations. The prodrug deoxyacyclovir is more readily absorbed from the GI tract than acyclovir. Another similar antiviral purine nucleoside analogue is ganciclovir, a synthetic guanine effective against human cytomegalovirus. Its mechanism of action is similar to that of acyclovir.

PENCICLOVIR AND FAMCICLOVIR

Famciclovir is the prodrug form of penciclovir. Penciclovir is very similar to acyclovir in terms of mechanism of action and spectrum. Although it is much less potent than acyclovir, penciclovir accumulates to much higher concentrations inside the cell. Penciclovir has been studied in cats receiving famciclovir at 62.5 mg for 3 days; it appeared to be well tolerated.

RIBAVIRIN

Ribavirin is a synthetic triazole nucleoside (an analogue of guanosine) with a broad spectrum of activity against many RNA and DNA viruses, both in vitro and in vivo. Susceptible viruses include adenoviruses, herpesviruses, orthomyxoviruses, paramyxoviruses, poxviruses, picornaviruses, rhabdoviruses, rotaviruses, and retroviruses. Viral resistance to ribavirin is rare. The action of ribavirin involves specific inhibition of viral-associated enzymes, inhibition of the capping of viral mRNA, and inhibition of viral polypeptide synthesis. It is well absorbed, widely distributed in the body, eliminated by renal and biliary routes as both parent drug and

TABLE 59 DOSAGES OF ANTIVIRAL DRUGS

Drug	Preparation	Dose, Route, and Frequency	Indication
Idoxuridine	0.1% ophthalmic solution	1 drop, topical, every 5–6 hr	
	0.5% ophthalmic solution	1 drop, topical, every 1–2 hr	
Trifluridine	1% ophthalmic solution	1 drop, topical, every 2 hr initially (2 days), then 3–8 times daily	Ocular herpesvirus infection
Vidarabine	3% ophthalmic solution	0.4–1 cm ointment, topical, every 5–6 hr; 3–6 times daily	Ocular herpesvirus infection
	200 mg/mL suspension for injection	10–30 mg/kg/day, IV, as CRI for 12–24 hr	
Acyclovir	200-mg capsules or tablets	200 mg, PO, qid, every 4 hr, or 5 times daily	Feline herpesvirus
	5% cutaneous ointment	Cover lesion, topical, every 3 hr, 6 times daily	
	200 mg/5 mL suspension	80 mg/kg/day (mixed with peanut butter), PO, for 7–14 days	Pacheco's disease in birds
	500 mg/vial powder	250–500 mg/m ² , IV, tid, infused over at least 1 hr	
Ganciclovir	500 mg/vial powder	2–5 mg/kg, IV, bid-tid	
Ribavirin		11 mg/kg/day, IV, for 7 days	Susceptible viral infections
	6 g/100 mL vial powder	Using SPAC-2 nebulizer only, inhalation, 8–18 hr period daily	
Zidovudine	10 mg/mL syrup; 10 mg/mL injection	5–20 mg/kg (cats), PO or SC, bid-tid	FIV, FeLV
Amantadine	100- and 500-mg capsules	100 mg total (human), PO, once to twice daily	
	Syrup 10 mg/mL	100 mg/day total (juveniles), PO	
Rimantadine		200–300 mg/day total (human), PO	
Interferon α -2	3 $\times$ 10 ⁶ IU/vial	3 $\times$ 10 ⁶ IU/person/day, SC, IM; 0.5–5 U/kg/day, PO; 100,000 U/kg/day, SC	FeLV-associated disease
		1 U/day, PO	FeLV appetite stimulant
		15–30 U, PO, IM, SC, once daily on alternate weeks	FIP, FIV

CRI = constant-rate infusion; FeLV = feline leukemia virus; FIP = feline infectious peritonitis; FIV = feline immunodeficiency virus

metabolites, and has a plasma half-life of 24 hr in people. It does not have a wide margin of safety in domestic animals. Toxicity is manifest by anorexia, weight loss, bone marrow depression and anemia, and GI disturbances. It has been successfully administered by topical, parenteral, oral, and aerosol routes. Efficacy depends on the site of infection, method of treatment, age of the animal, and infecting dose of virus. Results of human influenza studies with ribavirin have been equivocal.

ZIDOVUDINE

Zidovudine (azidothymidine, AZT) is a thymidine analogue. Within the virus-infected cell, the 3'-azido group is used by retroviral reverse transcriptase and incorporated into DNA transcription, preventing viral replication. The shared mechanism of action is inhibition of RNA-dependent DNA polymerase (reverse transcriptase). This enzyme is responsible for conversion of the viral RNA genome into double-stranded DNA before it is integrated into the cell genome. Because these actions occur early in replication, the drugs tend to be effective for acute infections but are relatively ineffective for chronically infected cells. Cellular α -DNA polymerases are inhibited only at concentrations 100-fold greater than those necessary to inhibit reverse transcriptase, thus rendering this drug relatively safe to host cells. Cellular γ -DNA polymerase, however, is inhibited at lower concentrations.

AZT is effective against a variety of retroviruses at low concentrations. Resistance to AZT is associated with point mutations resulting in amino acid substitutions in the reverse transcriptase. Prolonged use of AZT can facilitate viral resistance. The risk of resistance also appears to correlate with CD4 cell count and the state of infection. Viral susceptibility to AZT may return after the drug has been discontinued for a period of time.

Granulocytopenia and anemia are the major adverse effects of AZT in human patients. The risk of toxicity increases in human patients with low (CD4) lymphocyte counts, high doses, and prolonged therapy. Granulocyte colony-stimulating factor is indicated for management of granulocytopenia. CNS adverse effects are more likely as therapy is begun. The risk of myelosuppression is increased by drugs that inhibit glucuronidation or renal excretion and may be increased in cats.

After a single dose of AZT at 25 mg/kg in cats, bioavailability is ~75%–100%. The

elimination half-life is ~1.5 hr, and volume of distribution is 0.82 L/kg. Drug concentrations remain above the effective concentration 50 (EC_{50}) of 0.19 mcg/mL for feline immunodeficiency virus for at least 24 hr after either IV or PO administration. Although this concentration is higher than that associated with myeloid suppression of human cells, adverse effects in cats are limited to transient restlessness, mild anxiety, and hemolysis.

Studies in cats regarding the efficacy of AZT (10–20 mg/kg, bid for 42 days) for feline leukemia virus infection indicated that AZT prevents retroviral infection if administered immediately after viral exposure and may reduce replication if administered to previously infected animals. Serum-neutralizing antibodies developed in some of the infected cats, and the cats became resistant to subsequent viral challenge. There was no altered progression of disease in cats when treatment was withheld until 28 days after infection, although the level of viremia was much lower than in untreated cats. AZT appeared to be nontoxic in uninfected cats, although 3 of 12 infected kittens became anorectic and icteric and were vomiting after 40 days of treatment. AZT may cause Heinz body anemia. CBCs should be performed on cats receiving AZT.

AMANTADINE

Amantadine, and its derivative rimantadine, are synthetic antiviral agents that appear to act on an early step of viral replication after attachment of virus to cell receptors. The effect seems to lead to inhibition or delay of the uncoating process that precedes primary transcription. Amantadine may also interfere with the early stages of viral mRNA transcription. Amantadine at usual concentrations inhibits replication of different strains of influenza A virus, influenza C virus, Sendai virus, and pseudorabies virus. It is almost completely absorbed from the GI tract, and ~90% of a dose administered PO is excreted unchanged in the urine over several days (human data). The main clinical use has been to prevent infection with various strains of influenza A viruses. However, in people, it also has been found to produce some therapeutic benefit if taken within 48 hr after the onset of illness. Amantadine and its derivatives may be given by the PO, intranasal, SC, IP, or aerosol routes. It produces few adverse effects, most of which are related to the CNS; stimulation of the CNS is evident at very high doses.

MISCELLANEOUS ANTIVIRAL AGENTS

Several drug classes continue to be investigated mainly because of their *in vitro* antiviral activities. Their potential clinical usefulness remains obscure in most instances. Included among these agents are thiosemicarbazones, guanidine, benzimidazoles, arildone, phosphonoacetic acid, rifamycins and other antibiotics, and several natural products.

Oseltamivir is a prodrug that, when hydrolyzed, yields the carboxylated

metabolite that inhibits viral neuraminidases of human influenza viruses. Mature influenza viruses bud off from the cell in a sphere of host phospholipid membrane. The virus will adhere to the cell until neuraminidase has been cleaved from the sialic acid residues of the host cell membrane. Neuraminidases allow separation and subsequent release of viral progeny. Hydrolysis, or activation, occurs in the GI tract and liver. The use of oseltamivir for treatment of viral diseases in dogs (parvovirus and parainfluenza) is thus far anecdotal.

ECTOPARASITICIDES

ECTOPARASITICIDES USED IN LARGE ANIMALS

Arthropod parasites (ectoparasites) are major causes of livestock production losses throughout the world. In addition, many arthropod species can act as vectors of disease agents for both animals and people. Treatment with various parasitocides to reduce or eliminate ectoparasites is often required to maintain health and to prevent economic loss in food animals. Some ectoparasitocides were derived from pesticides used to protect crops. The choice and use of ectoparasitocides depend to a large extent on husbandry and management practices, as well as on the type of ectoparasite causing the infestation. Endectocides are capable of killing both internal and external parasites. Accurate identification of the parasite or correct diagnosis based on clinical signs is necessary for selection of the appropriate parasiticide. The selected agent can be administered or applied directly to the animal, or introduced into the environment to reduce the arthropod population to a level that is no longer of economic or health consequence.

Parasites that live permanently on the skin, such as lice, keds, and mites, can be controlled by directly treating the host. Some mange mites burrow into the skin and are therefore more difficult to control with sprays than are lice and keds, which are found on the surface of the skin. However, once these obligate parasites are eradicated, reinfection occurs only from contact with other infected animals.

Ectoparasites with stages that live off the host (ticks, flies, etc) are less easily controlled. Only a small proportion of the ectoparasite population can be treated on the host at any one time, and other hosts may maintain them. Some tick species stay on the host only long enough to feed, which may be as short as 30 min or as long as 21 days. Biting flies, such as the horn fly, can be found continually on the backs and undersides of cattle, where they suck blood up to 20 times a day; other biting flies (such as stable flies and horse flies) and mosquitoes feed to repletion, then leave the animal to lay eggs. Nonbiting flies, such as the face fly or house fly, may visit infrequently but can be very annoying and may transmit disease agents. Larvae of certain blowflies live on the skin or in tissues of sheep and other animals and cause cutaneous myiasis. Larvae of other flies spend several months inside animals (eg, nasal bots in the nasal passages of sheep and goats, bots in the stomach of horses, and cattle grubs or warbles in the back or esophageal tissues). (*See also* FLIES, p 885.)

Many ectoparasite infestations are seasonal and predictable and can be countered by prophylactic use of ectoparasitocides. For example, in temperate countries, flies are seen predominantly from late spring to early autumn, tick populations often increase in the spring and autumn, and lice and mite infestations can be more common during the autumn and winter months. Treatments can be targeted at anticipated times of peak activity as a way to limit parasite populations and disease.

Products are available for parenteral administration or for topical application by various methods, including dips, sprays, pour-ons, spot-ons, dusting powders, and ear tags. The method used depends on the target parasite and host. (*See ROUTES OF ADMINISTRATION AND DOSAGE FORMS*, p 2508.) Importantly, most topical ectoparasiticides used in the USA are pesticides regulated by the U.S. Environmental Protection Agency (EPA). This is an important distinction from products regulated by the U.S. Food and Drug Administration (FDA), because it is illegal to use an EPA-regulated pesticide product inconsistent with its label directions (www.epa.gov). The regulating agency should be identifiable on the product label. The National Pesticide Information Retrieval System (NPIRS) is a searchable database of EPA-registered products (<http://ppis.ceris.purdue.edu/>).

Chemotherapeutic Agents

Most ectoparasiticides are neurotoxins, exerting their effect on the nervous system of the target parasite. Those used in large animals can be grouped according to structure and mode of action into the organochlorines, organophosphates and carbamates, pyrethrins and pyrethroids, macrocyclic lactones (ivermectins and milbemycins), formamidines, insect growth regulators, and a number of miscellaneous compounds, including synergists (eg, piperonyl butoxide). There are also a number of useful compounds with repellent rather than insecticidal activity, including butoxypolypropylene-glycol and N,N-diethyl-3-methylbenzamide (DEET, previously called N,N-diethyl-metatoluamide).

Organochlorines: Organochlorine compounds have been withdrawn in many parts of the world because of concerns regarding environmental persistence.

Organochlorines fall into three main groups: 1) chlorinated ethane derivatives, such as DDT (dichlorodiphenyltrichloroethane), DDE (dichlorodiphenyldichloroethane), and DDD (dicofol, methoxychlor); 2) cyclodienes, including chlordane, aldrin, dieldrin, heptachlor, endrin, and toxaphene; and 3) hexachlorocyclohexanes such as benzene hexachloride (BHC), which includes the γ -isomer, lindane.

Chlorinated ethanes cause inhibition of sodium conductance along sensory and motor nerve fibers by holding sodium channels open, resulting in delayed repolarization of the axonal membrane.

This state renders the nerve vulnerable to repetitive discharge from small stimuli that would normally cause an action potential in a fully repolarized neuron.

The cyclodienes appear to have at least two component modes of action: inhibition of γ -aminobutyric acid (GABA)-stimulated Cl^- flux and interference with Ca^{2+} flux. The resultant inhibitory postsynaptic potential leads to a state of partial depolarization of the postsynaptic membrane and vulnerability to repeated discharge. A similar mode of action has been reported for lindane, which binds to the picrotoxin site of GABA receptors, resulting in an inhibition of GABA-dependent Cl^- ion flux into the neuron.

DDT and BHC were used extensively for flystrike control but subsequently replaced in many countries by more effective cyclodiene compounds, such as dieldrin and aldrin. Both the development of resistance and environmental concerns led to their withdrawal. DDT and lindane were widely used in dip formulations to control sheep scab, but they have mostly been replaced by the organophosphates and subsequently the synthetic pyrethroids.

Organophosphates and Carbamates:

The organophosphates comprise a large group of chemicals, many of which are available for topical application and in ear tags as well as for premise control of parasites. There have been many products available worldwide for use in domestic animals, although only a few of the available compounds continue to be used for on-animal treatment.

Organophosphates are neutral esters of phosphoric acid or its thio analogue that inhibit the action of acetylcholinesterase (AChE) at cholinergic synapses and at muscle endplates. The compound mimics the structure of acetylcholine (ACh); when it binds to AChE, it causes transphosphorylation of the enzyme. The phosphorylated AChE is unable to break down accumulated ACh at the postsynaptic membrane, leading to neuromuscular paralysis. The degree of transphosphorylation of the enzyme helps to determine the activity of the organophosphate. Eventually, the AChE is metabolized by oxidative and hydrolytic enzyme systems.

Organophosphates can be extremely toxic in animals and people, inhibiting AChE and other cholinesterases (*see* p 3064). Chronic toxicity results from inhibition of an enzyme known as neuropathy target esterase (NTE) or neurotoxic esterase and is associated with particular

compounds. NTE hydrolyzes the fatty acids from the membrane lipid, phosphatidylcholine, and inhibition of NTE appears to cause structural changes in neuronal membranes and a reduction in conduction velocity, which may be manifest as posterior paralysis in some animals. Cases of organophosphate toxicity are treated with oximes or atropine.

Organophosphates used topically include coumaphos, diazinon, dichlorvos, malathion, tetrachlorvinphos, trichlorfon, phosmet, and pirimiphos. Ear tags containing chlorpyrifos, coumaphos, diazinon, or pirimiphos are available. These compounds are generally active against fly larvae, flies, lice, ticks, and mites on domestic livestock, although activity varies between compounds and differing formulations. Chlorpyrifos can be used in microencapsulated form for residual activity and improved safety. Diazinon and propetamphos have been available in dip formulations to control psoroptic mange in sheep. Both eliminate mites and protect in a single application when correctly applied. Diazinon provides longer residual protection than propetamphos. In cattle, a number of compounds have been used for systemic control of warble fly grubs and lice as pour-on applications or in hand sprays, spray races, or dips for tick control.

Carbamate insecticides are closely related to organophosphates and are anticholinesterases. Unlike organophosphates, they appear to cause a spontaneously reversible block on AChE without changing it. The main carbamate compound used in veterinary medicine is propoxur. Carbaryl, another carbamate previously used in veterinary medicine, has been withdrawn from the veterinary market.

Pyrethrins and Synthetic Pyrethroids:

A number of pyrethroids are available in many countries as pour-on, spot-on, spray, and dip formulations with activity against biting and nuisance flies, lice, and ticks on domestic livestock. Flumethrin and high cis-cypermethrin are also active against mites and have been used to treat psoroptic mange of sheep.

Natural pyrethrins are derived from pyrethrum, a mixture of alkaloids from the *Chrysanthemum* plant. Pyrethrum extract, prepared from the pyrethrum flower head, contains several molecules collectively known as pyrethrins (pyrethrin I and II, cinerin I and II, and jasmolin I and II). Pyrethrins are lipophilic molecules that generally undergo rapid absorption, distribution, and excretion. They provide

excellent knockdown (rapid kill) but have poor residual activity because of instability. Pyrethrin I is the most active ingredient for kill, and pyrethrin II for rapid insect knockdown.

Pyrethroids are synthesized chemicals modeled on the natural pyrethrin molecule. They are more stable, thus have longer residual activity, and have a higher potency than natural pyrethrins.

The mode of action of pyrethrins and synthetic pyrethroids appears to be interference with sodium channels of the parasite nerve axons, resulting in delayed repolarization and eventual paralysis. Synthetic pyrethroids can be divided into two groups (types I and II, depending on the presence or absence of an α -cyano moiety). Type I compounds have a mode of action similar to that of DDT, involving interference with the axonal Na^+ gate leading to delayed repolarization and repetitive discharge of the nerve. Type II compounds also act on the Na^+ gate but do so without causing repetitive discharge. The lethal activity of pyrethroids seems to involve action on both peripheral and central neurons, while peripheral neuronal effects alone probably produce the knockdown effect. Some preparations contain a synergist (eg, piperonyl butoxide), which inhibits breakdown of pesticides by microsomal mixed-function oxidase (cytochrome P450) systems in insects.

Pyrethroids are generally safe in mammals and birds but are highly toxic to fish and aquatic invertebrates. Concerns have been expressed over their environmental effects, particularly in relation to the aquatic environment, leading to their withdrawal as sheep dips in some countries.

Some of the more common pyrethroids used include β -cyfluthrin, bioallethrin, cyfluthrin, cypermethrin, deltamethrin, fenvalerate, flumethrin, lambda cyhalothrin, phenothrin, permethrin, prallethrin, and tetramethrin. The content of some synthetic pyrethroids is also expressed in terms of the drug isomers, eg, cypermethrin preparations may contain varying proportions of their cis and trans isomers. Thus, cypermethrin (cis:trans 60:40) 2.5% is equivalent to cypermethrin (cis:trans 80:20) 1.25%. In general, cis isomers are more active than the corresponding trans isomers.

Macrocyclic Lactones (Avermectins and Milbemycins): Avermectins and the structurally related milbemycins, collectively referred to as macrocyclic lactones, are fermentation products of *Streptomyces avermitilis* and *S. cyanogriseus*, respec-

tively. Avermectins differ from each other chemically in side chain substitutions on the lactone ring, whereas milbemycins differ from the avermectins through the absence of a sugar moiety from the lactone skeleton.

A number of macrocyclic lactone compounds are available for use in animals and include the avermectins abamectin, doramectin, eprinomectin, ivermectin, and selamectin, and the milbemycins moxidectin and milbemycin oxime. These compounds are active against a wide range of nematodes and arthropods and are often referred to as endectocides.

Endectocidal activity, particularly against ectoparasites, is variable and depends on the active molecule, the product formulation, and the method of application. Macrocyclic lactones can be given PO, parenterally, or topically (as pour-ons and spot-ons). The method of application depends on the host and, to some degree, on the target parasites. In cattle, for example, available endectocide products can be given PO, by injection, or topically using pour-on formulations. The latter are generally more effective against lice (*Linognathus*, *Haematopinus*, and to some extent *Bovicola*) and headfly (*Haematobia/lyperosia*) infestations than equivalent compounds administered parenterally. In sheep, PO administration of some endectocides has little effect against psoroptic mite infestations (*Psoroptes ovis*), but parenteral administration increases activity, providing both protection and control depending on the product used.

The route of administration and product formulation influence the rates of absorption, metabolism, excretion, and subsequent bioavailability and pharmacokinetics of individual compounds. Avermectins and milbemycins are highly lipophilic, a property that varies with only minor modifications in molecular structure or configuration. After administration, these compounds are stored in fat, from which they are slowly released, metabolized, and excreted. Ivermectin is absorbed systemically after PO, SC, or dermal administration; it is absorbed to a greater degree and has a longer half-life when given SC or dermally. Excretion of the unaltered molecule is mainly via the feces, with <2% excreted in urine of ruminants. In cattle, the reduced absorption and bioavailability of ivermectin given PO may be due to its metabolism in the rumen. The affinity of these compounds for fat explains their persistence in the body and the extended periods of protection afforded against some species of internal and external parasites. The prolonged

half-life of these compounds also determines residue levels in meat and milk and the subsequent compulsory withdrawal periods after treatment in food-producing animals.

Macrocyclic lactones bind to glutamate receptors of glutamate-gated chloride channels, triggering Cl⁻ ion influx and hyperpolarization of parasite neurons, leading to flaccid paralysis. These molecules have low affinity for mammalian ligand-gated chloride channels and do not readily cross the blood-brain barrier.

Formamidines: Amitraz is the only formamidine used as an ectoparasiticide. It appears to act by inhibition of the enzyme monoamine oxidase and as an agonist at octopamine receptors. Monoamine oxidase metabolizes amine neurotransmitters in ticks and mites, and octopamine is thought to modify tonic contractions in parasite muscles. Amitraz has a relatively wide safety margin in mammals; the most frequently associated adverse effect is sedation, which may be associated with an agonist activity of amitraz on α_2 -receptors in mammalian species.

Amitraz is available as a spray or dip for use against mites, lice, and ticks in domestic livestock. It controls lice and mange in pigs and psoroptic mange in sheep. In cattle, it has been used in dips, sprays, or pour-ons for control of single-host and multihost tick species. In dipping baths, amitraz can be stabilized by the addition of calcium hydroxide and maintained by standard replenishment methods for routine tick control. An alternative method involves the use of total replenishment formulations in which the dip bath is replenished with full concentration of amitraz at weekly intervals before use. Amitraz is contraindicated in horses.

Chloronicotinyls and Spinosyns:

Imidacloprid is a chloronicotinyl insecticide, a synthesized chlorinated derivative of nicotine. Spinosad is a fermentation product of the soil actinomycete *Saccharopolyspora spinosa*. Both compounds bind to nicotinic acetylcholine receptors (but at different sites) in the insect's CNS, leading to inhibition of cholinergic transmission, paralysis, and death. Spinosad has been developed in some countries for use on sheep to control blowfly strike and lice.

Insect Growth Regulators: Insect growth regulators (IGRs) are used throughout the world and represent a relatively new category of insect control

agents. They constitute a group of chemical compounds that do not directly kill the adult parasite but interfere with growth and development. Because they act mainly on immature parasite stages, IGRs are not usually suitable for rapid control of established adult parasite populations. Where parasites show a clear seasonal pattern, IGRs can be applied before any anticipated challenge as a preventive measure. They are widely used for blowfly control in sheep but have limited use in other livestock.

Based on their mode of action, IGRs can be divided into chitin synthesis inhibitors (benzoylphenyl ureas), chitin inhibitors (triazine/pyrimidine derivatives), and juvenile hormone analogues (S-methoprene, pyriproxyfen). Several benzoylphenyl ureas have been introduced to control ectoparasites. Chitin is a complex aminopolysaccharide and a major component of the insect's cuticle. During each molt, it has to be newly formed by polymerization of individual sugar molecules. The exact mode of action of the benzoylphenyl ureas is not fully understood. They inhibit chitin synthesis but have no effect on the enzyme chitin synthetase. It has been suggested that they interfere with the assembly of the chitin chains into microfibrils. When immature insect stages are exposed to these compounds, they are not able to complete ecdysis and die during molting. Benzoylphenyl ureas also appear to have a transovarial effect. Exposed adult female insects produce eggs in which the compound is incorporated into the egg nutrient. Egg development proceeds normally, but the newly developed larvae are incapable of hatching. Benzoylphenyl ureas show a broad spectrum of activity against insects but have relatively low efficacy against ticks and mites. The exception is fluzazuron, which has greater activity against ticks and some mite species.

Benzoylphenyl ureas are highly lipophilic molecules. When administered to the host they build up in body fat, from which they are slowly released into the bloodstream and excreted largely unchanged. Diflubenzuron and flufenoxuron are used to prevent blowfly strike in sheep. Diflubenzuron is available in some countries as an emulsifiable concentrate for use as a dip or shower. It is more efficient against first-stage larvae than second and third instars and is therefore recommended as a preventive, providing protection for 12–14 wk. It may also have potential to control a number of major insect pests such as tsetse flies. Fluzazuron is available in some countries for

use in cattle as a tick development inhibitor. When applied as a pour-on, it provides longterm protection against the 1-host tick, *Rhipicephalus (Boophilus) microplus*.

Triazine and pyrimidine derivatives are closely related compounds that are also chitin inhibitors. They differ from the benzoylphenyl ureas both in chemical structure and mode of action, i.e. they appear to alter the deposition of chitin into the cuticle rather than its synthesis.

Cyromazine, a triazine derivative, is effective against blowfly larvae on sheep and lambs and also against other *Diptera* such as houseflies and mosquitoes. At recommended dose rates, cyromazine shows only limited activity against established strikes and must therefore be used preventively. Blowflies usually lay eggs on damp fleece of treated sheep. Although larvae are able to hatch, the young larvae immediately come into contact with cyromazine, which prevents the molt to second instars. The efficacy of a pour-on preparation of cyromazine does not depend on factors such as weather, fleece length, and whether the fleece is wet or dry. Control can be maintained for up to 13 wk after a single pour-on application, or longer if cyromazine is applied by dip or shower.

Dicyclanil, a pyrimidine derivative, is highly active against dipteran larvae. A pour-on formulation, available in some countries for blowfly control in sheep, provides up to 20 wk of protection.

The juvenile hormone analogues mimic the activity of naturally occurring juvenile hormones and prevent metamorphosis to the adult stage. Once the larva is fully developed, enzymes within the insect's circulatory system destroy endogenous juvenile hormones, prompting development to the adult stage. The juvenile hormone analogues bind to juvenile hormone receptor sites, but because they are structurally different, are not destroyed by insect esterases. Metamorphosis and further development to the adult stage does not proceed. S-Methoprene is a terpenoid compound with very low mammalian toxicity that mimics a juvenile insect hormone and is used as a feed-through larvicide for hornfly (*Haematobia*) control on cattle.

Miscellaneous Compounds: Piperonyl butoxide and MGK 264 (N-octyl bicycloheptene dicarboxinide) are used as synergistic additives in the control of arthropod pests. They are commonly formulated together with insecticides such as natural pyrethrins. The degree of potentiation of insecticidal

activity is related to the ratio of components in the mixture; as the proportion of piperonyl butoxide or MGK 264 increases, the amount of natural pyrethrins required to evoke the same level of kill decreases. The insecticidal activity of other pyrethroids, particularly of knockdown agents, can also be enhanced by the addition of piperonyl butoxide or MGK 264. Piperonyl butoxide inhibits the microsomal enzyme system of some arthropods and is effective against some mites. In addition to having low mammalian toxicity and a long record of safety, it rapidly degrades in the environment.

Various products from natural sources, as well as synthetic compounds, have been used as insect repellents. Such compounds include cinerins, pyrethrins and jasmolins (see p 2750), citronella oil, di-N-propyl isocinchomeronate, butoxypolypropylene glycol, picaridin, DEET, and DMP (dimethylphthalate). The use of repellents is advantageous as legislative and regulatory authorities become more restrictive toward the use of conventional pesticides. They are used mainly to protect horses against blood-sucking arthropods, particularly midges (*Cuticoides*).

Insecticides may be used to provide environmental control of some insects by application to premises. The insect pheromone (Z)-9-tricosene is incorporated into some products to attract insects to the site of application.

Other Control Methods

Biologic Control: The use of naturally occurring biologic pathogens, such as nematodes, bacteria, fungi, and viruses, offer an interesting approach to ectoparasite management. *Bacillus thuringiensis* has been used on sheep to prevent blowfly strike and body lice. The use of fungal pathogens such as *Metarhizium anisopliae* has also been investigated for control of ticks on livestock and mites on cattle and sheep.

Off-host Control: The control of populations of arthropod pest species using nonreturn traps and targets (screens), usually accompanied by semiochemical baits, has been considered widely for parasites such as ticks or flies. The aim is to attract and kill targeted pests in appropriate numbers during the stages in which they are off the host. This approach has been used as a component of the eradication of the primary screwworm fly, *Cochliomyia hominivorax*, from North America and

for control of the horn fly, *Haematobia irritans*. Given the large numbers of adult females that must be attracted and killed to achieve effective population management, this is often not possible with the visual and olfactory baits available. One notable exception is in the control of the tsetse fly (*Glossina* spp.), for which high levels of control can be achieved due to their very low rate of reproduction and the availability of highly effective baits and traps. In Australia, a nonreturn insecticide-free trap to catch *Lucilia cuprina* is commercially available. The ability of this trap and bait system to suppress fly populations and to reduce strike incidence has been investigated in the southern hemisphere with variable results, although reductions in strike incidence of up to 46% have been reported.

Safety Restrictions

It is important to be aware of and follow safety restrictions to prevent poisoning or injury to treated animals. All organophosphates available for use on animals are cholinesterase inhibitors. They should not be used simultaneously or within a few days before or after treatment or exposure to other cholinesterase-inhibiting drugs, pesticides, or chemicals. They should not be applied to young, sick, convalescent, or stressed animals.

Pyrethroid insecticides available for use on large animals are considered safe but have general precautionary statements on their labels, particularly in relation to disposal and their potential ecotoxicologic effects.

Some parasiticides may be used only by or under the supervision of a veterinarian; others are available via agricultural suppliers and pharmacists directly to the public. Approvals vary from country to country. Labels for pesticides contain explicit information on hazards to animals, people, and the environment; storage of unused insecticide; and disposal of the container. For each insecticide, the label is the primary source of information on uses and safety instructions, which should be carefully followed.

Restrictions are applied to many of the ectoparasiticides indicated for use in food-producing animals to ensure that unacceptable residues are not present in products intended for human consumption. These restrictions may require that animals are not slaughtered for prescribed periods after administration of the product or that the product is not used in animals produc-

ing milk for human consumption. Labels and data sheets on all products contain specific instructions on restrictions, including withdrawal periods, and must be followed.

ECTOPARASITICIDES USED IN SMALL ANIMALS

Flea and tick infestation is a major health problem in dogs and cats, and control presents an economic burden to owners. Traditionally, a wide array of ectoparasiticide has been available, and switching among brands was frequent, leading to problems in achieving acceptable external parasite control. Veterinarians are uniquely qualified to explain the host/parasite interrelationships and advise owners on selection of the most suitable control program. However, many pet owners still purchase flea and tick products in supermarkets or pet supply shops where professional advice is not available. Recent advances in product technology have greatly expanded the available options for veterinarians and pet owners. However, this wide array of available parasiticide can lead to confusion. Veterinarians should become familiar with these technologic improvements in both insecticidal chemistry and delivery systems and encourage client education by their staff.

Active Chemical Ingredients

Nomenclature can be confusing if the shorter approved name is not used and the full chemical name is written (eg, chlorpyrifos versus 0,0-diethyl 0-[3,5,6 trichloro 2] phosphorothioate). The use of trade names can cause added confusion. Although most commercial products contain only one active ingredient, it is not uncommon for two or more to be combined to provide enhanced efficacy or broader spectrum of activity. All labels should be read carefully for ingredients, age and species restrictions, and directions for use.

Macrocytic Lactones: Currently, three macrocytic lactones are used for control of internal and external parasites in dogs and cats: selamectin and afoxolaner, which are semisynthetic avermectins, and moxidectin, a semisynthetic milbemycin. Although the exact mode of action of macrocytic lactones is not fully elucidated, it is believed that they bind to glutamate-gated chloride channels in the parasites' nervous system, increasing their permeability and allowing for the rapid and continued

influx of Cl^- into the nerve cell. This inhibits nerve activity and causes paralysis of the parasite. Selamectin is presented as a single active ingredient; moxidectin is combined with imidacloprid (*see* NEONICOTINOIDS, below); and afoxolaner has been combined with fipronil (*see* PHENYLPIRAZOLONES, p 2756), S-methoprene (*see* INSECT GROWTH REGULATORS, p 2756), and praziquantel. These macrocytic lactones are applied topically, rapidly absorbed through the skin, and distributed via the blood. They have activity against a variety of internal and external parasites.

Cholinesterase Inhibitors: Two groups of compounds, organophosphates and carbamates, share the same mechanism of action—inhibition of acetylcholinesterase. This enzyme normally is responsible for acetylcholine (neurotransmitter) destruction. Applications of organophosphates or carbamates to insects produce spontaneous muscular contractions followed by paralysis. The binding of organophosphates to acetylcholinesterase is more persistent, if not permanent, whereas the interaction with carbamates is reversible. These compounds were once very popular for their prolonged action and potency. However, the use of organophosphates has declined because their low margin of safety and slight variance from approved use or continued use may lead to toxicity. When these compounds are used for flea or tick control, it should be determined before treatment whether any other cholinesterase inhibitor has been used on the animal or in its environment. Organophosphates for small animal therapy include chlorpyrifos, dichlorvos, malathion, diazinon, phosmet, fenthion, chlorfenvinphos, and cythioate. Carbamates include carbaryl and propoxur.

Chlorinated Hydrocarbons: These compounds are becoming less popular because of their persistence in the environment, although this factor brought the benefit of prolonged action. Lindane and methoxychlor are still occasionally used. (*See also* CHLORINATED HYDROCARBON COMPOUNDS, p 3060.)

Neonicotinoids: The neonicotinoids are a class of insecticides referred to as nitroquinidines, neonicotinyls, chloronicotines, and recently as chloronicotinyls. The neonicotinoids are modeled after natural nicotine. Three compounds in this category are currently available for veterinary use: dinotefuran, imidacloprid, and nitenpyram.

All neonicotinoids act as agonists on the postsynaptic acetylcholine receptors in insects. This inhibits cholinergic transmission, resulting in paralysis and death. Imidacloprid is applied as a spot-on topical product and is used primarily to control fleas on both dogs and cats. It also has excellent activity against lice. Although it has potent residual activity, it is readily soluble in water, so swimming and repeated bathing may compromise its duration of activity. Nitenpyram is administered PO in pill form to kill fleas in both dogs and cats. It is absorbed rapidly, with maximal blood concentrations reached within 1.2 hr in dogs and 0.6 hr in cats. Fleas begin to die within 20–30 min of administration, with 100% flea mortality within 3–4 hr. The compound is rapidly eliminated, with >90% excreted in the urine within 24–48 hr, primarily as unchanged nitenpyram. Even though imidacloprid and nitenpyram are classified similarly, their mechanisms of action appear to be different. Although imidacloprid is described as a paralytic, nitenpyram produces hyperexcitability in fleas before death.

The newest addition to the neonicotinoids is dinotefuran, considered a third-generation neonicotinoid. The structure of dinotefuran is unique in that it was derived from that of the acetylcholine molecule rather than nicotine. It has been proposed that dinotefuran does not bind to the same sites as imidacloprid and other neonicotinoids but at a different site in the nerve synapse. Dinotefuran is applied as a topical spot-on with different formulations for dogs and cats. The cat formulation is combined with the insect growth regulator pyriproxyfen and is used primarily to control fleas. The dog formulation contains pyriproxyfen and permethrin and is labeled for control of fleas, ticks, and mosquitoes.

Formamidines: This small group of acaricidal compounds has the proposed mode of action of binding to octopamine receptors, a specific group of receptors found in Acari. In veterinary medicine, the only approved formamidine is amitraz. It is used primarily as an acaricide to control ticks and mites. It is available as a dip for control of canine demodicosis, and it will also control scabies. An amitraz-impregnated collar is also marketed for control of ticks on dogs. Amitraz is not approved for use on cats.

Oxadiazines: Oxadiazine insecticides can control a broad spectrum of insects and

were originally developed for use against a variety of insects infesting vegetables, fruit, and row crops. Indoxacarb is the only member of this group currently being used in veterinary medicine. It is considered a pro-insecticide that is metabolized within the insect to a more active form, which is an N-decarbomethoxylated metabolite that is at least 40 times more potent than parent indoxacarb. This metabolic conversion of indoxacarb, known as bioactivation, is attributed to actions of esterase and amidase enzymes within the insect. The active metabolite exerts its effect by blocking the voltage-gated sodium ion channels in insects. Indoxacarb is administered topically in a spot-on formulation for control of fleas on dogs and cats. Indoxacarb has also been combined with permethrin for control of ticks on dogs.

Isoxazolines: Isoxazolines are a new class of compounds that have both potent insecticidal and acaricidal activities. Isoxazolines have a novel mode of action and specifically block arthropod ligand-gated chloride channels. Afoxolaner and fluralaner are currently the only two compounds approved for use in veterinary medicine. Both are unique in that they were the first oral flea and tick products. The compounds are readily absorbed after oral administration and provide 4–12 wk of insecticide and acaricide activity.

Insect Growth Regulators: These compounds inhibit the development of immature stages of insects. They are generally classified as either juvenile hormone mimics (insect growth regulators) or as chitin synthesis inhibitors (insect development inhibitors). Methoprene, fenoxycarb, and pyriproxyfen are similar in structure to insect juvenile hormone and are classified as juvenile hormone mimics. When these compounds are applied to flea larvae or into their environment, they are absorbed by the larvae and act like natural insect juvenile hormone. Juvenile hormone analogues bind to juvenile hormone receptor sites; larvae are prevented from completing metamorphosis and subsequently die. These compounds also have ovicidal and embryocidal activity against flea eggs when applied topically to dogs and cats. Female fleas in the hair coat absorb the juvenile hormone analogue, which affects viability of developing eggs. These compounds are active against a wide range of insects, including mosquito larvae; methoprene is

used as a larvicide in the strategic control of mosquito-borne diseases. For flea control, their outdoor use should be limited to specific flea habitats to avoid adverse effects on beneficial insect species.

Lufenuron, a benzoylphenyl urea, inhibits the formation of chitin (a polymer of *N*-acetyl glucosamine), which is a major component of insect exoskeletons. During each larval molt, chitin is reformed by polymerization. Lufenuron interferes with polymerization and deposition of chitin, killing developing larvae either within the egg or after hatching. Lufenuron is administered PO to dogs or cats or by injection to cats. Female fleas feeding on treated animals are prevented from producing viable eggs or larvae. Other insect development inhibitors, such as diflubenzuron (another chitin inhibitor) and cyromazine (a moulting disruptor), also have considerable activity against developing fleas. Insect growth regulators and insect development inhibitors affect many insect species that undergo complete metamorphosis, but they have little or no activity against ticks or other Acari, which undergo incomplete metamorphosis.

Phenylpyrazoles: This group of compounds has broad-spectrum activity that is both insecticidal and acaricidal. The members of this group currently available for use in veterinary medicine worldwide include fipronil and pyriprole. These compounds bind to γ -aminobutyric acid and glutamate-gated receptor sites of insect nervous systems, inhibiting the flux of Cl^- into nerve cells, which results in hyperexcitability. These compounds have broad-spectrum activity against fleas, ticks, mites, and lice. Numerous fipronil-containing formulations are available worldwide, including an alcohol-based fipronil-only spray, several spot-on formulations that contain only fipronil, a spot-on combination with the insect growth regulator methoprene, and numerous combination formulations that contain fipronil and various pyrethroids. Fipronil is very lipophilic; it accumulates in the sebaceous glands, has very low solubility in water, and has prolonged residual activity on both dogs and cats.

Pyrethrins and Pyrethroids: These compounds rapidly disrupt sodium and potassium ion transport in nerve membranes, resulting in spontaneous depolarizations, augmented neurotransmitter secretion, and neuromuscular blockade,

causing paralysis. Although the activity is rapid, without sufficient exposure paralyzed insects can also recover rapidly. The synergists piperonyl butoxide and *N*-octyl bicycloheptene dicarboximide interfere with the insect detoxification mechanism and can potentiate the activity of pyrethroids. Natural pyrethrum is extracted from chrysanthemum flowers and is notable for its rapid but brief action and relative lack of toxicity in dogs and cats.

Synthetic pyrethroids are pyrethrum-like compounds that generally have greater potency and residual effects but are less well tolerated in cats. Some pyrethroids, such as permethrin, can be highly toxic to cats. Pyrethroids are generally classified by developmental generation. First-generation pyrethroids are generally unstable in heat and sunlight (eg, allethrin); second-generation are more photostable, isomeric mixtures (eg, cypermethrin, permethrin); third-generation are photostable and more neurologically active isomers obtained by isomeric enrichment (eg, λ -cyhalothrin, β -cyfluthrin); and fourth-generation are nonester pyrethroids (eg, MTI 800, flufenprox, etofenprox).

Spinosyns: Spinosyns are a novel family of insecticides derived from the fermentation of the actinomycete, *Saccharopolyspora spinosa*. The two most abundant products derived from the fermentation process are spinosyns A and D, which are the major active components of spinosad. Spinosad is used to control a wide variety of insects, including flies and fleas. Spinosyns have a novel mode of action, primarily targeting binding sites on nicotinic acetylcholine receptors distinct from other insecticides such as neonicotinoids. Spinosyns also affect γ -aminobutyric acid receptor function, which may contribute further to their insecticidal activity. These actions cause excitation of the insect nervous system, leading to involuntary muscle contractions, prostration with tremors, and finally paralysis. Spinosad has activity against fleas and is formulated as a chewable tablet for dogs and cats. A topical spot-on spinosyn formulation called spinetoram has been developed for cats.

Repellents: *N,N*-diethyl-3-methylbenzamide (DEET, previously called *N,N*-diethyl-met-atolamide) remains the most effective among currently available insect repellents for people. It is a broad-spectrum repellent effective against mosquitoes, biting flies, chiggers, fleas, and ticks.

However, the effectiveness of DEET formulations for dogs and cats has not been proved, and safety is a concern because concentrated formulations containing DEET have caused weakness, paralysis, liver disease, and seizures in pets. DEET should not be administered to dogs or cats.

The synthetic pyrethroid permethrin is a rapidly acting neurotoxicant that can produce what is termed a "hot-foot" effect and is often described as a repellency. Various permethrin formulations are labeled as repellents for ticks, mosquitoes, and fleas.

Synergists: Synergists are generally not considered toxic or insecticidal but are used with insecticides to enhance their activity. They are used primarily to potentiate the activity of pyrethrum or pyrethroids. Synergists inhibit cytochrome P450-dependent monooxygenases or glutathione S-transferases, enzymes produced by microsomes in insect tissues. They bind the oxidative enzymes that would normally break down the insecticide and prevent them from degrading the toxicant. Piperonyl butoxide and N-octyl bicycloheptene dicarboxamide are common synergists.

Target Parasite Efficacy

Because of specific formulation and drug delivery technology, certain insecticides are used in a wide variety of ectoparasite control products. Efficacy of specific compounds can vary against target species, and resistance to insecticides may develop in specific locations, especially with incorrect, prolonged, or repeated use. It cannot be assumed that ticks and fleas are controlled by the same active compounds; product labels should be carefully read. Products that contain compounds specifically active against the target parasite should be chosen, whether the concern is fleas, ticks, mites, or a combination of these parasites.

Duration of activity (ie, "knockdown" or sustained effects) can be the primary concern in product choices. Products should be evaluated based on both their immediate and residual speed of kill. A rapid residual speed of kill is critically important when attempting to manage flea allergy dermatitis and to reduce the chances of a tick transmitting a pathogen.

Modern parasiticides available for flea and tick control in companion animals provide superior parasite control, but an understanding of the life cycle of the

parasites, along with the mode of action of the particular molecules, is also important. Often, perceived product failures are a result of massive reinfestation from the environment, incorrect product use, or unrealistic expectations.

Safety

Although LD₅₀ data concerning the safety or toxicity of an insecticidal product is often helpful, LD₅₀ values are not always the best indicator of the safety of specific insecticide formulations applied to pets or premises. Consideration must be given to the concentration of product (mg/mL), application rate (mg or g/m² for environmental products, and mcg or mg/kg for topicals), route of exposure (dermal or oral), total dose, and the species exposed. The actual risk of exposure during treatment, after treatment, or after accidental ingestion can be assessed only after evaluation of these criteria.

Because animal toxicity can be modified by formulation technology, active ingredients are not the sole guide to safety assessment of a product. Most commercially available products have undergone adequate safety evaluation for regulatory approval; the label noting such approval remains the best source of information. Cats are sensitive to many insecticides, and use of these insecticides on or near cats must be done with caution. Human and environmental safety also should be considered, especially when treating premises (eg, some compounds may break down into more toxic components; older products on the shelf might have been withdrawn because of safety concerns). Generalizations should not be made, because formulations generally safe for grass application may induce skin reactions, or even fatal reactions, in sensitive individuals and certain breeds of dogs and cats.

Delivery Systems

Consumer convenience is an important factor in product choice, especially for flea and tick control. An array of delivery systems has historically been available: powders, aerosols, sprays, shampoos, rinses, dips, spot-ons, mousses, injectables, oral tablets or liquids, and impregnated collars. However, the safety, efficacy, and ease of use of the newer spot-on and oral application systems have rendered many of the older application technologies essentially obsolete.

GROWTH PROMOTANTS AND PRODUCTION ENHANCERS

Achieving increased efficiency of conversion of feed into human food products of high quality, without posing any significant risk to the consumer, is an important goal of livestock producers worldwide. The physiologic mechanisms involved in converting feed into muscle, fat, and bone by animals are increasingly being elucidated. Recently, consumer concerns about additives for food production have focused on animal safety, organoleptic quality, and the potential human health hazards of the food we eat.

A number of approaches may be taken to improve conversion of animal feed into meat; two of the more practical approaches are hormonal treatments and antimicrobial feed additives. The hormonal approach includes administration of anabolic steroid hormones, use of growth hormone (GH) or insulin-like growth factor (IGF-1) to augment endogenous GH levels, and use of β -adrenergic agonists (β AAs) to preferentially increase nutrient partitioning to muscle (see TABLE 60). The antimicrobial feed additives approach includes feeding of antibiotics to decrease populations of pathogenic bacteria in host GI tracts, use of compounds to manipulate ruminal fermentation by changing the ruminal microflora population in healthy animals, and use of probiotics to promote beneficial microflora in the GI tract.

The use of hormonal treatments and antimicrobial feed additives in production animals is currently under debate in many areas and is banned in some because of concerns surrounding their possible effects on people.

The EU has banned beef produced using growth-promotant implants since 1981. Despite subsequent findings by the European Economic Community's own panel of scientific experts, referred to as the "Lamming Committee," by the World Trade Organization, and by the international Codex Alimentarius Commission indicating that appropriate use of approved growth-promoting hormones poses no human health risk to consumers, the EU has continued its ban.

More recently, use of β AAs for growth promotion in swine and beef production has come under scrutiny in the international meat trade community. Some countries, including the EU, Russia, and China, have

placed a total ban on beef and pork from nations that allow the use of β AAs, whereas other countries have adopted the maximum residue limits (MRLs) for the compounds as established by the Codex Alimentarius Commission. The FDA applies a greater MRL in the USA than the Codex standard.

The use of antimicrobial compounds specifically for growth-promotion purposes, as opposed to their use for control or treatment of bacterial infection, has also come under increased attention internationally because of rising concerns over antimicrobial resistance by pathogenic bacteria of concern in human medicine. Direct cause-effect evidence of antimicrobial use in livestock leading to bacterial resistance in human medicine is virtually nonexistent, requiring more complicated epidemiologic study. However, numerous studies have linked use of specific drugs in livestock, either for disease therapy or for growth-promotion purposes, to increased prevalence of drug resistance in target bacterial species. Results of these investigations are equivocal and have been the focal point of intense scrutiny and debate. In the absence of resoundingly clear cause-and-effect data, and because preservation of the continued efficacy of existing antimicrobial compounds is paramount, the cautionary principle has prevailed and will likely lead to greater restrictions on the use of antimicrobials for growth promotion in livestock and for therapeutic purposes as well.

STEROID HORMONES

In general, the principle that dictates which type of hormone to be used is the need to supplement or replace the particular hormone type that is deficient in the animals to be treated. Females produce estrogens normally, so better results are obtained from the administration of androgens, eg, trenbolone acetate (TBA). Estrogens should not be used in animals to be retained for breeding purposes.

Manufacturers' instructions must be followed to ensure proper implant placement and dose administration. Anabolic hormones should not be administered by IM injection for growth-promoting purposes. Additionally, steroid

hormones must not be used for anabolic or other purposes unless the indication is specifically approved by the appropriate regulatory body. The EU has banned the use of hormonal growth promoters in meat production. Appropriate surveillance programs have been established to ensure compliance by producers.

Endogenous Steroids

The steroidal compounds used for anabolic purposes in food animals are estradiol, progesterone, and testosterone. Gender and maturity of an animal influence its growth rate and body composition. Bulls grow

8%–12% faster than steers, have better feed efficiencies, and produce leaner carcasses. Superior performance of bulls is due to the steroids produced in the testes (mainly testosterone but also estradiol, which in ruminants is also anabolic and is produced in relatively large quantities). Testosterone, or one of its physiologically active metabolites, binds to receptors in muscle and stimulates increased incorporation of amino acids into protein, thereby increasing muscle mass without a concomitant increase in adipose tissue. Estradiol, on the other hand, may act by stimulation of the somatotrophic axis to increase growth hormone and thus IGF 1 production and

TABLE 60

NATURAL STEROID HORMONES FOR CONSIDERATION AS GROWTH PROMOTERS

Hormone		Dosage	Duration of Effect (days)	Growth Response	Potential Adverse Effects
Estradiol	1 - Pellet	20 mg EB ^b + 200 mg P4 ^c (steers)	100–120	10%–15%	Transient increase in sexual behavior
	2 - Pellet	20 mg EB + 200 mg testosterone propionate (heifers, cull cows)	100–120	5%–15%	Udder development
	3 - Pellet	10 mg EB + 100 mg P4 (veal calves)	100–120	0–8%	
	4 - Silastic rubber	45 mg estradiol (steers)	365	10%–15%	Transient increase in sexual behavior
	5 - Silastic rubber	24 mg estradiol (steers)	200	10%–15%	Transient increase in sexual behavior
	6 - Polylactic acid	28 mg estradiol (steers)	365	10%–15%	Transient increase in sexual behavior
Progesterone	See 1 and 3 above				
Testosterone	See 2 above				

^a Implants must be placed SC between the ear cartilage and skin to comply with label instructions so that consumption of residues may be avoided.

^b Estradiol benzoate

^c Progesterone

availability by modulation of the IGF binding proteins. Naturally produced endogenous steroids are not orally active, require picogram concentrations of estradiol and nanogram concentrations of testosterone in blood for physiologic effects, and can transiently affect the behavior of treated animals (see TABLE 60).

Estradiol: A potent anabolic agent in ruminants at blood concentrations of 5–100 pg/mL, estradiol is administered as an ear implant, either as compressed tablets or silastic rubber implants. When estradiol is formulated as compressed tablets, a second steroid (usually testosterone, TBA, or progesterone) is typically present when administered to feedlot cattle fed a high-energy diet, in a ratio of ~1 part estradiol to either 5 or 10 parts of the other, androgenic, steroid. The release of hormones from compressed pellets is biphasic, with a relatively rapid rate lasting 2–7 days after insertion (50–100 times greater than baseline), followed by a slower rate of release for the next 30–100 days (5–10 times greater than baseline). Hormone concentrations gradually decline up to day 80–100, when concentrations are no different from those in control animals.

Estradiol formulated in silastic rubber enhances the effective life span of the implant relative to pelleted formulations. The pattern of release includes a short-lived spike in plasma estrogen concentration for 2–5 days after insertion, followed by a stable but modest increase (5–10 times greater than baseline). Toward the end of the effective life span of the implant, there is a gradual decline to estradiol concentrations found in control animals.

Estradiol, on its own, increases nitrogen retention, growth rate by 10%–20% in steers, lean meat content by 1%–3%, and feed efficiency by 5%–8%. It can be used in steers to best advantage, but it also has anabolic effects in heifers and veal calves. It works best in lambs in conjunction with androgens. It is not effective as an anabolic agent in pigs.

Testosterone: A potent anabolic agent at the relatively high concentrations of 1–5 ng/mL in peripheral circulation, testosterone is not used on its own as an anabolic agent in farm animals, because it is very difficult to achieve the effective physiologic concentrations for long periods (up to 100 days) with current delivery systems. It is generally used as a propionate formulation in conjunction with 20 mg estradiol benzoate (EB) in a compressed tablet implant; its major role in

the compressed pellet may be to slow down the release rate of estradiol. In high concentrations in blood, testosterone induces male sexual behavior (eg, aggression and mounting), but this is not seen with the concentrations delivered by compressed pellets in the ear (1 ng/mL). Behavior resulting from use of 20 mg EB and 200 mg progesterone is not different from that seen after the use of 20 mg EB and 200 mg testosterone propionate.

Progesterone: Unambiguous data suggesting progesterone is anabolic in farm animals does not exist. Its major use is to slow the release of estradiol from compressed pellet implants.

Synthetic Steroids

Synthetic steroids are commercially available in some countries because of their efficacy, their relatively mild androgenicity, and because they cause few behavioral anomalies (see TABLE 61). Commercial synthetic steroids are androgenic (TBA) or progestogenic (mestrolacetate [MGA]).

Synthetic steroidal androgens are not commonly used as anabolic agents except for TBA. TBA is currently the only synthetic androgen approved for use for growth promotion in cattle; it is used to a lesser extent in sheep and not in pigs or horses. It has weak androgenic activity but has greater anabolic activity than testosterone. When administered repeatedly during the feedlot phase when cattle are fed a high-energy diet, TBA can alter the physical appearance and behavior of steers, causing them to look and act like bulls. TBA has significant anabolic effects on its own in female cattle and sheep, but in castrated males it gives maximal response when used in conjunction with estrogens. It is administered as a pellet-type implant containing 140 200 mg TBA for heifers and cull cows, and it can be used with estradiol in doses ranging from 140 200 mg TBA as either combined or separate implants.

MGA is an orally active synthetic progestagen. It is fed at dosages of 0.25–0.5 mg/day per heifer in the feed. It suppresses recurrent estrus in feedlot heifers and increases growth rate and feed efficiency (see TABLE 61). It is not effective in pregnant or spayed heifers or in steers. Its mode of action is to suppress ovulation, presumably by suppressing luteinizing hormone (LH) pulse frequency; however, large follicles develop, which can increase concentrations of estradiol and growth hormone, and hence growth. MGA is permitted for use in the

TABLE 61

SYNTHETIC STEROID HORMONES FOR CONSIDERATION AS GROWTH PROMOTERS

Hormone ^a	Dosage	Duration of Effect (days)	Growth Response	Potential Adverse Effects
TBA	200 mg (heifers, cull cows)	60–90	5%–12%	
TBA + EB	200 mg TBA + 28 mg EB (steers, heifers)	90–120	10%–20%	Transient increase in sexual behavior
	100 mg TBA + 14 mg EB (steers)	90–120	10%–20%	Transient increase in sexual behavior
TBA + E	200 mg TBA + 20 mg E (steers, heifers)	90–120		
	120 mg TBA + 24 mg E (steers)	90–120		
	140 mg TBA + 14 mg E (heifers)	90–120		
	80 mg TBA + 16 mg E (steers)	90–120		
	80 mg TBA + 8 mg E (heifers)	90–120		
	40 mg TBA + 8 mg E (steers and heifers grazing pasture)	90–120		
TBA + E	200 mg TBA + 40 mg E (steers)	200		
Zeranol	36 mg zeranol	90–120	10%–15%	
	12 mg zeranol	90–120	10%–15%	
MGA	0.25–0.5 mg/day, PO	As long as it is given	3%–10%	Increased mammary development after long-term administration

^a TBA = trenbolone acetate; EB = estradiol benzoate; E = estradiol 17 β ; MGA = melengestrol acetate

Note: All administered as pellet implants except MGA, which is administered in feed.

USA but not in the EU. When used in the absence of a growth-promoting implant, MGA increases growth rate through the increased estradiol released by the follicles; however, when used in conjunction with either estradiol or combination estradiol/TBA implants in the feedlot, the growth-promoting benefits of MGA are primarily derived from suppression of the excess, unproductive, and potentially harmful activities associated with recurrent estrus.

Synthetic Nonsteroidal Estrogens

Two major classes of synthetic nonsteroidal estrogens have been used as production enhancers in food animals. **Stilbene estrogens** (either diethylstilbestrol [DES] or hexestrol) have been banned in most countries as anabolic agents because of residue and food safety concerns.

The discovery of a naturally occurring estrogen, zearalenone (produced by the fungi *Fusarium* spp.), led to the develop-

ment of the synthetic analogue zeranol.

Zeranol is estrogenic and has a weak affinity for the uterine estradiol receptor. It is used in animal production as a SC ear implant at a dose of 36 mg for cattle and 12 mg for sheep, with a duration of activity of 90–120 days. In steers, zeranol increases nitrogen retention, growth rate by 12%–15%, and feed conversion by 6%–10%. However, lower responses are seen in heifers. Its effects are additive to those of androgens (generally TBA).

Use in Cattle

Calves have a high conversion of feed into animal tissue compared with young growing swine or poultry. Therefore, their responses to anabolic agents are variable. Responses of 0–10% have been obtained when zeranol was given to 3-mo-old castrated male calves. Bull calves in an intensive bull beef system can be given an estrogen implant at 1–2 mo of age to suppress testicular development, which may lead to subsequent reduction in mounting and aggression. A growth response of ~5%–8% is also obtained from this implant. Reimplantation every 80–100 days is necessary if compressed pellet implants are used.

A major limitation to the use of anabolic agents in lightweight weaned calves is the low liveweight gain they may achieve because of poor nutritional status. Hence, anabolic agents should be considered only if the weanlings are expected to gain >0.25 kg/day. Zeranol, estradiol, and TBA can be used in male castrates. Dairy heifer replacements cannot be given steroid implants as weanlings.

Greater and more consistent responses are obtained in yearling and older cattle than in calves or weanlings, due primarily to greater intake and to the higher plane of nutrition. In the case of pellet-type implants with effectiveness of 90–120 days, consideration can be given to reimplanting cattle midway through the grazing season, provided gains >0.5 kg/day are maintained. Silastic implants of estradiol are effective for 200–400 days, depending on dose used. Daily gains in feedlot cattle fed a high-energy diet may be increased 20%–30% after implantation with an estrogen and an androgen; daily gain in pasture cattle is typically improved by 10%–15%.

Responses to growth promotion are good when animals are on a high plane of nutrition. Feed conversion efficiency is improved, and lean meat content of the carcass is generally increased. Although less clear, conformation of implanted cattle tends to improve. Negative impacts of implants on marbling content of the loin muscle can be minimized by finishing cattle to a fat-constant endpoint.

In steers and heifers in the feedlot and provided a high-energy diet, use of an androgen plus an estrogen hormone combination is common. Pellet-type implants are effective for as long as 150 days; reimplanting cattle after 70–100 days should be considered because of decreasing response from the pellet-type implants over time.

Results from large-pen studies (>25 animals/pen) show that heifers benefit from a combination of estradiol, TBA, and MGA. In small-pen research, however, when fed in combination with growth-promoting implants, MGA use results in reduced gain, feed efficiency, and ribeye area, as well as increased fatness. These contrary findings suggest that although progesterone may have an “anti-growth promoting” effect, the growth-promotion benefit realized from suppression of estrus overcomes the minor negative physiologic impact of progesterone in conventional large feedlot pens.

In some studies in which bulls were treated with estrogens, growth rate increased by 2%–10%, and testicular growth was suppressed with a subsequent reduction in mounting and aggression. This should make the bulls easier to manage on the farm and less subject to “dark cutting” after slaughter. The mechanism involved appears to be the reduction of the gonadotropic hormones LH and follicle-stimulating hormone (FSH) from the pituitary gland by estrogen, which has a strong negative feedback effect on LH and FSH secretion. This reduction in LH and FSH results in decreased testicular size and lower testosterone levels, with a consequent reduction in aggressive behavior. However, there appears to be sufficient testosterone secreted to maintain an anabolic effect. Therefore, the repeated use of estrogens in bulls beginning at 1–3 mo of age may lead to a hormonal castration effect with increased growth rate.

Use in Horses

The use of anabolic agents in horses is not recommended because of adverse effects on the reproductive system. Administration of a steroid hormonal androgen analogue decreases testicular size in stallions. Decreased hormonal concentrations, especially LH, testosterone, and inhibin, adversely affect testicular histology and spermatogenesis and transiently decrease sperm output and quality. One of the most commonly used compounds is 19-nortestosterone for therapy in debilitated and anemic horses. However, use of these compounds is contraindicated, and long-term treatment or large doses have serious adverse effects on reproductive tract function.

Use in Other Species

In **pigs**, the growth responses from the use of estradiol, progesterone, and zeranol are variable but generally low. TBA seems to increase lean meat content of pig carcasses.

In **sheep**, the responses to anabolic agents parallel those obtained in cattle. The most consistent responses have been obtained in lambs finished on high-concentrate diets; a 10%–15% increase in daily gain can be expected. Anabolic steroids should not be used in lambs to be retained for breeding. Also, implantation with zeranol reduces testicular development in ram lambs and delays the onset of puberty and reduces the ovulation rate in female sheep. Moreover, the short finishing period and the extensive nature of some production systems militate against widespread practical use of growth promotants in sheep on economic grounds.

In **poultry**, responses to estrogens include increased fat deposition. Androgens, however, have given conflicting responses. Hence, their use is of no practical significance at this time.

In **fish**, methyl testosterone can induce sex reversal in rainbow trout, thereby promoting growth and improved feed conversion efficiency.

Possible Complications

Any hormonal implant has a negative feedback effect on pituitary gonadotropins, thereby reducing LH and FSH secretion. Therefore, they can affect the onset of puberty and the regularity of estrous cycles, as well as reduce conception rate in females and testicular development (and thus sperm output) in males. Hormonal growth promotants should never be used in animals that are or may be used for breeding purposes, nor should they be used before puberty to increase growth in yearling thoroughbreds or young pedigree bulls for show purposes. If given to pregnant heifers, TBA results in increased incidence of severe dystocia, masculinization of female genitalia of the fetus, increased calf mortality, and reduced milk yield in the subsequent lactation.

The major problem thought to be associated with estrogenic implant use in the feedyard has been a transient increase in mounting behavior and aggression, commonly referred to as buller syndrome (see p 1552). However, it is also believed that the estrogen in the implant alone is not sufficient to cause bullers. The "buller" is the animal being pursued by one or more pen mates that repeatedly attempt to mount the buller throughout the day and several days.

Buller syndrome generally affects 2%–3% of the feedyard steer population, but this rate can double or triple during the late summer and early fall months. An increase in yearling steers off native grass pasture (which are usually given a high-dose implant immediately on arrival), diurnal temperature fluctuations (hot days and cool nights that shift social activity to early evening hours), dusty pen conditions (exacerbated by evening social activity), feeding corn or hay that may be moldy, and incomplete fermentation on freshly harvested silage can also contribute to increases in buller syndrome. Feedlot pens with a greater number of animals experience a greater incidence of buller activity, and the incidence of bullers increases linearly with increasing number of animals within a pen above 80–100 animals per pen. This suggests the agonistic behavior is a population phenomenon, requiring a critical mass of both the dominant, mounting animals and the animals they are attempting to mount. Bullers have been shown to have greater circulating concentrations of monoamine oxidase and reduced circulating concentrations of progesterone than non-buller pen mates. These effects generally last for 1–10 days after implantation and then subside. However, there have been a few reports of undesirable behavior in steers that lasted for 4–10 wk. The cause of this unpredictable adverse behavior is not clear; it may be a function of rearing and socialization climate. It is generally more severe in dairy cattle used for beef production. If the problem is severe, the buller steers should be identified and removed; if very severe, removal of the implants or administration of 50–100 mg of progesterone in oil for a number of days to suppress behavior should be considered.

In addition to buller syndrome, estrogenic implants may increase the size of rudimentary teats.

Factors Affecting Response

A number of factors affect the response to growth-promoting implants, including genetic makeup, plane of nutrition, and the sex and age of the animal.

Animals should be gaining a minimum of 0.25 kg/day before an economic response is obtained. Implants are best used in animals on a high plane of nutrition and under good husbandry conditions. They are an aid to, but not a substitute for, good husbandry. Consequently, there is little economic incentive in implanting cattle destined for a 3- to 4-mo "store period," during which time animals are fed to gain

little or no weight. Responses are reduced in calves (based on health condition and diet), and responses are good in yearlings.

Prior implantation does not affect the response to the next implantation. Also, once the implant effect has ceased, the rate of gain reverts to the rate that would be expected in nonimplanted animals, assuming the level of feeding is the same. Also, extra weight induced by implants in early life is transferred through to extra carcass weight at slaughter.

GROWTH HORMONE

The peptide most commonly used to enhance growth and production is growth hormone (GH). Its chemical structure is species-specific, and it has a short half-life (20–30 min). It is not orally active and is rapidly digested and cleared by the gut, liver, and kidney; thus, it must be administered via a parenteral route. Sustained-release (14–28 days) formulations have been developed for use in cattle to obviate the need for daily injections. When administered to cattle, GH increases growth rate (5%–10%), feed conversion efficiency, and the carcass lean:fat ratio. Gender has little effect on response in cattle. Response to GH is lower in older cattle with greater fat deposition. There is an interaction between magnitude of response and nutritional level; protein content and specific amino acid composition may be important to achieve maximal responses. The effects of GH are largely additive to those obtained from steroid implants. GH improves growth and feed efficiency in sheep but not in poultry. Recombinant GH in pigs has dramatic effects, resulting in an increase in daily gain (20%), decrease in feed intake (5%), and a decrease in the feed:gain ratio (20%). A 10% increase in lean content and a 35% decrease in adipose tissue may be realized in swine. Administration of bovine GH at 25 mg/day to lactating cattle increases milk yields of dairy cows by as much as 20%. GH has been approved for commercial use in some countries to increase milk production.

β-ADRENERGIC AGONISTS

As of 2015, there are two β-adrenergic agonists (βAAs) approved for use as growth promotants in feedlot cattle in the USA: ractopamine and zilpaterol. Phenethanolamine βAAs are chemically similar in structure to epinephrine and norepinephrine and have paracrine, neurotransmitter, and endocrine (hormonal) effects. There is a range of βAA compounds resulting from structural modifications and aromatic ring

substitution. The βAAs bind to β-adrenergic receptors, which have been classified into β1, β2, and β3 subtypes based on the physiologic response obtained. β1 receptors are located primarily in cardiac muscle but also can be found in skeletal muscle, β2 receptors in tracheal and skeletal muscle, and β3 receptors in brown adipose tissue. In general, βAAs have specificity for receptor subtypes, thereby providing specificity regarding their physiologic actions. However, there are multiple receptor subclasses in most tissues, and the relative concentrations of β1 and β2 receptors in a tissue determine the physiologic response. Muscle and adipose cells have predominantly β2 receptors. βAA use leads to an increase in muscle mass caused by upregulation of mRNA transcription, resulting in increased protein synthesis, and a decrease in carcass fat due to decreased rates of lipid accretion. The exact proportion of receptor subtypes varies between tissues and also across species, resulting in species-specific responses to select βAAs. For example, swine are believed to have more β1 than β2 receptors in their skeletal muscle; ruminants are believed to have more β2 than β1 receptors. The physiologic activity of βAAs depends on the dose, receptor binding specificity, mode of administration, rate of absorption, and metabolic clearance rate in treated animals. Also, because tissue becomes refractory to exogenous βAA administration, βAAs are fed only during the final days of the finishing phase; extended feeding ultimately results in a complete loss of tissue response to βAAs.

The major use of βAAs in food animal production is to increase carcass leanness and lean tissue produced per animal. In cattle and sheep, weight gain, gain:feed ratio, and meat content are increased by 10%–20% and lipid content is decreased by 7%–20%. In swine and chickens, responses are much lower, with pigs responding better than chickens. Weight gain is increased by 2%–4%, and gain:feed ratio is slightly improved in chickens but not in pigs. Meat content is increased by 2%–4% and lipid content decreased by 7%–8% in chickens and pigs.

Adverse effects depend on compound administered, dose used, and species treated, but those selected for commercial use have minimal adverse effects. They are orally active. Dosage level of the compound used affects the response obtained; the optimal dose often varies for different production variables measured. The most consistent effects are increased proportion of lean meat, but the effects on meat quality

vary with compound used, dosage given, duration of treatment, and species treated. Certain compounds have been reported to decrease tenderness of meat in cattle. The use of β -agonists as growth promoters is banned in the EU. Illegal use of clenbuterol in cattle and certain β AAs in poultry is a threat in some countries, requiring vigilance by regulatory authorities. The longterm accumulation of these compounds in hair and ocular tissue has been used to screen for their presence in some countries.

ANTIMICROBIAL FEED ADDITIVES

Maintenance of healthy animals requires prevention of infection by pathogenic organisms. In addition, specific alteration of a host's microflora may have beneficial effects on animal production by alteration of ruminal flora, resulting in changes in the proportions of volatile fatty acids produced during ruminal digestion. Thus, antimicrobial compounds may improve production efficiency of healthy animals fed optimal nutritional regimens. Production-enhancing antimicrobial compounds can be classified as ionophore or nonionophore antibiotics. This distinction is important, because ionophores have no use in human medicine and do not have any link or possible effect on antimicrobial resistance to therapeutic antibiotics in either people or food animals; to group all antimicrobials together for debate about the risk to therapeutic antibiotics is ill advised and overly

simplistic. Antimicrobial compounds are administered in the feed at low dose rates relative to high doses required for therapeutic effects. Feed additives can be given once the rumen is functioning, although some antibiotic compounds can be fed to calves before this point.

Antimicrobial growth promoters commonly used in livestock are detailed in TABLE 62. Antimicrobials are used in male and female animals without adverse effects on ovarian and testicular development or function because they are poorly absorbed. Unlike anabolic steroids, they do not affect carcass composition. Antimicrobials are commonly used in conjunction with estradiol, zeranol, or TBA, and generally their combined effects are additive.

Ionophore Antibiotics

Ionophores (eg, monensin and lasalocid) modify the movement of monovalent (sodium and potassium) and divalent (calcium) ions across biologic membranes, modify the rumen microflora, decrease acetate and methane production, increase propionate, may improve nitrogen utilization, and can increase dry matter digestibility in ruminants. Their main effect is to increase feed efficiency, but they may also improve growth rates of ruminants on high-roughage diets. Administration of monensin to cattle results in 2%–10% improvement in liveweight gain (in animals on a high-roughage diet), 3%–7% increase in

TABLE 62

ANTIBACTERIAL GROWTH PROMOTERS FOR POTENTIAL USE IN LIVESTOCK PRODUCTION

Compound	Class	Absorption	Effects
Bambermycins	Phosphoglycolipid	Not absorbed	Increase FCE ^a , growth promotion in poultry, cattle
Lasalocid sodium	Ionophore		Increase FCE in cattle
Monensin sodium	Ionophore	Poorly absorbed	Increase FCE, increase DLWG ^b in cattle and lambs
Salinomycin	Ionophore		Increase DLWG and FCE
Virginiamycin	Peptide	Not absorbed	Growth promotion in poultry
Zinc bacitracin	Peptide	Not absorbed	Growth promotion in poultry

^a Feed conversion efficiency

^b Daily liveweight gain

feed conversion efficiency, and up to a 6% decrease in food consumption. Initially, monensin was used only as a feed additive for ruminants fed in confinement, but its use has been extended to grazing animals. Other ionophores generally have similar effects. Doses range from 6–40 ppm in the diet. Ionophores are absorbed from the gut, rapidly metabolized by the liver, and reenter the gut from bile. Some ionophores also have a therapeutic use (eg, for prevention of coccidiosis in ruminants and poultry).

Although ionophore antibiotics are used for prevention of coccidiosis in ruminants and poultry, ionophores are not used in human medicine, and there are no medically important analogues of the ionophores used in human medicine. Therefore, there is no obvious relationship between ionophore use in livestock production and the concern regarding resistance of bacterial pathogens to antimicrobial compounds important in human medicine.

Nonionophore Antibiotics

These compounds are used to selectively modify microbial populations within animals to improve production efficiency and to maintain health by combating low-level infections, particularly in intensive systems. Phosphoglycolipid antibiotics (eg, flavophospholipol) alter ruminal flora by inhibiting the action of some gram-positive gut microorganisms and peptoglycan formation, yielding similar production responses to those produced by ionophores. In addition, flavophospholipol has been shown to influence the hindgut microflora populations, resulting in competitive exclusion of some harmful pathogens such as *Escherichia coli* and various species of *Salmonella*. A less understood effect of flavophospholipol is the reduction in plasmid transfer of antimicrobial resistance. Given the seemingly contradictory and highly charged interests of desire for a generalized reduction in the use of antibiotics for livestock production and the potential use of a specific antibiotic for reducing antimicrobial resistance, this potentially volatile topic has not been comprehensively assessed.

The means by which specific compounds exert their antimicrobial effect differ. Antibiotics may have a nitrogen-sparing effect, thereby increasing the availability of amino acids to the animal.

Most feeds for broiler and pig production in some countries contain antimicrobial growth promoters. These compounds can also be administered to calves, yearlings, and finishing cattle either in milk replacer or in supplementary concentrates. Antibiotic compounds, in general, increase growth rate

by 2%–10% and feed conversion efficiency by 3%–9%. Their effects are greater in young animals, and production responses are reduced when production conditions are optimized (good housing, optimal health, and hygiene). They have minimal effects on carcass composition other than that because of improved growth rate.
